should be used in using the transverse experiments to obtain structural and dynamic information. This is in part due to the difficulty in executing accurate, meaningful CPMG and $T_{1\rho}$ experiments. It may also be due to the fact that a single spectral density function is not a faithful representation of the molecular motions over the entire range of motion.

Given the six equations for the six different coherences and the up to 10 unknown parameters (δ_H , δ_P , p , and τ_c , and the six transverse random field terms; see Table 1), a measurement of the six coherences is not enough information to give one accurate, uniquely determined values for all of those parameters. In addition, as we have seen in the example presented above, there are experimental problems, since it is very difficult indeed to measure linewidths (coherences) accurately, especially for very narrow lines. In our experience, neither linewidth measurements nor Carr–Purcell–Meiboom–Gill spin echo experiments give highly reliable results, especially at the higher temperatures where some of the linewidths are relatively narrow. $T_{1\rho}$ experiments, if done carefully, give reasonably good results.

The most fundamental difficulty is that one has 6 equations and there are probably 10 unknown parameters. This would seem to indicate that experimental information about the transverse relaxation must be complemented by additional data from longitudinal relaxation experiments. In practice, a better way to obtain information about the molecular parameters is to carry out longitudinal relaxation time experiments. Although the data analysis is considerably more difficult, the experiments are easier to execute, and give more reliable and more reproducible results.^{6–8}

1 INTRODUCTION

Nuclear magnetic resonance is uniquely capable of revealing structure and dynamics on a molecular level. An understanding of nuclear spin relaxation is fundamental to an understanding of nuclear magnetic resonance in general. The theoretical framework needed to promote this understanding is conveniently constructed in terms of the time evolution of the density operator under the influence of some Hamiltonian as expressed by the Liouville–von Neumann equation. The basic theory needed for what follows may be found in *Liouville Equation of Motion*. It will be presumed that the reader is familiar with the contents of this article.

The emphasis here will be on molecules in liquids, though many of the principles presented are applicable to solids and gases. The experimental observables of NMR are magnetizations induced in a sample as a consequence of subjecting it to various static and time-varying magnetic fields. The quantum mechanical operators corresponding to these observables act only on the nuclear spin degrees of freedom of the system. Furthermore, these operators are proportional to the spin angular momentum operators or products thereof and, hence, can be dealt with using finite basis sets of states or operators. Relaxation, however, is a consequence of interactions between the nuclear spins and the rest of the system, referred to as the ‘lattice’ or ‘bath’. In most cases, the lattice cannot be treated exactly using quantum mechanics, because the density operator and the Hamiltonian cannot be defined in explicit mathematical detail. The strategy generally employed, then, is to treat the effects of the lattice classically as a random time-dependent modulation of the nuclear spin operators while retaining a quantum mechanical description of the nuclear spins themselves. All externally applied magnetic fields are likewise treated classically. Our goal is to derive equations that correctly describe the observed temporal behavior of the experimental observables. This is done by proposing a Hamiltonian for the system under study, solving the Liouville–von Neumann equation for the time evolution of the density operator, computing the expected time evolution of the experimental observables, and comparing the result with measured values of these observables. Secondly, one wants to extract from this temporal behavior of the observables information about the fundamental nature of the system under investigation. For example, bond angles and

rates of molecular reorientation due to Brownian motion dramatically affect the results of an NMR experiment. How can this kind of information be extracted from the behavior of the magnetization in a sample as a function of time? This article will present the time-dependent perturbation theory methods commonly used in NMR to explain observed phenomena, discuss the various mechanisms that influence relaxation in liquids, and present some simulations exemplifying how nuclear spins behave as a consequence of these mechanisms.

This article presumes a basic knowledge of the nuclear magnetic resonance phenomenon, including nuclear spin polarization in an external static magnetic field and interaction of nuclear spins with applied radiofrequency fields. For those not acquainted with these concepts, several basic texts may be consulted.^{1–3} The reader is assumed to have some grasp of basic quantum mechanics and angular momentum theory at the level generally taught in undergraduate physical chemistry courses. Some command of linear algebra and integral and differential calculus is also assumed. All abbreviations and symbols are either defined in the endpapers or are defined in context. Vectors will be distinguished by bold italic type, and the same symbol in normal weight type will denote the magnitude of a vector or, with appropriate subscripts, its components. Quantum mechanical operators will have a hat, for example $\hat{H}$. Liouville space operators or superoperators will have a double hat, for example $\hat{\hat{L}}$.

No experimental data will be presented in this article. The experimental literature on coupled relaxation has been recently reviewed.⁴ Rather, many simulations using the GAMMA magnetic resonance simulation platform⁵ will be used, so that particular aspects of the subject may be illustrated and contrasted without lengthy digressions into experimental detail. While some references to the original literature will be given, most references will be to texts where additional details of the concepts discussed can be found.

1.1 What Is Nuclear Spin Relaxation?

To begin, let us consider nuclear spin relaxation from a phenomenological viewpoint. When a sample containing nuclear spins (e.g., water, which contains ^1H nuclei) is placed in a strong, uniform, static magnetic field $\mathbf{B}_0$, the sample is observed to develop a macroscopic magnetization $\mathbf{M}_0$ parallel to $\mathbf{B}_0$. The direction of $\mathbf{B}_0$ is taken to be the z direction of a laboratory-fixed coordinate system. Certain nuclei, for example ^{15}N , develop magnetization antiparallel to $\mathbf{B}_0$. The magnetization of a sample placed suddenly in a strong field increases with time and asymptotically approaches a steady state value. The magnitude of the steady state magnetization is proportional to the number of magnetic nuclei in the sample and to the strength of $\mathbf{B}_0$ (it depends on temperature also, but constant temperature will be assumed for now). Each nucleus of an isotope having a nonzero nuclear spin contributes an amount of magnetization characteristic of that particular isotope. If one used deuterium oxide rather than normal water, for example, both the rate of approach to the steady state and the steady-state magnetization would be different. If the sample is left in the magnet for a long time so that it has closely approached the steady state, this condition is called *thermal equilibrium*. If the magnetization is perturbed from thermal equilibrium, by a pulse of radiofrequency

field at the appropriate frequency, it will return to thermal equilibrium—again asymptotically. This process that causes the magnetization to approach thermal equilibrium is called *nuclear spin relaxation*. The time needed for a sample to achieve thermal equilibrium is, of course, infinite, since the approach is asymptotic. However, the time needed to reasonably approximate thermal equilibrium is in the range of milliseconds to hundreds of seconds for liquids, depending on the nature of the sample and the nuclei involved.

The rest of this article will consist mainly of a detailed discussion of the behavior of the magnetization as a function of time and how measurement of this behavior can be used to determine the structural and dynamical features of the molecules bearing the magnetic nuclei.

1.2 Classical Treatment: Bloch's Equations

The first investigations of nuclear-spin relaxation were conducted soon after the discovery of NMR.^{6–8} The main results of this work can be summarized by the following equations:

$$\left. \begin{aligned} \frac{dM_x}{dt} &= [M_y(\gamma B_0 - \omega) - M_z\gamma B_y] - \frac{M_x}{T_2} \\ \frac{dM_y}{dt} &= -[M_x(\gamma B_0 - \omega) - M_z\gamma B_x] - \frac{M_y}{T_2} \\ \frac{dM_z}{dt} &= [M_x\gamma B_y - M_y\gamma B_x] - \frac{M_z - M_0}{T_1} \end{aligned} \right\} \quad (1)$$

These phenomenological equations are generally referred to as the Bloch equations and are cast here in terms of a reference frame rotating at an angular frequency ω about the z axis with respect to a laboratory-fixed frame. A particularly lucid discussion of the Bloch equations may be found in the text by Slichter.⁹ This system of coupled linear differential equations with constant coefficients has solutions wherein the magnetization precesses about the effective field in the rotating frame having components $(B_x, B_y, B_0 - \omega/\gamma)$. In order for B_x and B_y to be stationary in the rotating frame, they must be oscillating in the laboratory frame so that their sum rotates at frequency ω . This will be discussed in mathematical detail in Section 2.7. For usual high-resolution experiments with liquids, ω will be of the order of tens or hundreds of megahertz, thus, radiofrequency technology is used to produce B_x and B_y in the laboratory frame.

However, the main interest here is in the terms involving T_1 and T_2 . If $\omega = \gamma B_0$ and $B_x = B_y = 0$ then equation (1) uncouple and yield particularly simple solutions wherein M_x and M_y relax exponentially to zero governed by T_2 while M_z relaxes exponentially toward M_0 governed by T_1 . Specifically, the solution of equation (1) is given by

$$\left. \begin{aligned} M_x(t) &= M_x(0) \exp(-t/T_2) \\ M_y(t) &= M_y(0) \exp(-t/T_2) \\ M_z(t) &= M_0 + [M_z(0) - M_0] \exp(-t/T_1) \end{aligned} \right\} \quad (2)$$

where $M(0)$ is the magnetization at time zero. These equations accurately describe the evolution of the macroscopic magnetization whenever the system under study may be regarded as an ensemble of spins interacting only with the lattice and not

with each other. The relaxation of a surprisingly large number of materials that have been studied is satisfactorily explained by equation (2).

The fact that the magnetization changes with time implies that the nuclei are undergoing transitions among the available quantum mechanical states. Just as the magnetization may be manipulated by inducing transitions with externally applied rf pulses, any natural phenomenon that produces a time-varying field at a nucleus can induce transitions. The effect of all of these natural phenomena is to drive the macroscopic magnetization toward the thermal equilibrium value. See Section 3 for a discussion of specific examples of natural phenomena that can be mechanisms of spin relaxation. The decay of M_x and M_y involves exchange of energy among the spins, whereas the evolution of M_z toward its steady state value involves transfer of energy between the spins and the lattice.

1.3 When There Are Two or More Coupled Spins

When two or more spins are coupled by some sort of interaction, equation (1) may not be sufficient to explain the observed evolution of the magnetization. Consider, for example, a ^{13}C – ^1H moiety such as might be found in the formate ion.¹⁰ In a conceptually simple experiment, the ^1H magnetization is inverted, and then the ^1H and ^{13}C magnetizations are followed as a function of time. Additional details of this experiment can be found in Section 4.1.1. If there were no interaction between ^1H and ^{13}C then each of the spins could be treated separately according to equation (1), and the resulting evolution would be as shown in Figure 1(a). The ^1H magnetization recovers to thermal equilibrium exponentially as expected, and the ^{13}C magnetization remains unperturbed; however, when one actually performs this experiment, the results are as shown in Figure 1(b). The ^{13}C magnetization grows beyond thermal equilibrium, and then decays back to thermal equilibrium. Apparently, magnetization is flowing from the ^1H to the ^{13}C nuclei; this behavior cannot be predicted by equation (1). The mechanism that has been introduced to produce this effect is dipole–dipole (DD) coupling between the two nuclei. This is an example of cross relaxation. The theory of which this is a simple example will be the subject of the rest of this article.

2 TIME-DEPENDENT PERTURBATION THEORY

The theoretical model generally adopted for high-resolution NMR of liquids is that of a molecule bearing the spin system of interest immersed in a solvent. The concentration of such molecules is sufficiently low that intermolecular interactions among the spins of interest need not be considered. Because of the short range and random nature of the interactions involved, this assumption is adequately met even at fairly high concentrations. The macroscopic sample may then be considered as an ensemble of isolated systems each consisting of a single spin system of interest immersed in a bath or lattice the exact state of which is of no interest. The terms ‘bath’ and ‘lattice’ will be used interchangeably to refer to all the degrees of freedom of one member of the ensemble not directly associated with the nuclear spins in which we

Figure 1 Simulation of relaxation of a two-spin (^{13}C – ^1H) system after a proton π nonselective pulse: (a) relaxed only by external random fields ($T_1 = 1.6$ s, $J = 140$ Hz); (b) relaxed also by dipole–dipole coupling between the two spins (internuclear distance 0.109 nm, spherical top, correlation time 10 ps). The intensity is scaled so that the total ^{13}C magnetization at thermal equilibrium is unity, and that of ^1H is then greater by a factor $\gamma_{\text{H}}/\gamma_{\text{C}}$, or about four. See Section 4.1.1 for a more detailed discussion of the experiment

are interested. For example, the translational, rotational, and vibrational states of the molecule bearing the spin system of interest as well as the states of any nuclear or electron spins in solvent molecules would be in this category. The number of degrees of freedom of the lattice is so great as to be effectively infinite, with essentially a continuum of energy eigenstates. Using the terms somewhat loosely, the ‘heat capacity’ of the lattice is assumed to be so much greater than that of the nuclear spins that no interaction between

the two can change the ‘temperature’ of the lattice. The nuclear spins also interact with externally applied magnetic fields, which are treated classically. In this discussion, the external magnetic field will be only the usual static field $\mathbf{B}_0$, the direction of which is taken to be the z axis of our laboratory coordinate system. Pulses will be treated as instantaneous rotations. A more general treatment of pulses and time-dependent external fields in general has been given by Smith et al.^{11–13}

To begin our theoretical development, the Hamiltonian for one member of our ensemble can be expressed as a combination of terms acting on the spin system $\hat{\mathcal{H}}_s$, terms acting on the bath $\hat{\mathcal{H}}_b$, and terms for the interaction between the two $\hat{\mathcal{H}}_I$:

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_s + \hat{\mathcal{H}}_b + \hat{\mathcal{H}}_I \quad (3)$$

The density operator $\hat{\rho}(t)$ encompasses both spin system and bath. The Liouvillian $\hat{\mathcal{L}}$ is a commutation or derivation superoperator relating to the Hamiltonian according to

$$\hat{\mathcal{L}} = \hat{\mathcal{H}} \otimes \hat{E} - \hat{E} \otimes \hat{\mathcal{H}} \quad (4)$$

For a discussion of superoperators and their relationship to operators see Section 5 of *Liouville Equation of Motion*. The Hamiltonian for a spin system $\hat{\mathcal{H}}_s$ interacting only with $\mathbf{B}_0$ contains terms from Zeeman interactions, chemical shieldings, scalar couplings, etc. A detailed discussion of high-resolution NMR Hamiltonians may be found in the first of the series of articles by Smith et al.¹¹ Some of these interactions involve terms that are dependent upon spin system orientation relative to $\mathbf{B}_0$, in which case interaction terms involving the rotational state of the molecule will be of interest. Such terms are of principal interest for spin relaxation studies in liquids, since molecules in liquids are rotating rapidly and changing rotational state frequently owing to collisions. Because of this, it is useful to express individual terms of the Hamiltonian in a general spherical tensor format. The Hamiltonian may be expressed as¹¹

$$\hat{\mathcal{H}} = \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m \hat{T}_m^{\mu} \hat{F}_{-m}^{\mu} \quad (5)$$

These tensors can be easily rotated from one coordinate system to another.¹⁴ Here the $\hat{T}_m^{\mu}$ are spin operators acting on the system of interest, the $\hat{F}_{-m}^{\mu}$ are operators on the lattice states or functions relating to the externally applied magnetic fields, and ξ_{μ} are interaction constants, which will vary depending upon the nature of the interaction. The index μ is used to label a particular interaction, and each interaction has one or more associated values of the rank l . For each l , one must sum over the projection index m as shown. All of the terms in this sum can be assigned to one of the three Hamiltonians on the right-hand side of equation (3). Terms involving $l = 0$ and $m = 0$ for the spin operators are bath terms. Those involving $l = 0$ and $m = 0$ for the lattice operators as well as those depending only on the applied external field are spin terms. All others are interaction terms.

Both $\hat{T}_m^{\mu}$ and $\hat{F}_{-m}^{\mu}$ transform like spherical harmonics under rotations,¹⁴ and are related to their adjoints as follows:

$$\left. \begin{aligned} (\hat{F}_m^{\mu})^{\dagger} &= (-1)^m \hat{F}_{-m}^{\mu} \\ (\hat{T}_m^{\mu})^{\dagger} &= (-1)^m \hat{T}_{-m}^{\mu} \end{aligned} \right\} \quad (6)$$

The superscript $\dagger$ indicates the adjoint or Hermitian conjugate of the operator. When the operator is represented in Liouville space using some operator basis, this means transpose the vector and take the complex conjugate of each element.

The Liouville equation in the Schrödinger representation is

$$\frac{d|\hat{\rho}(t)\rangle}{dt} = -\frac{i}{\hbar} \hat{\mathcal{L}} |\hat{\rho}(t)\rangle \quad (7)$$

(For a more detailed development of this type of equation, see Section 5 of *Liouville Equation of Motion*). It defines the time evolution of the density operator for the entire system, spins and lattice, in terms of the Liouvillian of equation (4). In this representation, the density superket is time-dependent whereas the Liouvillian is not. This implies, as mentioned above, that no time-varying magnetic fields are applied. Unfortunately, equation (7) is completely intractable, because the lattice and interaction Hamiltonians $\hat{\mathcal{H}}_b$ and $\hat{\mathcal{H}}_I$ cannot be clearly defined and the dimension of the Liouville space of the lattice would be far too large for meaningful calculations to be performed. Hence, we are forced to seek an approximate method for solving the Liouville equation. Nuclear spins relax very slowly compared with most events on a molecular scale, so it is reasonable to suppose that the interaction $\hat{\mathcal{H}}_I$ is very weak. Further, collisions between the molecule of interest and solvent molecules should be treatable as a random process amenable to statistical methods. These two facts lead one to attempt a solution of equation (7) using perturbation theory and statistical mechanics.

2.1 The Interaction Representation

We begin the application of time-dependent perturbation theory by making use of the interaction picture of the problem to permit focusing on the small interaction terms. If we transform all the operators in the Liouville equation into an interaction representation based on the combined bath and spin system Hamiltonians, we can effectively ‘remove’ the pure bath and pure spin system contributions, a procedure that simplifies equation (7) and, it is to be hoped, facilitates its integration:

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{i}{\hbar} \hat{\mathcal{L}}'_I(t) |\hat{\rho}'(t)\rangle \quad (8)$$

(for a discussion of interaction representations and transformations, see Section 4.1 of *Liouville Equation of Motion*). Operators (superkets) and superoperators in the interaction representation are indicated by a prime. These relate to the Schrödinger representation via

$$\left. \begin{aligned} \hat{\mathcal{L}}_0 &= \hat{\mathcal{L}}_s + \hat{\mathcal{L}}_b \\ |\hat{\rho}'(t)\rangle &= \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) |\hat{\rho}(t)\rangle \\ \hat{\mathcal{L}}'_I(t) &= \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) \hat{\mathcal{L}}_I \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) \end{aligned} \right\} \quad (9)$$

2.2 Second-Order Perturbation Theory

Because of the inherently complex interaction between bath and spin system, as embodied in the superoperator $\hat{\mathcal{L}}'_I(t)$, the equation of motion must be solved using some sort of approximation technique. One approach is to use

a Dyson expansion of the integral. The initial steps are trivial—equation (8) is integrated formally from an arbitrary starting time t_0 to some later time t :

$$\left. \begin{aligned} \int_{t_0}^t d|\hat{\rho}'(t_1)\rangle &= -\frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) |\hat{\rho}'(t_1)\rangle \\ |\hat{\rho}'(t)\rangle &= |\hat{\rho}'(t_0)\rangle - \frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) |\hat{\rho}'(t_1)\rangle \end{aligned} \right\} \quad (10)$$

We can now make a change of variable in equation (10),

$$|\hat{\rho}'(t_1)\rangle = |\hat{\rho}'(t_0)\rangle - \frac{i}{\hbar} \int_{t_0}^{t_1} dt_2 \hat{\mathcal{L}}'_1(t_2) |\hat{\rho}'(t_2)\rangle \quad (11)$$

and substitute back into the integrand of equation (10) to produce

$$\begin{aligned} |\hat{\rho}'(t)\rangle &= |\hat{\rho}'(t_0)\rangle \\ &\quad - \frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) \left[|\hat{\rho}'(t_0)\rangle - \frac{i}{\hbar} \int_{t_0}^{t_1} dt_2 \hat{\mathcal{L}}'_1(t_2) |\hat{\rho}'(t_2)\rangle \right] \\ &= |\hat{\rho}'(t_0)\rangle - \frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) |\hat{\rho}'(t_0)\rangle \\ &\quad - \frac{1}{\hbar^2} \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \hat{\mathcal{L}}'_1(t_1) \hat{\mathcal{L}}'_1(t_2) |\hat{\rho}'(t_2)\rangle \end{aligned} \quad (12)$$

This process is iterated, substituting equation (11), with the appropriate change of variable for $|\hat{\rho}'(t_2)\rangle$, into equation (12). With each iteration, the lower order integrals involve only the initial density superket. Continuing the iterations and assuming that the series eventually converges so that the last term involving $|\hat{\rho}'(t_n)\rangle$ may be ignored produces the Dyson series

$$\begin{aligned} |\hat{\rho}'(t)\rangle &= |\hat{\rho}'(t_0)\rangle + \sum_{n=1}^{\infty} \left(-\frac{i}{\hbar} \right)^n \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \cdots \\ &\quad \times \int_{t_0}^{t_{n-1}} dt_n \hat{\mathcal{L}}'_1(t_1) \hat{\mathcal{L}}'_1(t_2) \cdots \hat{\mathcal{L}}'_1(t_n) |\hat{\rho}'(t_0)\rangle \end{aligned} \quad (13)$$

If it could be shown that the interaction Liouvillians at different times commute then the time ordering would be inconsequential, and equation (12) would be equivalent to a Taylor series for an exponential:

$$|\hat{\rho}'(t)\rangle = \exp \left[-\frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) \right] |\hat{\rho}'(t_0)\rangle \quad (14)$$

If the interaction Liouvillian (in the interaction representation) were time-independent then the integral would be trivial and the solution in the interaction representation would be

$$|\hat{\rho}'(t)\rangle = \exp \left[-\frac{i}{\hbar} \hat{\mathcal{L}}'_1(t - t_0) \right] |\hat{\rho}'(t_0)\rangle \quad (15)$$

We shall assume that the Liouvillians at different times do not commute, but that terms higher than second order are negligible, i.e., that *second-order perturbation theory* is

adequate to describe the system. The equation of motion is then approximated by

$$\begin{aligned} |\hat{\rho}'(t)\rangle &= |\hat{\rho}'(t_0)\rangle - \frac{i}{\hbar} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t_1) |\hat{\rho}'(t_0)\rangle \\ &\quad - \frac{1}{\hbar^2} \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \hat{\mathcal{L}}'_1(t_1) \hat{\mathcal{L}}'_1(t_2) |\hat{\rho}'(t_0)\rangle \end{aligned} \quad (16)$$

2.3 Application of the Wangness–Bloch–Redfield Assumptions

Equation (16) is still not in a form that can be handled either analytically or numerically for useful systems. We therefore apply several additional approximations that will eventually lead to a manageable expression. Recognizing that the first integral term in equation (16) is nondissipative, it can at most add a constant term to the density matrix. Furthermore, we shall shortly deal with an ensemble of spin systems, and the average effect of the interaction Liouvillian at any point in time is zero for an isotropic liquid. This is true for a bath interacting in an essentially random fashion with the system of interest. Therefore the first integral term in equation (16) may be ignored, giving

$$|\hat{\rho}'(t)\rangle = |\hat{\rho}'(t_0)\rangle - \frac{1}{\hbar^2} \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \hat{\mathcal{L}}'_1(t_1) \hat{\mathcal{L}}'_1(t_2) |\hat{\rho}'(t_0)\rangle \quad (17)$$

If the integrand is continuous over the integration range then we can differentiate equation (17) to obtain a differential equation again:

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{1}{\hbar^2} \int_{t_0}^t dt_1 \hat{\mathcal{L}}'_1(t) \hat{\mathcal{L}}'_1(t_1) |\hat{\rho}'(t_0)\rangle \quad (18)$$

It is assumed that the integral really only depends upon the difference $\tau = t - t_1$, so that the variable of integration may be changed as follows:

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{1}{\hbar^2} \int_{t_0}^t d\tau \hat{\mathcal{L}}'_1(t) \hat{\mathcal{L}}'_1(t - \tau) |\hat{\rho}'(t_0)\rangle \quad (19)$$

It is further assumed that the density superket does not change rapidly over the range of the integral, so that replacing $|\hat{\rho}'(t_0)\rangle$ with $|\hat{\rho}'(t)\rangle$ does not introduce significant error. This yields

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{1}{\hbar^2} \int_0^t d\tau \hat{\mathcal{L}}'_1(t) \hat{\mathcal{L}}'_1(t - \tau) |\hat{\rho}'(t)\rangle \quad (20)$$

A final assumption is that t will be long enough that the integrand will have decayed to zero and no error will be introduced by extending the limit of integration to infinity. Then we have

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{1}{\hbar^2} \int_0^\infty d\tau \hat{\mathcal{L}}'_1(t) \hat{\mathcal{L}}'_1(t - \tau) |\hat{\rho}'(t)\rangle \quad (21)$$

2.4 The Semiclassical Liouville Equation

At this point, it is essential to depart from the treatment of the entire system of spins and bath and focus only on the smaller system of interest, namely, the spin system. The total system density operator can always be represented as a tensor product of two density operators, one spanning the spin system subspace and one spanning the lattice subspace:

$$|\hat{\rho}(t)\rangle = |\hat{\sigma}(t)\rangle |\hat{\rho}_b(t)\rangle \quad (22)$$

Keep in mind that it is the smaller spin system represented by the reduced density operator $|\hat{\sigma}(t)\rangle$ that is of interest, not the entire system $|\hat{\rho}(t)\rangle$. The latter resides in a Liouville space of unmanageable dimensionality whereas the dimension of the former is normally small enough that its evolution in time can be mathematically detailed with some precision. One can define a superket $|\hat{\rho}_s(t)\rangle$ that resides in the full Liouville space of the spin system and bath, and yet contains only the information regarding the spin system of interest:

$$\left. \begin{aligned} |\hat{\rho}_s(t)\rangle &= \hat{P}|\hat{\rho}(t)\rangle = \hat{E}_s \otimes (|\hat{\rho}_b(t)\rangle \otimes \langle \hat{E}_b|) \\ |\hat{\sigma}(t)\rangle &= (\hat{E}_s \otimes \langle \hat{E}_b|) |\hat{\rho}_s(t)\rangle = (\hat{E}_s \otimes \langle \hat{E}_b|) \hat{P}|\hat{\rho}(t)\rangle \\ &= (\hat{E}_s \otimes \langle \hat{E}_b|) \hat{E}_s \otimes (|\hat{\rho}_b(t)\rangle \otimes \langle \hat{E}_b|) \end{aligned} \right\} \quad (23)$$

The equation of motion for $|\hat{\rho}_s(t)\rangle$ is obtained by use of the projection superoperator $\hat{P}$ in the approximate equation of motion:

$$\frac{d|\hat{\rho}_s'(t)\rangle}{dt} = -\frac{1}{\hbar^2} \hat{P} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \hat{\mathcal{L}}_1'(t-\tau) \hat{P}|\hat{\rho}_s'(t)\rangle \quad (24)$$

Back-transformation into the Schrödinger representation produces

$$\begin{aligned} \frac{d|\hat{\rho}_s'(t)\rangle}{dt} &= -\frac{i}{\hbar} \hat{\mathcal{L}}_s |\hat{\rho}_s(t)\rangle - \frac{1}{\hbar^2} \hat{P} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \\ &\quad \times \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \hat{P}|\hat{\rho}_s'(t)\rangle \end{aligned} \quad (25)$$

This equation is general for any system interacting with a large bath, so long as the constraints outlined in Section 2.3 are fulfilled. The Liouvillians $\hat{\mathcal{L}}_s$ and $\hat{\mathcal{L}}_b$ commute, and $\hat{\mathcal{L}}_b$ cannot operate on $|\hat{\rho}_s(t)\rangle$, so that $\exp(-i\hbar^{-1}\hat{\mathcal{L}}_0\tau)\hat{P} = \exp(-i\hbar^{-1}\hat{\mathcal{L}}_s\tau)\hat{P}$. Then,

$$\begin{aligned} \frac{d|\hat{\rho}_s(t)\rangle}{dt} &= -\frac{i}{\hbar} \hat{\mathcal{L}}_s |\hat{\rho}_s(t)\rangle - \frac{1}{\hbar^2} \hat{P} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \\ &\quad \times \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \hat{P}|\hat{\rho}_s'(t)\rangle \end{aligned} \quad (26)$$

It is beyond the scope of this article to show that the net result of continued manipulations produces

$$\begin{aligned} &\hat{P} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \hat{P}|\hat{\rho}_s'(t)\rangle \\ &= \hat{P} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \\ &\quad \times \hat{P}|\hat{\rho}_s'(t) - \hat{\rho}_s'(\infty)\rangle \end{aligned} \quad (27)$$

Further details of this step may be found in an article by Szymanski et al.¹⁵ The projection operators allow us now to work exclusively with the reduced density operator and place all operators into the corresponding reduced space. Switching to the difference (reduced) density operator $\Delta\hat{\sigma}$, we now perform an ensemble average over all the spin systems in the sample to yield

$$\begin{aligned} \frac{d|\hat{\sigma}(t)\rangle}{dt} &= -\frac{i}{\hbar} \hat{\mathcal{L}}_s |\hat{\sigma}(t)\rangle - \frac{1}{\hbar^2} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \\ &\quad \times \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \\ &\quad \times |\hat{\sigma}(t) - \hat{\sigma}(\infty)\rangle \\ &= -\frac{i}{\hbar} \hat{\mathcal{L}}_s |\hat{\sigma}(t)\rangle - \frac{1}{\hbar^2} \int_0^\infty d\tau \hat{\mathcal{L}}_1'(t) \\ &\quad \times \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \hat{\mathcal{L}}_1'(t-\tau) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_s \tau\right) \\ &\quad \times |\Delta\hat{\sigma}(t)\rangle \end{aligned} \quad (28)$$

As in the Hilbert space formulation of Wangness–Bloch–Redfield theory, it remains to isolate the time dependence in the integral function in order to formulate spectral densities.

2.5 The Spin and Interaction Hamiltonians

The lattice Hamiltonian $\hat{\mathcal{H}}_b$ now influences the equation of motion only in that the system relaxes toward thermal equilibrium at the temperature of the bath $|\hat{\sigma}(\infty)\rangle$. We must now define in detail the form of the spin and interaction Hamiltonians. The principal influence of the lattice is to reorient the spin system. Equation (5) can then be interpreted as follows to account for both the spin system and its interaction with the lattice:

$$\hat{\mathcal{H}}_s + \hat{\mathcal{H}}_I(t) = \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m \hat{T}_m^{\mu} F_{-m}^{\mu}(t) \quad (29)$$

The lattice operators are now manifested as random functions of time that reorient the spin system. This is referred to as the *semiclassical model* for the Hamiltonian; the interaction terms of the Hamiltonian are time-dependent through the lattice functions $F_{-m}^{\mu}(t)$, but the operators that act on the spin system are independent of time. Invoking the ergodic hypothesis, the ensemble average can be replaced by a time average, and, if all orientations are equally probable (an isotropic liquid), many of the interactions average to zero in first order. The isotropic terms, $l = m = 0$, in equation (29) are independent of spin system orientation, and, hence, do not need to be time-averaged. These terms yield for a system of n spins the isotropic Hamiltonian commonly found in texts on high-resolution NMR:

$$\hat{\mathcal{H}}_s = \hat{\mathcal{H}}_0 = -\sum_{i=1}^n \hbar \omega_i \hat{I}_{iz} + 2\pi \hbar \sum_{i=2}^n \sum_{j=1}^{i-1} J_{ij} \hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j \quad (30)$$

The symbol J is widely used in the literature for both scalar couplings and spectral densities, which will be introduced in equation (41). We prefer to retain this notation in both cases, trusting that the reader will be able to discern from the context which is meant in a given case. Other Hamiltonian components that are orientation-dependent and, therefore, time-dependent will be categorized in the interaction Hamiltonian term of equation (29):

$$\hat{\mathcal{H}}_I(t) = \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m \hat{T}_m^{\mu} F_{-m}^{\mu}(t) \quad (31)$$

Although it is not explicit, note that the sum over μ in equation (29) includes the rotationally invariant components, whereas the sum in equation (31) does not include them. Furthermore, since the lattice operators are now simply functions, the adjoint used in equation (6) is replaced by a complex conjugate, so that $[F_m^{\mu}(t)]^* = (-1)^m F_{-m}^{\mu}(t)$. The equation of motion is then

$$\begin{aligned} \frac{d|\hat{\sigma}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_0 |\hat{\sigma}\rangle - \frac{1}{\hbar^2} \int_0^{\infty} d\tau \hat{\mathcal{L}}_1 \\ & \times \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \hat{\mathcal{L}}_1 \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) |\Delta\hat{\sigma}\rangle \end{aligned} \quad (32)$$

2.6 The Relaxation Superoperator

Making use of the semiclassical interaction model for $\hat{\mathcal{H}}_I$ given in equation (29), the interaction Liouvillian can be constructed:

$$\begin{aligned} \hat{\mathcal{L}}_I(t) = & \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m (\hat{T}_m^{\mu} \otimes \hat{E} - \hat{E} \otimes \hat{T}_m^{\mu}) F_{-m}^{\mu}(t) \\ = & \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m \hat{\Gamma}_m^{\mu} F_{-m}^{\mu}(t) \end{aligned} \quad (33)$$

Substitution of this relationship into equation (32) produces

$$\begin{aligned} \frac{d|\hat{\sigma}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_0 |\hat{\sigma}\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} (-1)^{m+m'} \hat{\Gamma}_m^{\mu} \\ & \times \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t-\tau)} \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) \\ & \times \hat{\Gamma}_{m'}^{\mu'} \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_0 \tau\right) |\Delta\hat{\sigma}\rangle \end{aligned} \quad (34)$$

Our objective is to separate quantities that depend on the time variable τ from the spin operators, which do not. The spherical spin tensor operator components $\hat{T}_m^{\mu}$ generally will not commute with $\hat{\mathcal{H}}_0$ and, hence, will not commute with $\hat{\mathcal{L}}_0$ either, so one cannot isolate the exponentials involving τ .

One can express the spherical tensor operators in a basis comprising the eigenoperators of the static Hamiltonian superoperator $\hat{\mathcal{L}}_0$:

$$\left. \begin{aligned} |\hat{T}_m^{\mu}\rangle &= \sum_p |\hat{T}_{m,p}^{\mu}\rangle \\ |\hat{T}_m^{\mu}(t)\rangle &= \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) |\hat{T}_m^{\mu}\rangle \\ &= \sum_p \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) |\hat{T}_{m,p}^{\mu}\rangle = \sum_p e^{-i\Omega_p t} |\hat{T}_{m,p}^{\mu}\rangle \end{aligned} \right\} \quad (35)$$

The Ω_p are the transition frequencies in the laboratory frame, eigenvalues of the Liouvillian $\hat{\mathcal{L}}_0$. The range of p is from 1 to the dimension of the spin system Liouville space. For a system of n spin- $\frac{1}{2}$ nuclei, this would be 2^{2n} . Such a treatment is equivalent to expanding the spin operators in terms of a basis consisting of the eigenfunctions of the static Hamiltonian $\hat{\mathcal{H}}_0$, as is done in the usual Hilbert space development of the Redfield equation.^{9,16} Using these relations, the equation of motion now becomes

$$\begin{aligned} \frac{d|\hat{\sigma}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_0 |\hat{\sigma}(t)\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} (-1)^{m+m'} \\ & \times \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t-\tau)} \\ & \times \hat{\Gamma}_m^{\mu} \sum_p \hat{\Gamma}_{m',p}^{\mu'} e^{-i\Omega_p \tau} |\Delta\hat{\sigma}(t)\rangle \end{aligned} \quad (36)$$

This expansion uses the close relationship between a similarity transformation superoperator and the exponential of a commutation superoperator. The commutation superoperator of the isotropic spin system Hamiltonian is given by

$$\hat{\mathcal{L}}_0 = \hat{\mathcal{H}}_0 \otimes \hat{E} - \hat{E} \otimes \hat{\mathcal{H}}_0 \quad (37)$$

The similarity transformation superoperator will, in this instance, be given by

$$\begin{aligned} \hat{G} |\hat{T}_m^{\mu}\rangle &= \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}}_0 t\right) \otimes \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}}_0 t\right) |\hat{T}_m^{\mu}\rangle \\ &= \left| \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}}_0 t\right) \hat{T}_m^{\mu} \exp\left(\frac{i}{\hbar} \hat{\mathcal{H}}_0 t\right) \right\rangle = |\hat{T}_m^{\mu}(t)\rangle \end{aligned} \quad (38)$$

The two superoperators are related by

$$\hat{G} = \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_0 t\right) \quad (39)$$

The exponential term in τ can now be grouped with the rest of the variables involving τ , and the desired separation of spin operators and τ -dependent lattice functions is thus achieved:

$$\begin{aligned} \frac{d|\hat{\sigma}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_0 |\hat{\sigma}(t)\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} (-1)^{m+m'} \\ & \times \sum_p \hat{\Gamma}_m^{\mu} \hat{\Gamma}_{m',p}^{\mu'} \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t-\tau)} e^{-i\Omega_p \tau} |\Delta\hat{\sigma}(t)\rangle \end{aligned} \quad (40)$$

The integral is defined as the spectral density function by

$$\mathcal{J}_{mm'}^{\mu\mu'}(\Omega) = \int_0^\infty d\tau \overline{F_{-m}^\mu(t) F_{-m'}^{\mu'}(t-\tau)} e^{-i\Omega\tau} \quad (41)$$

The spherical tensor properties of the $F_{-m}^\mu(t)$ guarantee that the integrand averaged over all orientations with equal probability will be nonzero only when $m' = -m$ and the result will be independent of m . Thus, one can write equation (41) in terms of a reduced spectral density $J^{\mu\mu'}$:

$$\mathcal{J}_{mm'}^{\mu\mu'}(\Omega) = (-1)^m \delta_{-mm'} J^{\mu\mu'}(\Omega) \quad (42)$$

Furthermore, it is presumed that the lattice functions are stationary random variables, i.e., that the result of a time average does not depend on the time at which the averaging process is started, and we may set $t = 0$ in the integrand of equation (41). The reduced spectral density is then

$$J^{\mu\mu'}(\Omega) = \int_0^\infty d\tau \overline{F_{-m}^\mu(0) F_{-m'}^{\mu'}(\tau)} e^{-i\Omega\tau} \quad (43)$$

A detailed discussion of spectral densities and how they relate to the dynamical and geometrical parameters of the spin system is found in *Relaxation of Coupled Spins from Rotational Diffusion*.

The relaxation superoperator is defined by

$$\hat{\Gamma} = \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l (-1)^m \sum_p \hat{\Gamma}_m^{\mu} \hat{\Gamma}_{-m,p}^{\mu'} J^{\mu\mu'}(\Omega_p) \quad (44)$$

The equation of motion for the density superket may be written very compactly using these definitions:

$$\frac{d|\hat{\sigma}(t)\rangle}{dt} = -\frac{i}{\hbar} \hat{\mathcal{L}}_0 |\hat{\sigma}(t)\rangle - \frac{1}{\hbar^2} \hat{\Gamma} |\Delta\hat{\sigma}(t)\rangle \quad (45)$$

The relaxation superoperator may be written as a sum of terms of the form

$$\hat{\Gamma} = - \sum_{\mu} \sum_{\mu'} \hat{\Gamma}^{\mu\mu'} \quad (46)$$

with the individual terms defined by

$$\hat{\Gamma}^{\mu\mu'} = \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l (-1)^m \sum_p \hat{\Gamma}_m^{\mu} \hat{\Gamma}_{-m,p}^{\mu'} J^{\mu\mu'}(\Omega_p) \quad (47)$$

The $\hat{\Gamma}^{\mu\mu'}$ terms express how the various interactions characterizing the spin system correlate with one another to produce relaxation. If $\mu = \mu'$, the relaxation is termed *autocorrelated*; otherwise, it is called *cross correlated*. This latter term must not be confused with *cross relaxation*, which is simply the flow of magnetization from one nucleus to another rather than from a nucleus to the lattice. Cross relaxation may involve either autocorrelated or cross-correlated relaxation mechanisms. This concept will be discussed further in Section 3.

2.7 The Rotating Frame

It is common practice in NMR to work in a rotating frame, or simultaneously in multiple rotating frames. One use of the rotating frame is to remove Zeeman contributions to the Hamiltonian by rotating about the field axis at or near the Larmor frequency of a spin. Although not of significance in rendering a formal solution to the Liouville equation in the case presented here, in numerical solutions of the equation of motion this avoids computational roundoff, which can occur in mixing frequencies on a megahertz scale (from the static magnetic field) with those on a hertz scale (from chemical shifts and scalar couplings).

Transformation into a rotating frame about the static magnetic field axis, the z axis, is accomplished using the rotation operator

$$\hat{R}_z(\theta) = \exp\left(-\frac{i}{\hbar} \hat{F}_z \theta\right) \quad (48)$$

In this case, the angle of rotation is written as $\theta = \Omega t$, where Ω is the angular frequency of the rotation. The form of the Liouville equation in the rotating frame is only a slight modification of that in the laboratory frame. In the frame rotating about the z axis at angular frequency Ω ,

$$\frac{d|\hat{\rho}(t)\rangle}{dt} = -\frac{i}{\hbar} \left[\hat{\mathcal{L}}(t) + \hat{\Gamma}_z(\Omega) \right] |\hat{\rho}(t)\rangle \quad (49)$$

The superoperator $\hat{\Gamma}_z(\Omega)$ is formed as the commutator of $\Omega \hat{F}_z$. Superkets and superoperators in the rotating frame are indicated by an underscore and relate to the laboratory frame via the rotation superoperator

$$\hat{\hat{R}}_z(\Omega t) = \hat{R}_z(\Omega t) \otimes \hat{R}_z^*(\Omega t) \quad (50)$$

The transformations have the form

$$\left. \begin{aligned} |\hat{\hat{\rho}}(t)\rangle &= \hat{\hat{R}}_z(\Omega t) |\hat{\rho}(t)\rangle \\ \hat{\hat{\mathcal{L}}}(t) &= \hat{\hat{R}}_z(\Omega t) \hat{\mathcal{L}} \hat{\hat{R}}_z^{-1}(\Omega t) \end{aligned} \right\} \quad (51)$$

That equations (49) and (7) are equivalent is shown by carrying out the differentiation as follows, making the indicated substitutions:

$$\begin{aligned} \frac{d|\hat{\hat{\rho}}(t)\rangle}{dt} &= \frac{d}{dt} \left[\hat{\hat{R}}_z(\Omega t) |\hat{\rho}(t)\rangle \right] \\ &= \frac{d}{dt} \left[\hat{\hat{R}}_z(\Omega t) \right] |\hat{\rho}(t)\rangle + \hat{\hat{R}}_z(\Omega t) \frac{d|\hat{\rho}(t)\rangle}{dt} \\ &= -\frac{i}{\hbar} \hat{\hat{\Gamma}}_z(\Omega) \hat{\hat{R}}_z(\Omega t) |\hat{\rho}(t)\rangle + \hat{\hat{R}}_z(\Omega t) \frac{d|\hat{\rho}(t)\rangle}{dt} \\ &= -\frac{i}{\hbar} \hat{\hat{\Gamma}}_z(\Omega) \hat{\hat{R}}_z(\Omega t) |\hat{\rho}(t)\rangle \\ &\quad - \frac{i}{\hbar} \hat{\hat{R}}_z(\Omega t) \hat{\mathcal{L}} \hat{\hat{R}}_z^{-1}(\Omega t) \hat{\hat{R}}_z(\Omega t) |\hat{\rho}(t)\rangle \\ &= -\frac{i}{\hbar} \left[\hat{\hat{\mathcal{L}}}(t) + \hat{\hat{\Gamma}}_z(\Omega) \right] |\hat{\hat{\rho}}(t)\rangle \end{aligned} \quad (52)$$

From spherical tensor arguments, we know that the static Hamiltonian $\hat{\mathcal{H}}_0$ is isotropic and rotationally invariant. Thus, it is left unaffected by transformation into the rotating frame, as we might suspect since $[\hat{\mathcal{H}}_0, \hat{F}_z] = 0$, and from equation (30), we can write

$$\hat{\mathcal{H}}_0 = \hat{\mathcal{H}}_0 = \sum_{i=1}^n \hbar \omega_i \hat{I}_{iz} + 2\pi \hbar \sum_{i=1}^n \sum_{j=1}^{i-1} J_{ij} \hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j \quad (53)$$

The interaction Hamiltonian as given by equation (31) will become as follows in the rotating frame:

$$\hat{\mathcal{H}}_I(t) = \sum_{\mu} \xi_{\mu} \sum_{m=-l}^l (-1)^m \hat{T}_m^{\mu} F_{-m}^{\mu}(t) \quad (54)$$

The bath variables are functions of time in this semiclassical treatment, and are unaffected by the rotation operator, which acts only on spin operators.

The question now is how the solution of equation (49) differs from that already presented in the laboratory frame. The form of the rotating frame Liouville equation is very similar to that in the laboratory frame, and the approach to a solution is the same. We define an effective Hamiltonian according to

$$\hat{\mathcal{H}}_{\text{eff}} = \hat{\mathcal{H}}_0 + \Omega \hat{F}_z \quad (55)$$

and transform into an interaction representation based on $\hat{\mathcal{H}}_{\text{eff}}$ rather than $\hat{\mathcal{H}}_0$ to remove the static components of the rotating frame Hamiltonian from our differential equation. It is of some interest to note that this particular $\hat{\mathcal{H}}_{\text{eff}}$ is time-independent both in the frame rotating about the z axis and in the laboratory frame. The new equation of motion has exactly the same form as equation (8), but all quantities have been transformed into the rotating frame:

$$\frac{d|\hat{\rho}'(t)\rangle}{dt} = -\frac{i}{\hbar} \hat{\mathcal{L}}_I'(t) |\hat{\rho}'(t)\rangle \quad (56)$$

We are still using a prime to signify the interaction representation. Equation (56) is the analog to equation (8), and a modified equation (9) is used to relate the interaction representation to the rotating frame:

$$|\hat{Q}'\rangle = \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} t\right) |\hat{Q}\rangle \quad (57)$$

The order in which one alters these reference frames can, in this instance, be switched, because $\hat{\mathcal{H}}_{\text{eff}}$ commutes with $\hat{R}_z$. That is to say, for the effective Hamiltonian of this treatment, the following relations hold:

$$\begin{aligned} |\hat{Q}'\rangle &= \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} t\right) |\hat{Q}\rangle = \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} t\right) \\ &\quad \times \exp\left(\frac{i}{\hbar} \hat{F}_z \Omega t\right) |\hat{Q}\rangle \\ &= \exp\left(\frac{i}{\hbar} \hat{F}_z \Omega t\right) \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} t\right) |\hat{Q}\rangle \end{aligned} \quad (58)$$

The steps taken towards the solution of equation (56) are virtually identical to the treatment performed in the laboratory frame, we simply write the analog to equation (34):

$$\begin{aligned} \frac{d|\hat{Q}\rangle}{dt} &= -\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} |\hat{Q}\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} (-1)^{m+m'} \hat{T}_m^{\mu} \\ &\quad \times \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t + \tau)} \\ &\quad \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} \tau\right) \hat{T}_{m'}^{\mu'} \exp\left(\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} \tau\right) |\Delta \hat{Q}\rangle \end{aligned} \quad (59)$$

The difference is that now we perform the expansion in terms of eigenoperators of the effective Hamiltonian and note that these are still in the rotating frame. Analogs of equation (35) in this treatment are

$$\left. \begin{aligned} |\hat{T}_m^{\mu}\rangle &= \sum_p |\hat{T}_{m,p}^{\mu}\rangle \\ |\hat{T}_m^{\mu}(t)\rangle &= \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} \tau\right) |\hat{T}_m^{\mu}\rangle \\ &= \sum_p \exp\left(-\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} \tau\right) |\hat{T}_{m,p}^{\mu}\rangle \\ &= \sum_p e^{-i\omega_p \tau} |\hat{T}_{m,p}^{\mu}\rangle \end{aligned} \right\} \quad (60)$$

This choice of representing the interaction Hamiltonian produces an important relationship between the spin operators and the commutator superoperator of $\hat{F}_z$:

$$\hat{F}_z^D |\hat{T}_m^{\mu}\rangle = m |\hat{T}_m^{\mu}\rangle \quad (61)$$

Equation (59) then becomes

$$\begin{aligned} \frac{d|\hat{Q}(t)\rangle}{dt} &= -\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} |\hat{Q}(t)\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} \\ &\quad \times (-1)^{m+m'} \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t + \tau)} \\ &\quad \times \hat{T}_m^{\mu} \sum_p e^{-im_p \omega_0 \tau} \hat{T}_{m',p}^{\mu'} e^{i\omega_p \tau} |\Delta \hat{Q}(t)\rangle \end{aligned} \quad (62)$$

In these equations, we are using ω_p for the transition frequencies associated with the effective Hamiltonian $\hat{\mathcal{H}}_{\text{eff}}$ in order to distinguish them from the transition frequencies Ω_p associated with the isotropic Hamiltonian $\hat{\mathcal{H}}_0$. Another, more common, viewpoint is that ω_p are the transition frequencies in the rotating frame whereas Ω_p are the transition frequencies in the laboratory frame.

When we transform the spin tensor superoperator components out of the rotating frame, the rotating frame frequencies disappear from the relaxation matrix in that the spectral densities are always evaluated at laboratory frame frequencies as

follows:

$$\begin{aligned} \frac{d|\hat{\underline{\sigma}}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} |\hat{\underline{\sigma}}(t)\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} \\ & \times (-1)^{m+m'} \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t+\tau)} \\ & \times \hat{\Gamma}_m^{\mu} \sum_p e^{-im_p \Omega_0 \tau} \hat{\Gamma}_{m',p}^{\mu'} e^{i\omega_p \tau} |\Delta \hat{\underline{\sigma}}(t)\rangle \end{aligned} \quad (63)$$

$$\begin{aligned} \frac{d|\hat{\underline{\sigma}}(t)\rangle}{dt} = & -\frac{i}{\hbar} \hat{\mathcal{L}}_{\text{eff}} |\hat{\underline{\sigma}}(t)\rangle - \frac{1}{\hbar^2} \sum_{\mu} \sum_{\mu'} \xi_{\mu} \xi_{\mu'} \sum_{m=-l}^l \sum_{m'=-l'}^{l'} \\ & \times (-1)^{m+m'} \int_0^{\infty} d\tau \overline{F_{-m}^{\mu}(t) F_{-m'}^{\mu'}(t+\tau)} \\ & \times \hat{\Gamma}_m^{\mu} \sum_p \hat{\Gamma}_{m',p}^{\mu'} e^{i\Omega_p \tau} |\Delta \hat{\underline{\sigma}}(t)\rangle \end{aligned} \quad (64)$$

The end result is that the relaxation matrix is unaffected by rotation about the z axis. The solution in the rotating frame—highly preferred over that in the laboratory frame in computation—is often used as is; i.e., no transformation is performed to place the density matrix back into the laboratory frame after the solution of $|\hat{\underline{\sigma}}(t)\rangle$ is obtained.

A word of caution is in order. Although the transformation into a single rotating frame about the static field axis does not affect the relaxation matrix, this is not true for a transformation into a multiple rotating frame. Multiple rotating frames are particularly useful in dealing with heteronuclear spin systems, but in such cases a secular approximation must be applied. Fortunately, the nonsecular terms will be oscillating at frequencies that are on the order of the difference between the isotope Larmor frequencies. For the vast majority of cases, these will be at least several megahertz at common field strengths. At low field strengths or in the event that two isotopes have very similar Larmor frequencies, only a single rotating frame can be used, but will typically suffice to place all transition frequencies on a reasonable scale for accurate computation.

3 RELAXATION MECHANISMS AND CROSS CORRELATION

We have shown that spin system relaxation is dictated by the superoperator $\hat{\Gamma}$, and, according to equation (46), it is a sum over products of superoperators corresponding to the active interactions as indexed by symbols μ and μ' . Using this equation, we can proceed to formulate superoperators for individual relaxation mechanisms. To complete the formulation of $\hat{\Gamma}$, it is only necessary to give explicit form to equation (31) for each of the relaxation mechanisms active in the spin system under study. In this section, such will be done for several of the mechanisms most frequently encountered in liquid samples.

3.1 Intramolecular Dipole–Dipole Coupling

Relaxation by dipolar interactions is the most commonly treated relaxation mechanism in NMR. As such, we shall begin our specific relaxation discussions with the dipolar interaction and the dipole–dipole relaxation mechanism. The dipolar Hamiltonian for a system of n spins is given by

$$\begin{aligned} \hat{\mathcal{H}}^D = & \sum_{i=2}^n \sum_{j=1}^{i-1} \xi_{ij}^D \sum_{m=-2}^2 (-1)^m F_{-m}^{(2)}(D, \theta_{ij}, \phi_{ij}) \hat{T}_m^{(2)} \\ & \times (D, i, j) \end{aligned} \quad (65)$$

The index μ has been resolved into the label D and a sum over all pairs of spins in the system. The spherical polar coordinates (θ_{ij}, ϕ_{ij}) specify the orientation of the internuclear vector for each pair of spins relative to the laboratory fixed coordinate system, and are implicitly time-dependent through the rotational diffusion of the molecule. Only the $l = 2$ spherical tensor components contribute to this mechanism. The dipolar interaction is symmetric about the internuclear vector, so that only two orientational parameters are required. The two spins interact through space, so that it is immaterial whether they are proximate through chemical bonds or not. The dipolar interaction constant is given by

$$\xi_{ij}^D = -2\sqrt{\frac{6\pi}{5}} \frac{\gamma_i \gamma_j}{r_{ij}^3} \quad (66)$$

The required rank-2 spatial functions are identical to the spherical harmonic functions as given by

$$\left. \begin{aligned} F_0^{(2)}(D, \theta_{ij}, \phi_{ij}) &= Y_0^{(2)}(\theta_{ij}, \phi_{ij}) \\ &= \sqrt{\frac{5}{16\pi}} (3 \cos^2 \theta_{ij} - 1) \\ F_{\pm 1}^{(2)}(D, \theta_{ij}, \phi_{ij}) &= Y_{\pm 1}^{(2)}(\theta_{ij}, \phi_{ij}) \\ &= \mp \sqrt{\frac{15}{8\pi}} (\cos \theta_{ij} \sin \theta_{ij} e^{\pm i\phi_{ij}}) \\ F_{\pm 2}^{(2)}(D, \theta_{ij}, \phi_{ij}) &= Y_{\pm 2}^{(2)}(\theta_{ij}, \phi_{ij}) \\ &= \sqrt{\frac{15}{32\pi}} (\sin^2 \theta_{ij} e^{\pm 2i\phi_{ij}}) \end{aligned} \right\} \quad (67)$$

Since the molecule reorients in a liquid, these angles are time-dependent and contribute to the lattice spectral densities as described in Section 2.6.

The rank-2 spherical tensor operators are given by

$$\left. \begin{aligned} \hat{T}_0^{(2)}(D, i, j) &= \sqrt{\frac{1}{6}} (3 \hat{I}_{iz} \hat{I}_{jz} - \hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j) \\ \hat{T}_{\pm 1}^{(2)}(D, i, j) &= \mp \frac{1}{2} (\hat{I}_{i\pm} \hat{I}_{jz} + \hat{I}_{iz} \hat{I}_{j\pm}) \\ \hat{T}_{\pm 2}^{(2)}(D, i, j) &= \frac{1}{2} \hat{I}_{i\pm} \hat{I}_{j\pm} \end{aligned} \right\} \quad (68)$$

For a system composed of two spins, both $I = \frac{1}{2}$, the spin operators take on the following matrix representations when

expressed in the product basis $\{|\alpha\alpha\rangle, |\alpha\beta\rangle, |\beta\alpha\rangle, |\beta\beta\rangle\}$:

$$\left. \begin{aligned} \frac{1}{2\sqrt{6}} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & -1 & 0 \\ 0 & -1 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad \frac{1}{4} \begin{bmatrix} 0 & -1 & -1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix} \\ \frac{1}{2} \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \end{aligned} \right\} \quad (69)$$

The commutation superoperators required for equation (44) are formed from the spin tensor components as follows:

$$\hat{\Gamma}_m^{\text{Dij}} = \hat{T}_m^{(2)}(\mathbf{D}, i, j) \otimes \hat{E} - \hat{E} \otimes \hat{T}_m^{(2)}(\mathbf{D}, i, j) \quad (70)$$

The dipole-dipole contribution to relaxation is thus given by

$$\begin{aligned} \hat{\Gamma}^{\text{DD}} &= \sum_{i=2}^n \sum_{j=1}^{i-1} \sum_{k=2}^n \sum_{l=1}^{k-1} \xi_{ij}^{\text{D}} \xi_{kl}^{\text{D}} \sum_{m=-2}^2 (-1)^m \\ &\times \sum_p \hat{\Gamma}_m^{\text{Dij}} \hat{\Gamma}_{-m,p}^{\text{Dkl}} J^{\text{DDijkl}}(\Omega_p) \end{aligned} \quad (71)$$

3.2 Chemical Shielding Anisotropy

Another important interaction contributing to relaxation arises from the anisotropic part of the chemical shielding Hamiltonian (SA). Because the energies involved are dependent on the static magnetic field strength, this type of relaxation becomes more important as the spectrometer field strength increases. The Hamiltonian for shielding anisotropy is given by

$$\hat{\mathcal{H}}^{\text{S}} = \sum_{i=1}^n \xi_i^{\text{S}} \sum_{m=-2}^2 (-1)^m F_{-m}^{(2)}(\mathbf{S}, \theta_i, \phi_i, \chi_i) \hat{T}_m^{(2)}(\mathbf{S}, i) \quad (72)$$

In this case, the index μ has been resolved into the label $\mathbf{S}$ and a sum over all the spins in the system. Only the $l = 2$ tensors are required. The set $\{\theta_i, \phi_i, \chi_i\}$ are the three Euler angles that orient the principal axes of a given shielding tensor into a common coordinate system according to

$$F_m^{(2)}(\mathbf{S}, \theta_i, \phi_i, \chi_i) = \sum_{m'=\pm 2} \mathcal{D}_{mm'}^{(2)}(\theta_i, \phi_i, \chi_i) F_{m'}^{(2)}(\mathbf{S}, \text{PAS}_i) \quad (73)$$

If the shielding tensor is symmetric ($\eta = 0$) then the spherical harmonic is sufficient to describe the lattice fluctuations, and equation (73) reduces to

$$F_m^{(2)}(\mathbf{S}, \theta_i, \phi_i, \chi_i) = Y_m^{(2)}(\theta_i, \phi_i) \quad (74)$$

Here PAS is used to indicate the principal axis system in which the rank-2 irreducible tensor is diagonal, and $\mathcal{D}_{mm'}^{(2)}$ are the elements of the rank-2 Wigner rotation matrices. We have neglected the $l = 1$ component in equation (72) because it is very small in almost all cases. Although the isotropic

component ($l = 0$) does not vanish for this interaction, as it does for the DD interaction in liquid systems, we have combined it with the Zeeman term in the Hamiltonian to produce the chemical shielding contribution to $\hat{\mathcal{H}}_0$, i.e., these contributions are absorbed into the ω_i of equation (30).

It is important to note that in the treatment of shielding anisotropy, the ‘spin’ tensors are actually ‘spin-space’ tensors in that they contain normalized components of the static magnetic field and are thus dependent upon its spatial orientation. Since this is stationary and oriented along the z axis in the laboratory frame, it is of no concern to the theory presented. However, using this type of formulation, one cannot rotate this tensor in spin space, as conceivably could be done for the dipolar Hamiltonian spin tensor. The shielding interaction constant, spatial functions, and ‘spin-space’ tensor components are given below, the latter having field components that stem from a normalized field vector $\mathbf{B}_n = \mathbf{B}_0/|\mathbf{B}_0| = \mathbf{B}_0/B_0$. The interaction constants are given by

$$\xi_i^{\text{S}} = \sqrt{\frac{6\pi}{5}} \nu_i B_0 \delta_{zz}(i) = \sqrt{\frac{6\pi}{5}} \frac{\gamma_i}{\gamma_{\text{H}}} \Omega_{\text{spec}} \delta_{zz}(i) \quad (75)$$

The SA tensor functions in the PAS are given by

$$\left. \begin{aligned} F_0^{(2)}(\mathbf{S}, \text{PAS}) &= \sqrt{\frac{5}{4\pi}} \\ F_{\pm 1}^{(2)}(\mathbf{S}, \text{PAS}) &= 0 \\ F_{\pm 2}^{(2)}(\mathbf{S}, \text{PAS}) &= \sqrt{\frac{5}{24\pi}} \eta \end{aligned} \right\} \quad (76)$$

The spherical tensor operators are given by

$$\left. \begin{aligned} \hat{T}_0^{(2)}(\mathbf{S}, i) &= \sqrt{\frac{1}{6}} (3\hat{I}_{iz}B_z - \hat{\mathbf{I}}_i \cdot \mathbf{B}_n) \\ \hat{T}_{\pm 1}^{(2)}(\mathbf{S}, i) &= \mp \frac{1}{2} (\hat{I}_{i\pm}B_z + \hat{I}_{iz}B_{\pm}) \\ \hat{T}_{\pm 2}^{(2)}(\mathbf{S}, i) &= \frac{1}{2} \hat{I}_{i\pm}B_{\pm} \end{aligned} \right\} \quad (77)$$

For a treatment of a single spin- $\frac{1}{2}$ particle, the rank-2 shielding ‘spin-space’ tensor components take on the following matrix forms when expressed in the standard spin basis $\{|\alpha\rangle, |\beta\rangle\}$ in the laboratory frame, with the field axis along $+z$:

$$\frac{1}{\sqrt{6}} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \quad -\frac{1}{2} \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \quad (78)$$

Although the shielding Hamiltonian is of rank 2, the $m = 2$ component disappears, and the shift anisotropy-shift anisotropy contribution to relaxation is thus given by

$$\hat{\Gamma}^{\text{SS}} = \sum_{i=1}^n \sum_{j=1}^n \xi_i^{\text{S}} \xi_j^{\text{S}} \sum_{m=-1}^1 (-1)^m \sum_p \hat{\Gamma}_m^{\text{Si}} \hat{\Gamma}_{-m,p}^{\text{Sj}} J^{\text{SSij}}(\Omega_p) \quad (79)$$

The $\hat{\Gamma}_m^{\text{Si}}$ are commutation superoperators are formed from the spin tensor component for spin i according to

$$\hat{\Gamma}_m^{\text{Si}} = \hat{T}_m^{(2)}(\mathbf{S}, i) \otimes \hat{E} - \hat{E} \otimes \hat{T}_m^{(2)}(\mathbf{S}, i) \quad (80)$$

3.3 Quadrupolar Interactions

Spins having spin angular momentum quantum numbers larger than $\frac{1}{2}$, $I \geq 1$, may possess an appreciable electric quadrupole moment, which can provide important relaxation mechanisms. The Hamiltonian for quadrupolar interactions is given by

$$\hat{\mathcal{H}}^Q = \sum_{i=1}^n \xi_i^Q \sum_{m=-2}^2 (-1)^m F_{-m}^{(2)}(Q, \theta_i, \phi_i, \chi_i) \hat{T}_m^{(2)}(Q, i) \quad (81)$$

As for the Q mechanism, the index μ has been resolved into the label Q and a sum over all the spins in the system. Only the $l = 2$ tensors are required. The set $\{\theta_i, \phi_i, \chi_i\}$ are the three Euler angles that orient the principal axes of the quadrupolar tensor into a common coordinate system according to

$$F_m^{(2)}(Q, \theta_i, \phi_i, \chi_i) = \sum_{m'=\pm 2} \mathcal{D}_{mm'}^{(2)}(\theta_i, \phi_i, \chi_i) F_{m'}^{(2)}(Q, \text{PAS}_i) \quad (82)$$

When the quadrupolar tensor is symmetric ($\eta = 0$), the spherical harmonic is sufficient to describe the lattice fluctuations and equation (82) reduces to

$$F_m^{(2)}(Q, \theta_i, \phi_i, \chi_i) = Y_m^{(2)}(\theta_i, \phi_i) \quad (83)$$

As for the shielding Hamiltonian, three angles are necessary for specification of the spatial tensor orientation. For an axially symmetric quadrupolar tensor, $\eta = 0$, only two angles are necessary, and in that case the spatial functions are equivalent to the rank-2 spherical harmonics given for the dipolar interaction. The quadrupolar interaction constants are given by

$$\begin{aligned} \xi_i^Q &= \hbar \sqrt{\frac{6\pi}{5}} \frac{\delta_{zz}(i)}{2I_i(2I_i - 1)} = \hbar \sqrt{\frac{6\pi}{5}} \frac{\text{QCC}_i}{2I_i(2I_i - 1)} \\ &= \hbar \sqrt{\frac{6\pi}{5}} \frac{2\pi \nu_i^Q}{2I_i(2I_i - 1)} \end{aligned} \quad (84)$$

where QCC is the quadrupolar coupling constant. The lattice interaction functions are given by

$$\left. \begin{aligned} F_0^{(2)}(\text{PAS}) &= \sqrt{\frac{5}{4\pi}} \\ F_{\pm}^{(2)}(\text{PAS}) &= 0 \\ F_{\pm 2}^{(2)}(\text{PAS}) &= \sqrt{\frac{5}{24\pi}} \eta \end{aligned} \right\} \quad (85)$$

The spherical tensor operators are given by

$$\left. \begin{aligned} \hat{T}_0^{(2)}(Q, i) &= \sqrt{\frac{1}{6}} (3\hat{I}_{iz}^2 - \hat{I}_i^2) \\ \hat{T}_{\pm 1}^{(2)}(Q, i) &= \mp \frac{1}{2} (\hat{I}_{i\pm} \hat{I}_{iz} + \hat{I}_{iz} \hat{I}_{i\pm}) \\ \hat{T}_{\pm 2}^{(2)}(Q, i) &= \frac{1}{2} \hat{I}_{i\pm}^2 \end{aligned} \right\} \quad (86)$$

For treatment of a spin-1 particle, the rank-2 quadrupolar spin tensor components are expressed in their matrix form as

$$\begin{aligned} \hat{T}_0^{(2)} & \quad \hat{T}_1^{(2)} = [\hat{T}_{-1}^{(2)}]^\text{T} \quad \hat{T}_2^{(2)} = [\hat{T}_{-2}^{(2)}]^\text{T} \\ \frac{1}{\sqrt{6}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & -2 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & -1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \end{aligned} \quad (87)$$

The spin index is implicit and the matrices are in the standard single spin basis $\{|\alpha\rangle, |\beta\rangle, |\gamma\rangle\}$. The quadrupole-quadrupole contribution to relaxation is thus given by

$$\hat{\Gamma}^{\text{QQ}} = \sum_{i=1}^n \sum_{j=1}^n \xi_i^Q \xi_j^Q \sum_{m=-2}^2 (-1)^m \sum_p \hat{\Gamma}_m^{\text{Qi}} \hat{\Gamma}_{-m,p}^{\text{Qj}} J^{\text{QQij}}(\Omega_p) \quad (88)$$

The superoperator $\hat{\Gamma}_m^{\text{Qi}}$ is formed from the spin tensor operators as follows:

$$\hat{\Gamma}_m^{\text{Qi}} = \hat{T}_m^{(2)}(Q, i) \otimes \hat{E} - \hat{E} \otimes \hat{T}_m^{(2)}(Q, i) \quad (89)$$

3.4 External Random Fields

Relaxation by random fields is often used as a ‘catch-all’ in order to account for relaxation that cannot be attributed to other relaxation mechanisms. The origin of the random fields is not precisely specified. They could, for example, arise from DD interactions with paramagnetic species or nuclear spins of solvent molecules. Consider a random field at spin i given by $\mathbf{B}(\mathbf{R}, i, t)$. The time average of the field must be zero, since all constant terms have been absorbed into the static Hamiltonian. However, the time-averaged amplitude of the field irrespective of its direction is nonzero, and this quantity $\mathbf{B}(\mathbf{R}, i) = |\overline{\mathbf{B}(\mathbf{R}, i, t)}|$ will define the interaction strength according to

$$\xi_i^{\text{R}} = \gamma_i B(\mathbf{R}, i) \quad (90)$$

A normalized random field with unit time-averaged amplitude can now be defined as follows:

$$\mathbf{b}(\mathbf{R}, i, t) = \frac{\mathbf{B}(\mathbf{R}, i, t)}{B(\mathbf{R}, i)} \quad (91)$$

The spherical components of this vector are

$$\left. \begin{aligned} b_0^{(1)}(\mathbf{R}, i, t) &= b_z(\mathbf{R}, i, t) \\ b_{\pm 1}^{(1)}(\mathbf{R}, i, t) &= \mp \sqrt{\frac{1}{2}} b_{\pm}(\mathbf{R}, i, t) \end{aligned} \right\} \quad (92)$$

These spherical components of the normalized random field may be identified with the lattice fluctuation functions as follows, and expressed in terms of the spherical harmonics and the time-dependent norm of the scaled random field:

$$F_m^{(1)}(\mathbf{R}, i, t) = b_m^{(1)}(\mathbf{R}, i, t) = |\mathbf{b}(\mathbf{R}, i, t)| Y_m^{(1)}(\theta_i, \phi_i) \quad (93)$$

In contrast to the other interactions we have discussed, all of which have constant amplitude but random orientation, the random field interaction must be assumed to vary randomly in both orientation and amplitude. All the time dependence of the lattice functions then cannot be vested in the spherical harmonics. The Hamiltonian for the random field interaction is

$$\hat{\mathcal{H}}^{\text{R}} = \sum_{i=1}^n \xi_i^{\text{R}} \sum_{m=-1}^1 (-1)^m F_{-m}^{(1)}(\mathbf{R}, i, t) \hat{T}_m^{(1)}(\mathbf{R}, i) \quad (94)$$

The spherical tensor operators are given by

$$\left. \begin{aligned} \hat{T}_0^{(1)}(\mathbf{R}, i) &= \hat{I}_{iz} \\ \hat{T}_{\pm 1}^{(1)}(\mathbf{R}, i) &= \mp \sqrt{\frac{1}{2}} \hat{I}_{i\pm} \end{aligned} \right\} \quad (95)$$

For a single spin- $\frac{1}{2}$ particle, the random field spin tensor components are

$$\left. \begin{aligned} \hat{T}_0^{(1)} &= \frac{1}{2} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \quad \hat{T}_1^{(1)} = -[\hat{T}_{-1}^{(1)}]^T \\ &= \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \end{aligned} \right\} \quad (96)$$

The random field–random field contribution to relaxation is thus given by

$$\hat{\Gamma}^{\text{RR}} = \sum_{i=1}^n \sum_{j=1}^n \xi_i^{\text{R}} \xi_j^{\text{R}} \sum_{m=-1}^1 (-1)^m \sum_p \hat{\Gamma}_m^{\text{R}i} \hat{\Gamma}_{-m,p}^{\text{R}j} J^{\text{RR}ij}(\Omega_p) \quad (97)$$

3.5 Cross Correlation Effects

According to equation (47), the relaxation matrix is a sum of terms, each of which involves two interactions. The index μ implicitly contains a spin or spin pair index, the type of interaction, and the interaction rank. Since there is no restriction on the double sum, there are a great many terms involving different spins or spin pairs and different mechanisms. If the value of any of the indices associated with μ' is different from that associated with μ , the term is referred to as a cross-correlation term. Such terms can involve two different spins or spin pairs of the same mechanism, or two different mechanisms. Some of these terms are zero because the interactions involved are not correlated, so the time average over the product of lattice functions yields zero, but many of them are not negligible and contribute dramatically to relaxation, as will be demonstrated in Section 4. Consider the DD mechanism with three or more spins in the system of interest as shown in equation (71). If $i \neq k$ or $j \neq l$ (both of these inequalities can hold if there are four or more spins) then we have an example of cross correlation. Interactions of different ranks will never correlate, but dipolar and shielding anisotropy interactions are both of rank-2, and cross terms like the following will occur in addition to those enumerated previously:

$$\left. \begin{aligned} \hat{\Gamma}^{\text{DS}} &= \sum_{i=2}^n \sum_{j=1}^{i-1} \sum_{k=1}^n \xi_{ij}^{\text{D}} \xi_k^{\text{S}} \sum_{m=-2}^2 (-1)^m \\ &\quad \times \sum_p \hat{\Gamma}_m^{\text{D}ij} \hat{\Gamma}_{-m,p}^{\text{S}k} J^{\text{DS}ijk}(\Omega_p) \\ \hat{\Gamma}^{\text{SD}} &= \sum_{i=1}^n \sum_{j=2}^n \sum_{k=1}^{j-1} \xi_i^{\text{S}} \xi_{jk}^{\text{D}} \sum_{m=-2}^2 (-1)^m \\ &\quad \times \sum_p \hat{\Gamma}_m^{\text{S}i} \hat{\Gamma}_{-m,p}^{\text{D}jk} J^{\text{SD}ijk}(\Omega_p) \end{aligned} \right\} \quad (98)$$

Some simulations showing the effects of cross correlation may be found in Sections 4.2 and 4.4.

4 SOME EXAMPLES

Now that the mathematical tools needed are at our disposal and several relaxation mechanisms have been presented, we can explore their effects using some simple spin systems as examples. This will be done by means of simulations using the GAMMA magnetic resonance simulation platform⁵ so that the various mechanisms can be turned on and off or adjusted at will to illustrate their effects. Most of our attention will be focused on longitudinal relaxation, though some transverse effects will be noted. In addition, the influence of molecular motion and geometry on the results of our ‘experiments’ will be examined. A growing body of experimental results⁴ indicates that the theoretical framework developed above predicts the results of experiments very accurately. Thus, we can proceed with some confidence to predict the results of experiments, though they may not yet be in the literature. The complexity of the relationship between these geometrical and dynamical parameters is such that it is clearly impossible to explore every variable fully here, but selected examples will be used to exhibit the sensitivity of experimental results to various physical parameters.

4.1 Coupled Relaxation Experiments: The AX Spin System

In this section, several experiments will be described that are used for studying longitudinal relaxation in coupled spin systems. Examples of their application to a ^{13}C – ^1H (AX) spin system will be given. Many of the basic principles of coupled relaxation can be illustrated using only this simple spin system. Some other pair of heteronuclei or a homonuclear spin system could be treated equally well.

The return to thermal equilibrium of magnetization that has been perturbed is governed by equation (45). Experiments to study spin relaxation normally consist of

1. preparing the spin system in a nonequilibrium state using rf pulses;
2. allowing the magnetization to relax for a period of time t_1 ;
3. projecting the magnetization of interest onto the observable single quantum coherences, again using rf pulses;
4. observing the resulting FID as a function of the time t_2 ;
5. Fourier transforming the FID to obtain a spectrum exhibiting the partially relaxed magnitudes of the various magnetizations.

This procedure is repeated for various values of t_1 and for various preparations of the nonequilibrium state until a sufficient body of data has been accumulated to elucidate all desired aspects of the relaxation of the system under study. Generally, one acquires enough data to overdetermine the relaxation, and then utilizes nonlinear least-squares fitting techniques to extract the values of the physical parameters of interest from the experimental data. Using the theory given above as implemented in the GAMMA platform, one can numerically simulate all of these steps. To exhibit all aspects of the relaxation behavior, it is generally necessary to perform several experiments, preparing the spin system in various ways. In each case, the relaxation during the evolution time t_1 is governed by equation (45), but the initial condition for the differential equation (i.e., the density operator at the start of the evolution period) is different in each case. Several

Figure 2 The proton hard pulse experiment used to create Figure 1. The wide pulse is a π pulse; the narrow one is a $\frac{1}{2}\pi$ pulse

such experiments are described below. More experimental details can be found in the review by Grant et al.⁴ We shall confine ourselves to exploring the effects of several relaxation mechanisms on some simple spin systems to illustrate the kinds of physical parameters to which spin relaxation is sensitive. Using the ^{13}C – ^1H (AX) spin system as a simple example, several typical experiments for studying coupled relaxation will be presented.

4.1.1 Nonselective Inversion: Hard Pulse

In the introduction (Section 1.3) the concept of cross relaxation due to dipolar coupling between the spins was introduced, and was illustrated in Figure 1. Figure 2 shows the proton hard pulse or nonselective inversion procedure used to create the simulations in Figure 1. This experiment illustrates many of the features of coupled relaxation and many of the effects of the various relaxation mechanisms. The protocol of the experiment is as follows:

1. Preparation: the system is started at thermal equilibrium, then a nonselective π pulse is applied at the proton resonance frequency. All the proton magnetization is now aligned along the negative z axis; the carbon magnetization remains at thermal equilibrium.
2. Evolution: the system is allowed to evolve for a time t_1 . The proton magnetization returns toward thermal equilibrium, with cross relaxation to the carbon.
3. Projection: a $\frac{1}{2}\pi$ pulse is applied at the carbon resonance frequency to project the z components of the carbon magnetization onto the carbon single quantum coherences.
4. Detection: the carbon FID is digitized.
5. The FID is Fourier transformed.

A series of values of t_1 was chosen and the procedure repeated for each value. The resulting spectra are shown in Figure 1. The ^1H spectra shown there were obtained by shifting the projection and observation steps to the proton frequency. Note that the two lines in each doublet evolve identically; this leads naturally to the idea of magnetization modes. More on this subject can be found in **Relaxation Mechanisms: Magnetization Modes**. It is generally more convenient and instructive to plot linear combinations of peak intensities corresponding to these magnetization modes. In Figure 1 note

that the four lines have been designated as C1, C2, H1, and H2. The magnetization modes for this AX system are

$$\left. \begin{aligned} M_C &= M_{C1} + M_{C2} \\ M_H &= M_{H1} + M_{H2} \\ M_\Delta &= M_{C1} - M_{C2} = M_{H1} - M_{H2} \\ M_T &= \text{sum over all state populations} \end{aligned} \right\} \quad (99)$$

The M_T mode is just the sum of the populations of all the states, which is assumed to be constant, since the number of spins in the sample is constant. This corresponds to using the irreducible spherical tensor operators for two nonidentical spins as basis operators. The procedure for generating these operators is discussed in detail by Wang and Grant.¹⁷ Figure 3 shows the effect of several relaxation mechanisms on the spin system of Figure 1. The dotted line shows evolution under DD relaxation alone; random field effects have been turned off. The system relaxes much more slowly than shown in Figure 1. The addition of SA relaxation results in evolution as shown by the light line. To this point, M_Δ has not been perturbed at all. However, when cross correlation between DD and SA (see Section 3.5) is added, the evolution shown by the heavy lines results. Thus, only the DD–SA cross correlation relaxation couples M_Δ to the other modes. Figure 4 shows expanded views of the lines of the doublet at thermal equilibrium for these same cases. When DD–SA relaxation is considered, the two linewidths, i.e., the T_2 values of the lines, are no longer equal, and the doublet is not symmetric. In this case, lineheights may not be used to follow the evolution of the magnetization modes, but integrated intensities must be used. This has been done in Figure 3.

Figure 3 Magnetization mode evolution plots showing the effect on a ^{13}C – ^1H spin system of DD relaxation (dotted line), the addition of SA on the ^{13}C of 100 ppm (light line), and finally with cross correlation between DD and SA (heavy lines). The spin system is as in Figure 1. The shielding tensor is axially symmetric, with the unique axis along the internuclear vector. A hard pulse perturbation as in Figure 2 is used. There is no random field relaxation. The M_Δ mode is shown only for the last case, since it is always zero in the first two cases

Figure 4 Expanded plots showing thermal equilibrium ^{13}C spectra from the data set of Figure 3. The light line shows only DD relaxation, while the heavy line includes DD-SA cross correlation. The doublet remains symmetric for DD relaxation, but addition of DD-SA cross correlation affects T_2 differentially for the two transitions, yielding an unsymmetrical doublet

Figure 5 The effect of internuclear distance on DD cross relaxation from M_H to M_C . Random field relaxation of $T_1 = 10$ s is also present for both ^{13}C and ^1H . All other aspects of the experiment are the same as for Figure 1

In Figure 1, relaxation following a π ^1H pulse has already been illustrated for a nominal bond distance of 0.109 nm. The DD relaxation mechanism depends on the inverse sixth power of the internuclear separation. Suppose, now, that the proton is more remote. Figure 5 shows a plot of M_C as a function of the proton carbon distance from 0.11 to 0.30 nm. The random field mechanism has been set for a T_1 of 10 s. The internuclear distance has a dramatic effect on the cross relaxation, and one would expect to be able to measure distances quite accurately by studying cross relaxation. However, the rotational diffusion correlation time has a similar effect, as shown in Figure 6. It is only possible to determine the ratio of these two quantities. In a large molecule where a number of internuclear distances are sought, it is often possible to determine at least one internuclear distance a priori, for example, by assuming that one C-H bond has its usual value for similar hybridization

of the carbon; then all other internuclear distances can be calculated. This calculation presumes that nuclei involved all reorient at the same rate, i.e., that the molecule is rigid. As the internuclear distance is increased, the DD mechanism weakens rapidly, but, even at 0.3 nm, the DD mechanism is still evident in that it produces cross relaxation. It is not the weakening of the DD mechanism that imposes this limit, but rather that it becomes weak compared to the combined effect of all other mechanisms.

So far, we have assumed that the molecule under study undergoes rotational diffusion as a spherical top, and the orientation of the internuclear vector with respect to some molecule-fixed coordinate system is irrelevant. If the molecule is diffusing as a symmetric top, this is no longer the case. Let the molecule-fixed coordinate system be that which diagonalizes the rotational diffusion tensor. Then Figure 7 shows the dependence of M_C on the angle θ between the

Figure 6 The effect of rotational correlation time on cross relaxation. A random field relaxation of $T_1 = 10$ s is present for both ^{13}C and ^1H . All other aspects of the experiment are the same as for Figure 5

Figure 7 The effect of motional anisotropy on cross relaxation from M_H to M_C for various angles between the internuclear vector and the unique axis of the rotational diffusion tensor. Curves are given for an oblate and a prolate top as shown. All other aspects of the experiment are the same as for Figure 1

unique axis of the top and the internuclear vector for motional anisotropies $D_{\perp}/D_{\parallel}$ of 0.3 and 3.0. To effect DD relaxation, molecular motion must change the direction of the internuclear vector. Thus, if the C–H vector is oriented parallel to the direction of $D_{\parallel}$ then changing the value of $D_{\parallel}$ has no effect on the relaxation. In Figure 7, $D_{\perp}$ has been kept constant as in Figure 1, and $D_{\parallel}$ has been altered to produce the anisotropies.

4.1.2 Inversion–Recovery

Figure 8 illustrates the inversion–recovery experiment. This procedure is identical to that commonly used for measuring ^{13}C T_1 values under ^1H decoupling, but here no decoupling is applied. The protocol for the experiment is as follows:

1. Preparation: the system is started at thermal equilibrium; then a π pulse is applied at the carbon resonance frequency. All the carbon magnetization is now aligned along the negative z axis; the proton magnetization remains at thermal equilibrium.
2. Evolution: the system is allowed to evolve for a time t_1 . The carbon magnetization returns to thermal equilibrium, with cross relaxation to the protons.
3. Projection: a $\frac{1}{2}\pi$ pulse is applied at the carbon resonance frequency to project the z components of the carbon magnetization onto the carbon single quantum coherences.
4. Detection: the carbon FID is digitized.
5. The FID is Fourier transformed.

Figure 9 shows the resulting simulated spectra for the AX spin system as in Figure 1. As before, the ^1H spectra shown in Figure 9 were obtained by shifting the projection and observation steps to the proton frequency. Note that magnetization flows from the ^{13}C to the ^1H in this case—the reverse of what was observed in Figure 1. For this simulation, only DD relaxation was used, to accentuate the effects of cross relaxation; thus, the relaxation times are substantially longer. Figure 10 shows a plot of M_C taken from the spectra of

Figure 8 The inversion–recovery experiment. The wide pulse is a π pulse; the narrow one is a $\frac{1}{2}\pi$ pulse

Figure 9. The dotted line shows a single exponential with the T_1 adjusted to best fit the actual evolution. The nonexponential behavior indicates that the ^{13}C magnetization is perturbed by the presence of the ^1H , i.e., by cross relaxation to the protons. The departure is slight, and might be overlooked in a real experiment unless careful studies were done with high S/N data. Thus, the hard pulse experiment of the previous section is a much more sensitive measure of the effects of cross relaxation. Again, the M_{Δ} mode is unperturbed.

4.1.3 Selective Inversion: Polarization Transfer

There are several variations of the selective inversion or soft pulse experiment, depending on which of the spectral lines are to be inverted and the method to be used for inversion. A simple low-power ‘soft’ rectangular pulse or a shaped pulse can be used to invert a single line. One member of a doublet can be inverted by adjusting the pulse amplitude so that the on-resonance peak experiences a π nutation while the off-resonance one experiences an effective field producing a 2π precession and is thus unchanged. These methods have been used before the advent of modern spectrometers with sufficient phase agility to accomplish polarization transfer or INEPT-type procedures such as the one described in Figure 11. This latter procedure is now the preferable one in most cases. It proceeds as follows:

1. Preparation: the system is started at thermal equilibrium; then a proton $(\frac{1}{2}\pi)_x$ pulse is applied to orient the two members of the proton doublet along the y axis. Precession due to scalar coupling for a period of $\frac{1}{2}J$ produces antiphase proton magnetization along the x axis that is then rotated back onto the z axis with a $(\frac{1}{2}\pi)_y$ pulse. The simultaneous π pulses in the center of the preparation period cause the evolution due to chemical shift to refocus, but do not affect the evolution due to scalar coupling. The carbon thermal equilibrium magnetization is inverted by the π pulse, and to this is added the antiphase magnetization generated in the proton domain. This yields a 1.5 : –2.5 doublet intensity ratio.
2. Evolution: the system is allowed to evolve for a time t_1 . Both the carbon and proton magnetizations return toward thermal equilibrium.

Figure 9 Simulated spectra resulting from the inversion–recovery experiment described in Figure 8. The spin system is the same as for Figure 1. Only DD relaxation is enabled

Figure 10 The M_C mode taken from the spectra of Figure 9 plotted versus time. The solid line is the actual evolution of the magnetization; the dotted line is the corresponding single exponential evolution

3. Projection: a $\frac{1}{2}\pi$ pulse is applied at the carbon or the proton resonance frequency to project the z components of the corresponding magnetization onto the single quantum coherences.
4. Detection: the carbon or proton FID is digitized.
5. The FID is Fourier transformed.

Figure 12 shows the spectra obtained by applying this sequence to the spin system of Figure 1. Note how proton magnetization is transferred to the ^{13}C in much the same way as happens in an INEPT experiment. In this case, the M_Δ mode is strongly perturbed, but, as shown in Figure 13, it is mono-exponential because this mode is not coupled to any other for an AX system with only DD relaxation. Even though the spectral lines evolve in a more complicated way and evolve differently for the ^1H than for the ^{13}C doublet, the difference of the two lines of the doublet M_Δ evolves identically and

mono-exponentially, whether measured in the ^1H or the ^{13}C spectrum as stated in equation (99). This is a manifestation of the fact that the operator corresponding to M_Δ is identical whether it is measured in the proton spectrum or the carbon spectrum. These two differences of line intensities are just two different views of the same measurable, and this measurable is not coupled to any other mode.

4.2 Angles Between Internuclear Vectors: The AX_2 Spin System

In Section 4.1.3, we observed how cross correlation between DD and SA interactions can influence relaxation. The AX_2 spin system introduces the possibility to have cross correlation between two different DD interactions. There are

Figure 11 Selective inversion of a proton doublet using nonselective pulses. The wide pulses are π ; the narrow ones are $\frac{1}{2}\pi$. The letters under the pulses indicate relative phases. If no phase is indicated, it is arbitrary

Figure 12 Spectra obtained by applying the selective inversion procedure of Figure 11 to the proton spin system described in Figure 1. Only the DD mechanism is enabled

Figure 13 Magnetization modes taken from the spectra of Figure 12 plotted as a function of evolution time. Here the single exponential (dotted) line precisely superimposes on M_{Δ} and is not visible. Compare with Figure 10

three different spin pairs (AX, AX', and XX'), each of which has a DD interaction, and there can be cross correlation among these various interactions (see Section 3.5). Because of the complexity of the way in which these cross correlations are folded into the elements of the relaxation superoperator, it is difficult to show how they influence relaxation in a clear way. However, the AX₂ spin system also introduces the angle between two internuclear vectors as a parameter of interest that is affected by this DD–DD cross-correlation. In Section 4.1.1, it was noted that for an AX spin system, the orientation of the internuclear vector with respect to some molecule-fixed frame is irrelevant for a spherical top. However, Figure 14 shows the influence of the angle between two internuclear vectors on the results of a proton hard pulse experiment. The magnetization

modes of interest here are

$$\left. \begin{aligned} M_C &= M_{C1} + M_{C2} + M_{C3} \\ M_{+-+} &= M_{C1} - M_{C2} + M_{C3} \end{aligned} \right\} \quad (100)$$

The M_{+-+} mode was not present in the AX spin system, and is coupled to both the total proton and total carbon magnetizations. Both of these modes show dramatic sensitivity to the HCH angle for spherical top diffusion.

4.3 Rotational Anisotropy: The AX₃ Spin System

The prototypical AX₃ spin system is a ¹³C methyl group. If a methyl is attached to a larger molecule, the free rotation

Figure 14 For a ¹H–¹³C–¹H (AX₂) system, the effect of the HCH angle on the cross relaxation of the observable magnetization modes. Only the DD mechanism is enabled in the simulations. The perturbation is a proton hard pulse as in Figure 2. All other conditions are the same as for Figure 1

Figure 15 For a $^{13}\text{C}-^1\text{H}_3$ (AX_3) system, the effect of motional anisotropy (shown as $D_{\perp}/D_{\parallel}$ for the various curves) on the cross relaxation of the M_C and M_{+---+} magnetization modes. Only the DD mechanism is enabled in the simulations. The geometry is tetrahedral, with the threefold axis of the methyl collinear with $D_{\parallel}$. The perturbation is a proton hard pulse as in Figure 2. All other conditions are the same as for Figure 1

about the threefold axis of the methyl combined with the much slower overall tumbling of the molecule as a whole results in high motional anisotropy. This situation is a good case for exploring the effect of motional anisotropy on spin relaxation. The magnetization modes of interest in this case can be written as linear combinations of the four transitions of the carbon quartet:

$$\left. \begin{aligned} M_C &= M_{C1} + M_{C2} + M_{C3} + M_{C4} \\ M_{+---+} &= 3M_{C1} - M_{C2} - M_{C3} + 3M_{C4} \end{aligned} \right\} \quad (101)$$

Figure 15 shows these ^{13}C magnetization modes as they evolve in a proton hard pulse experiment. Beginning with a spherical top, cross relaxation is observed much as in previous cases; however, as the anisotropy of the reorientation increases, the M_{+---+} mode is very sensitive, even switching to a negative excursion rather than a positive one under highly unsymmetrical reorientation.

4.4 *o*-Dichlorobenzene

The simulation in Figure 16 uses experimental parameters as for the protons of *o*-dichlorobenzene (an $\text{AA}'\text{BB}'$ spin system.) The basic parameters for this simulation were taken from a paper by Stark et al.¹⁸ The lower traces show spectra with full DD relaxation, including both autocorrelation and cross-correlation terms, whereas the upper traces have only autocorrelated DD terms. Under extreme narrowing (the two left traces), there is no apparent difference. When the correlation times are increased by a factor of 10, however, differences in maximum peak heights and linewidths are clearly visible. This simulation includes only dipolar relaxation terms, and uses a rigid asymmetric top as the motional model.

These few examples show the wealth of information available from coupled relaxation studies. Furthermore, many of the

Figure 16 Simulated proton spectra at 220 MHz of *o*-dichlorobenzene with DD relaxation including both autocorrelated and cross-correlated relaxation terms (lower traces) and with only autocorrelated terms (upper traces). The motion was modeled as a rigid asymmetric top with correlation times of 3.4, 5.4, and 1.9 ps (left traces) and 34, 54, and 19 ps (right traces). Artificial line broadening of 0.05 Hz was used for the spectra on the left to suppress truncation artifacts

multidimensional experiments that have become commonplace tools for the chemist and biochemist involve placing coupled spin systems in nonequilibrium states. In many cases, the cross relaxation and cross-correlation effects illustrated here markedly influence the results of such experiments, and due consideration must be given when interpreting these experiments.

The GAMMA platform has been made available to the public by its authors. The source code of the GAMMA-based program that generated all the simulations herein, as well as online simulations of these effects, are available courtesy of the National High Magnetic Field Laboratory at <http://gamma1.magnet.fsu.edu/~gamma/>.

1 INTRODUCTION

Stereochemistry (from the Greek *stereos*, meaning ‘solid’), the three-dimensional architecture of molecules at the atomic level, underlies our world of appearances, from the grit of grains of sand to the intricacies of an infant’s hand. It is a tenet that the macroscopic properties of solids are a consequence of this architecture. It is also thought that the myriad of chemical transformations depends in a subtle way on stereochemistry; the living cell, a microscopic center for the chemical reactions essential to life, depends on stereochemistry for the ‘recognition’ of one molecule by another during the initiation of reactions which, in turn, produce molecules whose biological utility again has an exquisite dependence on their architecture. Such are the working hypotheses at the root of an enormous effort to establish the stereochemistry of animate and inanimate materials.

NMR is playing an important role in this quest—witness the ubiquity of NMR spectrometers in chemical laboratories. One stereosensitive property of a molecule is the scalar interaction between magnetic nuclei nJ , in which n represents the number of intervening chemical bonds; n can run from unity, in all molecules, to at least 14 in some molecules (see *Indirect Coupling: Theory and Applications in Organic Chemistry*). For $n \geq 4$, nJ is often relatively small. As the resolution of NMR spectra improved, the presence of such long range coupling constants became clear and their relationship to stereochemistry became a subject of study. Among the earliest theoretical and experimental investigators of this topic were F. A. L. Anet, M. Barfield, A. A. Bothner-By, D. M. Grant, H. Günther, R. A. Hoffman, H. S. Gutowsky, G. J. Karabatsos, M. Karplus, J. Meinwald, and H. M. McConnell. Barfield has been particularly active over a long period in providing theoretical stimulation to experimentalists. A number of extensive reviews^{1–8} of the theory of long range coupling constants and their stereochemical applications are recommended.

The aim of this article is to provide an overview of the utility of long range coupling constants in stereochemical analysis.

A very brief discussion is given of stereochemical concepts, followed by a heuristic description of the origins of nJ , which is elaborated by specific examples drawn mainly from organic chemistry. This choice is dictated by the available space and is also colored by personal taste. Apologies are in order to those authors whose work may well have been cited. Only a few of the thousands of long range coupling constants can be included; even if only the more familiar NMR-active nuclei (^1H , ^{13}C , ^{19}F , and ^{31}P) were included for $4 \leq n \leq 12$, then the variety of chemical bonding patterns would require a substantial book for an adequate discussion.

2 STEREOCHEMISTRY

The electrons in a molecule move with speeds near a million meters per second and therefore traverse the space of a moderately sized molecule about a thousand million million times in one second. In so doing, the electrons tie the very small but relatively massive nuclei into a floppy, pulsating, rotating object, which is stable at ambient temperatures. At certain distances between the nuclei, the Coulombic forces of attraction between the nuclei and electrons outweigh those of repulsion between nuclei and between electrons. For nearest-neighbor nuclei these distances are called ‘bond lengths’; intuition is correct in suggesting that the electrons tend to concentrate in the regions between neighboring nuclei. If two electrons undergo this concentration one has a single bond, if four, a double bond, and so forth.

The diversity of molecular size and shape is breathtaking. The diatomic oxygen molecule, so necessary to our very existence, contains two nuclei and sixteen electrons. A small diamond, also thought necessary by some, is a single molecule containing some 10^{22} nuclei and six times as many electrons. When diamond burns in oxygen, one obtains the linear, triatomic molecule, carbon dioxide, which is considered obnoxious, yet is essential for photosynthesis. One of the aims of modern experimental and theoretical chemistry is the elucidation of the detailed shapes of these various three-dimensional objects, i.e. their stereochemistry.

Consider a tetra-atomic molecule ABCD. In (1), the four different nuclei are connected in a unique way: A is attached to B by a single bond and not to C, and so forth. This connection scheme defines the *connectivity* or *constitution* of the molecule and represents the first step in the stereochemical description. The angles between the internuclear vectors, A–B and B–C, for example, are called ‘bond angles’. An important angle θ , the torsion or dihedral angle between the two planes containing ABC and BCD, defines the *configuration* or the *conformation* of the molecule. If a very large energy input is needed to interconvert (1) and (3), i.e. if the thermal kinetic energy (motion of the molecules through space may lead to a collision in which one molecule receives energy from another) is small compared to the energy needed to twist (1) into (3), or vice versa, then one may speak of two configurations of the molecule, or of *configurational isomers*. If you have configuration (1) and, some time later, say days, (1) has not turned even partially into (3), even under heat, then you may speak of configuration. Often, such a situation requires a double bond between C and D, indicated by two strokes (double bond), and one refers to ‘breaking the double bond’ during configurational isomerization. If the energy needed

to interconvert (1) and (3) is not large compared to the thermal energies, then the sample of the substance ABCD may well contain appreciable amounts of (1) to (3). One has an equilibrium among conformational isomers or *conformers*. The relative amounts, or populations, of the conformers usually change as the temperature changes.

The two terms ‘configuration’ and ‘conformation’ relate to the human timescale. Near absolute zero in temperature, there would be little need for both terms; one would suffice in most instances. It all depends on the flexibility or floppiness of the molecule. A certain care is therefore needed in the description of the stereochemistry of a molecule. If the energy barrier to interconversion among (1) to (3) is small, then ABCD takes on all conformations, defined by θ , with similar probabilities. All angles from 0° to 180° are then significantly represented in the sample (ensemble). A molecule’s reactivity, how it combines with other molecules to form one or more product molecules, and how rapidly it does so, can depend strongly on its conformation/configuration; this is one reason for the study of stereochemistry.

A complete stereochemical description requires precise values of bond lengths and bond and torsion angles, preferably with a potential function describing the energy of a molecule as a function of θ . Furthermore, because the molecule vibrates (pulsates), a knowledge of all the other vibrational motions, such as bond stretches and bond angle deformations, together with their frequencies and amplitudes, is desirable. Finally, a map of the electron density, at least up to distances of 10^{-9} m from the molecular periphery, is also needed.

Needless to say, a variety of experimental and theoretical techniques is necessary for these purposes. Most techniques utilize the fact that rotational, vibrational and electronic energies of molecules are quantized and directly related to the stereochemical properties. The energies, or at least their differences, can be ascertained by stimulating transitions between the various states of different energies with the photons available from electromagnetic radiation. Other methods scatter the photons from the molecule in the gas or solid and, from interference patterns formed by the scattered photons, deduce electron densities and, by inference, the sites of the nuclei.

NMR techniques, by way of contrast, use the magnetic properties of nuclei and their magnetic interactions with other nuclei and/or electrons to deduce molecular stereochemistry. The magnetic interactions between the nuclei and electrons in

molecules are about a million times smaller than the electrostatic interactions which actually determine the stereochemistry. Therefore, at first sight it appears unreasonable to focus on the magnetic interactions as a source of stereochemical information. After all, the magnetic dipole moment of the nucleus is only weakly coupled to the very forces which mould the molecular shape. Paradoxically, it is this fact which allows NMR to be perhaps the single most general tool for stereochemical analysis. The magnetic field B_0 of the NMR spectrometer penetrates the molecular space almost unaltered and orients the magnet moment of the nucleus into certain definite directions. Under certain conditions the magnetic interactions between the nuclei and between the nuclei and the electrons appear as perturbations of the interaction between B_0 and the nuclei. As a consequence, the NMR spectrum, whose basic frequency represents the B_0 /nucleus energy, is somewhat shifted and split into a number of peaks or frequencies. These shifts and splittings, the latter being related to the J values, can be interpreted in terms of stereochemistry.

3 THE COUPLING CONSTANT BETWEEN NUCLEI

The scalar spin–spin interaction energy between two nuclei is represented by $h\hat{I}_i \cdot \hat{I}_j$, where $\hat{I}_i$ is the spin angular momentum vector operator of nucleus i . Because the magnetic moment μ is proportional to $\hat{I}$, J is also proportional to the product of the two nuclear moments (see *Nuclear Spin Properties and Notation*). In this article, J is given in units of hertz. The dot, or scalar, product in the expression above applies to molecules in the isotropic liquid or gaseous states. It depends on the relative orientations of the two spins, not on their positions in space. Therefore J is unchanged by molecular reorientations, unlike the dipolar interactions which average to zero during such reorientations (see *Dipolar and Indirect Coupling Tensors in Solids*). The directions of the nuclear spins are only very slightly coupled to the orientation of the molecule in space, but are coupled to B_0 . The scalar interaction modifies this latter coupling by definite amounts, proportional to J , and hence appears in the fine structure of the NMR spectrum. Figure 1 shows the ^1H NMR spectrum of the methyl protons of 1-phenylpropyne (4). In the absence of J only a single peak would occur; instead there exist many peaks arising from $^{6,7,8}J$, long range proton–proton coupling constants, over six, seven and eight formal bonds ($n = 6, 7, 8$). The long range coupling constants can be extracted by standard procedures (see *Analysis of High-Resolution Solution State Spectra*).

How does J come about? Consider a hydrogen atom. In addition to the electrostatic attraction between the electron and the proton, an energy of 13.6 eV, there exists a magnetic interaction of 6.0×10^{-6} eV (the hyperfine interaction, that is, very small), which aligns the spins of the proton and

Figure 1 The ^1H NMR spectrum at 300 MHz of the methyl protons of 1-phenylpropyne ($\text{C}_6\text{H}_5\text{C}\equiv\text{CCH}_3$) as a dilute solution in acetone- d_6 at 300 K, has a linewidth at halfheight of somewhat less than 0.03 Hz. The upper, theoretical, spectrum comes from a precise spectral analysis and has the long range coupling constants $^6J(\text{H},\text{CH}_3)$, $^7J(\text{H},\text{CH}_3)$, and $^8J(\text{H},\text{CH}_3)$ of $-0.298(1)$, $0.145(1)$, and $-0.254(1)$ Hz, respectively. electron in an antiparallel fashion, as in (5). Mutual flips of these alignments give rise to radiation at 1420 MHz which is detectable in radioastronomy, exemplifying the underlying unity of the natural sciences. The hyperfine interaction operates when the electron is very near the proton (the contact interaction).

(5)

3.1 A Model of 1J

Now consider the hydrogen molecule (6). Because the electrostatic energies ensure the antiparallel spin alignment of the two electrons (paired off, singlet state), a consequence of the quantum properties of small particles, the contact interaction favors the overall spin orientations shown in (6). The nuclear spin is said to 'spin polarize' the electrons in the sense that—although the net electron spin in the bond, 'down' minus 'up', is zero when averaged over the space of the bond—at the left of the bond in (6) there occurs more 'down' than 'up' spin, and vice versa on the right. The net

result is that an antiparallel arrangement, defining a positive J , of the proton spins (crossed arrows) is favored by about 10^{-12} eV. This magnetic energy is tiny compared with the electrostatic energies yet, paradoxically, is easily measured by NMR. In the hydrogen molecule, J is 280 Hz or 1.1×10^{-3} kJ mol $^{-1}$, which is miniscule compared with the bond energy of 460 kJ mol $^{-1}$. It is clear that J , transmitted via the electrons, is proportional, at each end of the coupling path, to the size of the magnetic moment of the nucleus and, therefore, to the product of the two nuclear magnetic moments.

(6)

J is a second-order property of the molecule in the sense that it results from the product of two first-order interactions; here, two contact interactions. In another sense, because that contact interaction perturbs the ground state molecular wavefunction, the theoretical computation of J must take this perturbation into account; it does so by mixing electronically excited states into the ground state in a complicated fashion. Hence the quantitative computation of J from first principles is not easy (see *Indirect Coupling: Theory and Applications in Organic Chemistry*). In the present article, qualitative models of nJ , $n \geq 4$, which nevertheless can be made semiquantitative, are used to illustrate its stereochemical applications. As will be seen, the torsional dependence of J can sometimes be ascertained by empirical methods which allow rather precise stereochemical conclusions.

3.2 Models of 2J and 3J

In (7), a pair of protons separated by two formal bonds, as in a CH_2 fragment of a molecule, is indicated to have a negative 2J . The coupling mechanism favors a parallel orientation of the proton spin vectors. This is so because the two electrons, in different bonds but near carbon, have a lower electrostatic energy if their spins are parallel than if they are antiparallel. The lower energy, an illustration of Hund's rule, is probably a consequence of the fact that these two electrons move in such a way that they are attracted more strongly by the carbon nucleus when their spins are parallel—the spin serves as a sort of traffic policeman, one electron tending not to get between the other electron and the nucleus. The picture in (7) is called the 'Dirac vector model' of 2J , predicting a negative value, for example, in methane, where 2J is indeed -12.4 Hz. However, $^2J(\text{H},\text{H})$ is positive in some molecules. This failure of the model is shared by another kind of model, which is now illustrated for 3J .

(7)

The HCCH or ethanic fragment in (8) is the prototype of an important class of vicinal or 3J interactions (*Vicinal Coupling Constants and Conformation of Biomolecules*). The Dirac vector model correctly predicts a positive 3J , but it cannot account for its dependence on the torsion angle θ in (9). In fact, it is a direct interaction (not a dipolar interaction, which is also sometimes called 'direct') between the electrons in the two C–H bonds which is important in correlating the electron, and hence the proton, spins. The direct interaction, proportional to valence bond exchange integrals, is minimal when the two C–H bonds lie in mutually perpendicular planes ($\theta = 90^\circ$). An acquaintance with trigonometry, together with the constraint that 3J be positive, suggests that the θ dependence between 0° and 180° is mainly on $\cos^2 \theta$, and perhaps slightly on $\cos \theta$. This is indeed true. The stereochemical significance is obvious. Note that the 'through bond' mechanism, as in (8), is relatively unimportant.

This manner of argument implies that geminal spin correlations, as in (7), could combine with vicinal spin correlations, as in (9), to yield long range coupling constants nJ ($n \geq 4$) in larger molecular fragments and is therefore related to their geometrically extended stereochemistry. This is also true. One drawback concerns the magnitude of long range coupling constants. Generally speaking, for saturated fragments (single bonds) the magnitude decreases as n increases, simply because nJ arises either from the product of small interactions of the kind shown in (8) and (9), or because the direct interaction between bonds decreases with their separation; the bond exchange integrals (interactions) giving rise to spin correlation between electrons in different bonds depend on interelectronic distances in these structures. In (9), 3J is of the order of 10 Hz at $\theta = 0^\circ$ or 180° , whereas 4J has a magnitude of about 1 Hz in the propanic fragment below. Note that at least some deviation from perfect pairing is necessary for a finite J . However, for unsaturated molecules, in which extensive electron delocalization occurs, nJ can be sizeable and does not necessarily drop off monotonically as n increases. As an extreme example, $^{10}J(\text{F},\text{F})$ in (10) is 0.2 Hz in magnitude.

4 nJ ($n \geq 4$) IN SATURATED MOLECULES

In the propanic fragment (11) to (14), direct and indirect mechanisms can contribute to $^4J(\text{H},\text{H})$. The direct mechanisms are important¹¹ in conformations (12) and (13). In (12), the two C–H bonds are proximate in space and $1 \rightarrow 3$ interactions are important. Coupling constants arising in this way are often called 'through space', which is a misnomer because the molecule itself is largely empty space; perhaps, 'proximate' nJ would be a better name. In (13), an all-*trans* or zig-zag conformer, there is a direct interaction between the orbitals on the carbon atoms (rear lobes) to which the coupled protons are bonded, resulting in a relatively large positive $^4J(\text{H},\text{H})$. Indirect mechanisms are associated with $1 \rightarrow 2'' \rightarrow 3$ and $1 \rightarrow 2''' \rightarrow 3$, vicinal–vicinal, and with $1 \rightarrow 2 \rightarrow 3$ or $1 \rightarrow 2' \rightarrow 3$, geminal–vicinal, interactions in (11); the latter are difficult to evaluate. The indirect mechanisms can contribute to $^4J(\text{H},\text{H})$ with either sign, so that $^4J(\text{H},\text{H})$ can be positive or negative,¹¹ depending on the dihedral angles θ and $\alpha\theta'$. In (14), the value of $^4J(\text{H},\text{CH}_3)$ is large, corresponding to $\theta = 180^\circ$.

A recent analysis (Schaefer et al., 1993) of the ^1H NMR spectrum of 2-phenyl-1,3-dithiane, (15), illustrates the stereochemical dependence of $^4J(\text{H},\text{H})$. The approximate torsion (dihedral) angles are given in (15). Note the positive shift of $^4J(\text{H},\text{H})$ as HCSC₂H, containing the heteroatom, sulfur, replaces the propanic fragment. A heteroatom attached to the propanic fragment can also alter 4J . Such substituent perturbations complicate stereochemical assignments and present challenges to the theorist [in fact, the positive shift noted for (15) can be reproduced with the INDO MO FPT formalism,¹² which takes a number of coupling mechanisms into account]. In principle, $^4J(\text{H},\text{H})$ is useful in the stereochemical analysis of other six-membered alicyclic rings which can occur in sugars and steroids, for example. Another example is provided¹³ by the five-membered ring in the anhydronucleoside (16). The signs and magnitudes of $^4J(\text{H},\text{H})$ are related to torsion angles¹⁴ in the furanose ring. Also, coupling constants over five bonds exist between H-1' and the methylene protons in (16).

As the molecular mass increases, the ^1H NMR spectra become very complex and the peak widths also increase due to unresolved long range coupling constants and to shorter relaxation times. Nevertheless, the presence of $^4J(\text{P},\text{H})$, as in the nucleotide (17) and whose magnitude is determined¹⁵ by the geometry of the P–O–C-5'–C-4' fragment, allows¹⁵ the assessment of $^3J(\text{H}-4',\text{H}-5')$ and $^3J(\text{H}-4',\text{H}-5'')$ in a double-helical dodecanucleotide (a DNA fragment). The vicinal coupling constants help in fixing the torsion angle in the fragment O–C-5'–C-4'–C-3'.

In rigid bicyclic systems,⁵ extended or multiple, all-*trans*, coupling pathways can exist, so that $^{4,5,6}J(\text{H,H})$ can be large [propanic (11), butanic, and pentanic paths]. Furthermore, C–H, F–H, P–H, F–F, Tl–H, and C–C long range couplings are known in such molecules; some of these are large for conformations analogous¹⁶ to (12) (proximate couplings). Many are tens of hertz in magnitude, or even as large¹⁷ as 820 Hz as in (18), a norbornane derivative; the electron density at the thallium nucleus is very large for this nucleus of atomic number 81.

5 $^nJ(n \geq 4)$ IN UNSATURATED MOLECULES

5.1 Alkenes and Acetylenes: σ, π Model

In unsaturated molecules such as alkenes and acetylenes the valence electrons are usually considered to be of two different types: σ and π electrons. Thus, in planar ethylene (19), the double bond between the carbon atoms is thought of as a single

σ bond and a single π bond; the latter is formed from electrons in p orbitals on the carbon atoms and yields maximum electron density above and below the plane of the molecule (the six nuclei lie in a plane in the most stable state of the molecule). This σ, π model has been very successful in the description of long range coupling constants although, again, it is a topic of critical discussion.¹⁸

The σ, π model of nJ begins with the recognition that the contact contribution depends on the probability that the electrons, involved in the transmission of nJ , are found at the sites of the coupled nuclei; the protons in ethylene, for example. However, electrons in π orbitals have a zero probability of being found at the nuclear sites—p orbitals have nodes in the plane of the nuclei.

This conundrum is resolved by the invocation of a σ, π spin polarization mechanism, rather similar to that involving the σ electrons in (7). The single p or π electron in (20) and (21) spin polarizes the σ electrons in the C–H bond and leads to an ‘up’ or a ‘down’ arrangement of the proton spin (crossed arrow). By Hund’s rule, (20) is energetically favored. This fact is represented by the σ, π hyperfine interaction parameter $Q_{\text{CH}}^{\text{H}} < 0$ (in the subscript the first symbol represents the atom carrying the unpaired spin, the two subscripts together indicate the bond being spin polarized, and the superscript designates the nucleus coupled to the unpaired electron). Q_{CH}^{H} is negative by definition—the p electron and the proton spins are parallel. Consolidation of this fact with the bonding in ethene (22) where the π electrons are spin correlated (paired off), leads to a π electron spin coupling pathway as shown, in addition to that through the σ bond. It is then found that $^3J^{\pi} \propto Q_{\text{CH}}^{\text{H}} \times Q_{\text{CH}}^{\text{H}}$, yielding about +1.5 Hz, which adds to $^3J^{\sigma}$ which is an order of magnitude larger, to give $^3J^{\pi} + ^3J^{\sigma}$.

Now, consider butadiene (23). The bond between the middle carbon atoms is not a single bond but has considerable ‘double-bond character’; it is said to have a mobile bond order between zero and one, a result of the relatively easy delocalization of π electrons (unlike σ electrons). The magnitude of $^5J^{\pi}$ depends on how strongly the p electrons at the central carbon atoms [dashed lines in (23)] are spin correlated. The

hyperfine interaction at each end of the coupling pathway provides the link between the σ and π electron systems. Note that ${}^5J^\pi > 0$, the proton spins in (23) being antiparallel, even though $Q_{\text{CH}}^{\text{H}} < 0$. The sign of J^π depends on the number of intervening bonds, being positive for n odd and negative for n even. Note also that this mechanism implies equal ${}^5J(\text{H,H})$ values in (23), i.e. the values are independent of the configuration at C-4. The observation that 5J_t is 1.3 Hz whereas 5J_c is 0.6 Hz implies a contribution to 5J_t from the σ electrons, ${}^5J^\sigma$. The coupling mechanisms discussed above for ${}^4J(\text{H,H})$ allow for two vicinal–vicinal interactions involving the central C–C bond in each and thus are expected to contribute most efficiently for an all-*trans* arrangement of the intervening bonds [extend structure (13)].

An estimate of ${}^5J^\pi$ can be made using the ‘methyl group replacement technique’, the use of which involves the following argument. In (24), a proton in one C–H bond of a methyl group has a positive hyperfine interaction $Q_{\text{CCH}}^{\text{H}}/0$ with the electron in the p orbital on the neighboring carbon atom [a so-called β -interaction, contrasting with the α -interaction in (20)]. Furthermore, $Q_{\text{CCH}}^{\text{H}} \propto \sin^2 \theta$ so that $Q_{\text{CCH}}^{\text{H}}$ is largest when the sigma C–H bond lies in the plane containing the p orbital (best overlap). For a rotating methyl group, with three C–H bonds, $\sin^2 \theta$ has an average value of 0.5.

It then turns out that $Q_{\text{CCH}}^{\text{H}} \approx -Q_{\text{CH}}^{\text{H}}$, with the consequence that ${}^6J^\pi(\text{H,CH}_3) \approx -{}^5J^\pi(\text{H,H})$. From the data on (23) it follows that ${}^5J^\pi \approx 0.7$ Hz and ${}^5J^\sigma \approx 0.6$ Hz. The model is not exact, of course, but has been used to estimate π electron contributions to nJ in a variety of molecules, including cumulenes ($\text{CH}_2=\text{C}_n=\text{CH}_2$) and acetylenes [$\text{HC}-(\text{C}\equiv\text{C})_n-\text{CH}$]. In such molecules, the extended spin correlation of the π electrons is relatively high,² leading to significant nJ for n as large as 9. Note that, as the mobile bond order of the central C–C bond in (23) decreases (dashed lines), ${}^5J^\pi$ will also decrease in magnitude. In this sense ${}^nJ^\pi$ is a measure of π electron delocalization: the mobile bond order in ethene (22) is unity, is about 0.4 for the central C–C bond in (23), and is less than unity for the other two C–C bonds. The use of ${}^nJ(\text{H,CH}_3)$ in testing the extent of delocalization in various molecules is described in a later section of this article.

5.2 Allylic and Homoallylic Couplings: ${}^4J(\text{H,H})$ and ${}^5J(\text{H,H})$

The $\sin^2 \theta$ dependence of $Q_{\text{CCH}}^{\text{H}}$ has many stereochemical applications, only two examples of which can be given here. ${}^4J_c(\text{H,CH}_3) \equiv {}^4J_c$ and ${}^4J_t(\text{H,CH}_3) \equiv {}^4J_t$ in propene (25) are called ‘allylic coupling constants’ and have values of -1.7 and -1.3 Hz, respectively. If the σ component of 4J were to vanish and the conformation of the methyl group was exactly the same as that in (25), but with rapid interconversion so that each C–H bond sampled each of the three values of θ (namely 0° , 120° , and 240°), then $\langle \sin^2 \theta \rangle$, the average value of $\sin^2 \theta$, would be 0.5. Actually, for free rotation of the methyl group, $\langle \sin^2 \theta \rangle$ is also 0.5, a consequence of the three-fold symmetry of a methyl group (a CH_2X group has lower symmetry, with important consequences for the derivation of internal rotational potentials, as described below). It would follow that 4J is a measure of the magnitude of ${}^3J^\pi$ in ethene ($Q_{\text{CH}}^{\text{H}} \approx -Q_{\text{CCH}}^{\text{H}}$).

However, because in (25) ${}^4J_c \neq {}^4J_t$, the argument is only semiquantitative. The inequality may be attributable to the presence of ${}^4J^\sigma$. Thus, if the all-*trans* arrangement [see (13)] is most effective for ${}^4J^\sigma$, giving a positive contribution to 4J_t , a rough assessment of ${}^3J^\pi$ in ethene would be $+1.7$ Hz. The true situation is more complex;¹¹ nevertheless, large negative 4J values are expected and observed for $\theta \approx 90^\circ$. An example in which ${}^4J \propto \sin^2 \theta$ is (26), where the ratio of the two coupling constants is 1.5, as compared with a ratio of 1.4 for the corresponding values of $\sin^2 \theta$. To within the combined errors of the J values and the two angles, the relationship is very likely satisfied.

Homoallylic coupling constants ${}^5J(\text{H,H})$ arise from protons in C–H bonds flanking the double bond at both ends. Hence ${}^5J(\text{H,H}) \propto Q_{\text{CCH}}^{\text{H}} Q_{\text{CCH}}^{\text{H}} \propto \sin^2 \theta \sin^2 \theta'$, where the two torsional angles θ and θ' are analogous to those in (25).

A somewhat subtle stereochemical problem involves the degree of nonplanarity of 1,4-dihydrobenzene (27a)–(27c). If the equivalent (isoenergetic), nonplanar conformers (27a) and (27c) are the most stable ones, they may interconvert via the planar conformer (27b). The molecule is then said to undergo ‘conformational isomerization by inversion’. The potential energy function opposing inversion has two minima, as indicated; the speed of inversion depends on how the available thermal energy compares to the potential hindering the inversion. Alternatively, the most stable conformer may be (27b). Then the internal potential has a single minimum; nonplanar conformers occur with decreasing probabilities as the bending angle α deviates increasingly from 180° .

In (27b), the angles θ and θ' are 60° for an idealized geometry, but are not equal in (27a). Hence ${}^5J_c = J_t$ in (27b), but ${}^5J_c \neq {}^5J_t$ in (27a). In solution ${}^5J_c = 1.2 {}^5J_t$, from which it might be deduced¹⁹ that α is about 172° . The derivation of α assumes two rigid forms (27a) and (27c), a so-called 'two-site analysis' in which the measured values of 5J_c and 5J_t are simple averages of their values in these conformers. However, another interpretation holds that torsion about the C–C bonds of a stable, planar (27b), producing nonplanar conformers, would also cause the inequality ${}^5J_c > {}^5J_t$, so that either potential curve could correspond to observation. In fact, today the available evidence from various sources is that (27b) is the stable form.

6 AROMATIC MOLECULES

6.1 Some Coupling Mechanisms

In benzene (28) the indicated ${}^{3,4,5}J(\text{H,H})$ are of obvious use in assigning substitution sites in derivatives of (28). ${}^4J(\text{H,H})$, corresponding to an all-*trans* arrangement, has only a small π component. The ${}^6J(\text{H,CH}_3)$ value of -0.60 Hz in toluene (29) indicates that ${}^5J(\text{H,H})$ in (28) is mainly J^π , while the ${}^7J(\text{CH}_3, \text{CH}_3)$ value of -0.60 Hz in (30) implies $Q_{\text{CH}}^{\text{H}} = -Q_{\text{CCH}}^{\text{H}}$ in these compounds. Furthermore,²⁰ in (31), which represents derivatives of anisole ($\text{X} = \text{O}$), thioanisole ($\text{X} = \text{S}$), and ethylbenzene ($\text{X} = \text{CH}_2$), it is true that ${}^5J(\text{C,C}) = -1.50 {}^6J(\text{C,H}) + 0.02$ and ${}^6J(\text{C,C}) = -0.37 {}^5J(\text{C,C}) + 0.02$. The signs and relative magnitudes of the corresponding hyperfine interaction parameters near C-4, as in (32), are then $Q_{\text{CH}}^{\text{H}} = -Q_{\text{CCH}}^{\text{H}}$, $Q_{\text{CH}}^{\text{C}} = -1.50 Q_{\text{CH}}^{\text{H}}$, and $Q_{\text{CC}}^{\text{C}} = 0.56 Q_{\text{CH}}^{\text{H}}$. Such relationships also hold for other nuclei in the side chain, such as ${}^{19}\text{F}$, typified by (33), showing that the π -electron mechanism is dominant for the indicated ${}^{5,6,7}J$ couplings and that they depend on $\sin^2\theta$.

6.2 Internal Rotational Potentials from Long-Range Coupling Constants

When conformations are well defined, that is when the barrier to interconversion between conformers is large

compared to the thermal energies (see Section 1), the angle dependence of a long-range coupling constant is a good indicator of conformation. An example from aromatic chemistry is a benzaldehyde derivative (34). ${}^5J(\text{H,CHO})$ is apparently a ${}^5J^\sigma$ and, as such, is large for the all-*trans* pathway. If the indicated J values are correct, then measurement of ${}^5J(\text{H,CHO})$ yields the populations of (34a) and (34b) by simple proportion. This simple strategy works well because nonplanar conformers are negligible at ambient temperatures.

Suppose, however, that the barrier to rotation about the ring–CHO bond were very small compared with thermal energies. In such circumstances the idea of one or a few conformations would lose utility because many angles θ would be of similar probability. In the limit of a zero barrier, an infinite number of conformations (all values of θ) would be present.

When the barrier to internal rotation about a bond is small, it is advantageous to discuss stereochemical problems in terms of the internal rotational potential $V(\theta)$, which gives the relative energy of the molecule at each value of θ . Can long range coupling constants be used to determine $V(\theta)$? In some instances, certainly. These statements are best illustrated with one of the many examples available.

Consider benzyl fluoride (35) and the potential hindering rotation about the exocyclic C–C bond. If (35b) and (35c) represent extrema in the potential, the barrier $V(\psi)$ [or $V(\theta)$] is said to be two-fold because it repeats itself twice between 0° and 360° [see (36)]. The barrier turns out to be solvent dependent,²¹ which is an advantage in the following logic. One has ${}^6J(\text{F,H}) = {}^6J_{90}^{\text{F}} \langle \sin^2\psi \rangle$ and ${}^6J(\text{H,H}) = {}^6J_{90}^{\text{H}} \langle \sin^2\theta \rangle$; here ${}^6J_{90}$ is the value when C–F or C–H lies 90° out of the benzene ring plane, and the angle brackets indicate an average over the internal motion controlled by the potential. The roughly tetrahedral geometry at the carbon atom of the CH_2F group implies $\langle \sin^2\theta \rangle = 0.75 - 0.5 \langle \sin^2\psi \rangle$. It follows that measurements of the two coupling constants in two different solvents yield both the ${}^6J_{90}$ values as well as $\langle \sin^2\psi \rangle$ and $\langle \sin^2\theta \rangle$ in each solvent. The latter can be calculated²² by quantum mechanical or classical methods as a function of the internal potential, V_2 . A comparison between the theoretical $\langle \sin^2\psi \rangle$, say, and its experimental values yields V_2 in the two solvents. Together with measurements of ${}^5J(\text{F,C})$, also a J^π , one finds that V_2 is 3.2 kJ mol^{-1} in very polar solvents and 0.7 kJ mol^{-1} in nonpolar solvents. Curve (a) in Figure 2 describes the potential form. Extrapolation to the vapor phase implies that the potential is now as in curve

Figure 2 Twofold internal rotational potential, as applicable to (35b)

(b) in Figure 2, which is qualitatively confirmed by high-level molecular orbital computations on the free molecule. The change in phase of the potential is of interest in the theory of solutions. A phase change can also be induced by substituents on the ring. Each derivative will possess its own, distinctive, solvent dependent, internal rotational potential, the determinations of which present as yet unmet challenges for the various spectroscopic and theoretical methods (*Liquid Crystalline Samples: Structure of Nonrigid Molecules*).

6.3 Stereospecific Long Range Coupling Constants in Extended Aromatic Molecules

Examples of nJ with n as large as 11 are provided by ${}^nJ(\text{F},\text{F})$ and ${}^nJ(\text{F},\text{C})$ in (36) and (37). It is known that the torsion angle θ in (37) is effectively 90° , the two benzene planes being perpendicular, and that it is near 45° in (36). Note that ${}^{7,8}J(\text{F},\text{C})$ and ${}^9J(\text{F},\text{F})$ vanish when $\theta \approx 90^\circ$, indicating that π electron spin correlation has been broken across the central C-4–C-5 bond; there is no π electron conjugation or delocalization between the two aromatic moieties in (37). The finite values of these nJ can be related²³ to $\cos^2\theta$ in (36), as can ${}^{11}J(\text{F},\text{F})$ when the fluorine atoms in (36) are replaced²⁴ by CH_2F groups. Of course, ${}^{11}J(\text{F},\text{F})$ will, in addition, be proportional to $\sin^2\psi$, where ψ is the angle by which the C–F bond turns out of the benzene plane, as in (35b); thus ${}^{11}J(\text{F},\text{F}) \propto \sin^2\psi \cos^2\theta$.

A composite mechanism must also operate for ${}^6J(\text{F},\text{C})$ at site 6 in (36) and (37) because it is larger in (37). The C-5–C-6 bond undergoes a hyperfine interaction with the π electron at C-4, characterized by Q_{CC}^{C} and analogous to Q_{CH}^{H} in (32), which is maximal in (37) and hence varies as $\sin^2\theta$. The other part of the mechanism varies as $\cos^2\theta$, just as for ${}^{7,8}J(\text{F},\text{C})$; hence ${}^6J(\text{F},\text{C}) = A\sin^2\theta + B\cos^2\theta$. Such composite mechanisms also occur in other conjugated systems,

an excellent example being styrene,²⁵ where an alkenic group is bonded to an aromatic system.

6.4 Electron Delocalization and Long Range Coupling Constants

Aromaticity is related to the delocalization of π electrons, leading to mobile bond orders. The structure and reactivity of a molecule are sensitive to the extent of delocalization. There are various definitions of mobile bond order, but all agree that the bond order is zero for a C–C bond, unity in ethene (19) or propene (25) and 2 for a triple bond, as in (4). Clearly, the allylic ${}^4J(\text{H},\text{CH}_3)$ in (25) depends on the π electrons. If delocalization were to decrease the mobile bond order, then the magnitude of ${}^4J(\text{H},\text{CH}_3)$ would also decrease. This idea has been exploited, particularly by Sternhell and co-workers,²⁶ to determine the mobile bond orders in aromatic systems; however, in this case 4J is called a ‘benzylic J ’. In (38)–(45), the degree of delocalization is evident from the indicated 4J . If -0.70 Hz in (41) is a measure of the delocalization of the π electrons in the prototypical aromatic molecule, benzene, then in (42), for example, some localization (double bond fixation) has been induced by the strong conjugation between the hydroxyl and nitro groups. In the cyclophane (45) the benzene moiety is strongly nonplanar, yet delocalization of the π electrons is still substantial.

Of course, ${}^7J(\text{CH}_3,\text{CH}_3) \equiv {}^7J = 0.60\text{ Hz}$ in 1,4-dimethylbenzene (30) is also a measure of delocalization of π electrons. The pyridine derivatives (46)–(48) are delocalized, whereas the benzoquinone (49) and the borazine (50) are not. Borazine itself is isoelectronic and isostructural with benzene and is sometimes considered as an inorganic analog of benzene.

6.5 $^4J(\text{C,C})$ in Some Condensed Aromatics

$^4J(\text{C,C})$ in condensed aromatics such as (51)–(54) are thought²⁷ to be transmitted mainly via the π electrons, which are delocalized to a large extent. $^4J(\text{C,C})$ was measured by enriching with ^{13}C at the position marked by an asterisk; the sign of $^4J(\text{C,C})$ is known only in the case where it is given in the structures. The generalized mobile bond order between the coupled sites vanishes for these even alternant hydrocarbons,²⁸ which suggests very little spin correlation of the electrons at these sites. Furthermore, the atom–atom polarizabilities, which might in this connection be thought of as indicating how the π electron at the second site responds to a perturbation at the first site, are also very small for the indicated atoms. However, the atom–atom polarizability involving the penultimate site in the shortest coupling path, indicated by solid triangles in (51) and (52), is relatively large except for the 4J of 0.3 Hz in (53) and that of 0.0 Hz in (54). This observation may represent an accidental coincidence; it has not been discussed in the scientific literature, but may be worth further study. It may be noted that $Q_{\text{C,C}}^{\text{C}}$ is sizeable and negative, and contributes to a negative $^4J(\text{C,C})$ because it measures the hyperfine interaction of a π electron at the nearest carbon atom (solid spade) with the ^{13}C nucleus at the coupled site (solid circle). In this connection it would be useful to have many more $^nJ(\text{C,C})$ values. There now exist methods²⁹ for finding nJ for unenriched molecules.

6.6 A Unique Conformation Determined from $^nJ(\text{H,H})$

Were a chemist asked to predict the conformation of 2-hydroxythiophenol (55) in solution, he or she might

well suggest an equilibrium among three planar structures, $\text{HS}\cdots\text{OH}$, $\text{HS}\cdots\text{HO}$, and $\text{SH}\cdots\text{OH}$. This suggestion depends on the knowledge that conjugation of the lone pairs of electrons on oxygen or sulfur with the aromatic π electrons creates a mobile bond order, $\text{C}\cdots\text{S}$ and $\text{C}\cdots\text{O}$ (partial double bonds), leading to planar structures with concomitant barriers to rotation about the exocyclic bonds. A more sophisticated chemist might also suggest that the $\text{HS}\cdots\text{HO}$ structure would be most stable because the electrically polar $\text{O}^- - \text{H}^+$ bond would seek the lone pair on sulfur, forming an intramolecular hydrogen bond, thereby stabilizing this structure. Indeed, the vibrational spectrum of (55) in CCl_4 solution has been interpreted in terms of an equilibrium among three planar forms.

On analysis,³⁰ the ^1H NMR spectrum of such a solution yields nine $^nJ(\text{H,H})$ ($4 \leq n \leq 6$) for protons in the side chains. These demonstrate unequivocally that the perpendicular conformation depicted in (55) is dominant. In view of the previous discussions, the large magnitudes of $^nJ(\text{SH,H})$ and the stereospecific $^5J(\text{OH,H-4})$ are consistent only with the indicated conformation, the one in which the $\text{S}-\text{H}$ bond lies in a plane roughly perpendicular to that of the rest of the molecule. The polar $\text{O}-\text{H}$ bond twists the 3p lone pair into the molecular plane, forming a hydrogen bond, and the $\text{S}-\text{H}$ bond must therefore twist out of that plane. The formal $^5J(\text{OH,SH})$ is an example of one kind of proximate J , in this case most probably being transmitted via the hydrogen bond.

7 PROXIMATE LONG RANGE COUPLING CONSTANTS

The stereochemistry of a molecule may be such that two of its fragments, while separated by many formal bonds, may still be proximate. Couplings between nuclei in the different fragments^{6,31} are called 'proximate' (originally, 'through space'). An example is the $^5J(\text{F,F})$ of 174 Hz in (56),³² which is thought to be transmitted by the interaction of the lone pair electrons on the two fluorine atoms. The internuclear distance is well within the sum of the van der Waals radii of the atoms. Another example is (57) where the proximity mechanism is relayed via an $\text{H}-\text{F}$ overlap to yield a $^4J(\text{F,C})$ the magnitude of which decays exponentially with the $\text{H}-\text{F}$ distance.³³ The scientific literature abounds with examples of proximate coupling constants between many different pairs of nuclei. Their stereochemical use is obvious. (See also *Coupling Through Space in Organic Chemistry*)

The most striking example³⁴ is a J of about 17 Hz between fluorine nuclei of 5-fluorotryptophan residues placed in the enzyme dihydrofolate reductase. The fluorine atoms are separated by dozens (n) of covalent bonds, yet must approach each other to within about 0.3 nm, a consequence of the folding pattern of the protein. The value of n may well be a record.

8 THE FUTURE OF LONG RANGE COUPLING CONSTANTS

One of the goals of mathematical chemistry is the computation of accurate stereochemical properties of molecules. Great progress has been made towards this goal, particularly for molecules for which the accurate measurement of small nJ values is feasible. As computers become faster, the general computation of nJ for reliable theoretical stereochemistries may also become a reliable procedure. Until then, measurements of nJ will likely retain their empirical utility. Furthermore, nJ values are normally measured in solution, in which perturbations by solvent molecules of conformational equilibria can be large; the nJ values may serve as checks of the theoretical descriptions or models of such perturbations.

1 INTRODUCTION

In modern solid-state NMR, resolution and sensitivity can be enhanced by means of cross polarization (CP) (see **Cross Polarization in Solids**, Volume 3, **Cross Polarization in Rotating Solids: Spin-1/2 Nuclei**, Volume 3), spin decoupling (see **Line Narrowing Methods in Solids**, Volume 4) and magic angle spinning (MAS) (see **Magic Angle Spinning**, Volume 5). Spectra of either crystalline or amorphous samples can be recorded. The assignment of these spectra is usually performed on the basis of chemical shift considerations in conjunction with multidimensional correlation experiments relying mostly on the use of dipolar couplings.

Due to their large size, dipolar couplings are the obvious interaction to use in solid-state NMR in order to perform coherence transfer and thus correlate nuclei. Thus, a large number of methods have been developed in order to reintroduce heteronuclear or homonuclear dipolar couplings under magic angle spinning (see **Homonuclear Recoupling Schemes in MAS NMR**, Volume 4). Since dipolar coupling is a through-space interaction, these methods yield information about short and long range distances. In liquids, analogous experiments using the nuclear Overhauser effect (NOE) (see **Nuclear Overhauser Effect**, Volume 5) are the basic components for molecular structure determination (see **Protein Structures: Relaxation Matrix Refinement**, Volume 6).

In this entry we present an overview of techniques analogous in many respects to some liquid-state NMR techniques (see **Polarization Transfer Experiments via Scalar Coupling in Liquids**, Volume 6), which make use of *scalar* couplings in solid-state NMR. Until the end of the 1990s, only highly mobile solids, such as plastic crystals, yielded spectra with enough resolution to observe directly scalar couplings.^{1,2} In such compounds, the dipolar couplings are partially averaged, and the J couplings are naturally resolved; thus, liquid-like sequences perform reasonably well. On the other hand, in more ordinary organic compounds, where motion is reduced, the strong dipolar couplings (say 20 kHz) hide the much smaller J couplings (say 100 Hz).

As we show in the following, improvements in magic angle spinning and spin decoupling techniques^{3–6} have led to reduced intrinsic linewidths, thereby making it possible to resolve homonuclear and heteronuclear scalar couplings. Under such conditions, techniques using scalar couplings have great potential for unambiguous spectral assignment, since the coherence transfer is performed by means of a through-bond interaction, and not through-space. Indeed, as in liquid-state NMR,⁷ an ideal approach to structure determination exploits the complementarity of through-space and through-bond interactions by using through-bond techniques to establish an unambiguous assignment of the NMR spectra before using through-space interactions to determine three-dimensional structure (see **Biological Macromolecules: Structure Determination in Solution**, Volume 2) and dynamics (see Figure 1).

2 USING HOMONUCLEAR J COUPLINGS

For the moment ^1H – ^1H J couplings (~ 10 Hz) are too small compared to residual linewidths (at best ~ 100 Hz) to be exploited to obtain correlations. However, homonuclear J couplings of nuclei such as ^{13}C , ^{31}P and ^{29}Si are large enough to be observed, and in this section we discuss experiments which make use of them.

2.1 ^{13}C Homonuclear Scalar Couplings

Because of the low (1.1%) natural abundance of ^{13}C , sensitivity is the primary problem when trying to observe carbon–carbon J couplings. There are some examples where experiments were successfully performed on natural abundance samples, but in general the techniques discussed below are aimed at (partially or fully) carbon-13 enriched samples. The size of the 1J coupling constants between directly bonded nuclei, which depends on the hybridization of the carbon orbitals and on the nature of the substituents, is usually found

Figure 1 Through-bond correlations are necessary to assign the spectrum. Through-space correlations are used to establish the three-dimensional structure

between 35 and 75 Hz. 2J and 3J coupling constants are much smaller, typically between 0 and 5 Hz in liquids. The J coupling is thus usually approximately 40 times smaller than the dipolar coupling between two carbon nuclei (see **Dipolar & Indirect Coupling Tensors in Solids**, Volume 3).

2.1.1 INADEQUATE

The most straightforward approach to obtaining carbon–carbon through-bond connectivities is by using an INADEQUATE experiment adapted for solids. The liquid-state version of this experiment was first proposed by Bax, Freeman and co-workers^{8,9} (see **INADEQUATE Experiment**, Volume 4). The INADEQUATE experiment selects only carbons that are directly bonded and filters any signals coming from isolated carbon nuclei (such as most of the natural abundance signal). The equivalent solid-state sequence is presented in Figure 2(a). Apart from the cross polarization period, and the fact that the sample is spinning at the magic angle, the experiment is completely analogous to its liquid-state cousin. After cross polarization from ^1H , the ^{13}C magnetization evolves during the delay 2τ under the homonuclear J coupling Hamiltonian

$$\mathcal{H} = \pi \sum_{i < j} J_{ij} 2I_{iz} I_{jz} \quad (1)$$

Figure 2 (a) The solid-state INADEQUATE pulse sequence. A 32 step phase cycle can be used, or alternatively the coherence transfer pathway can be selected using gradients. (b) Pulse sequence for solid-state refocused INADEQUATE. An extra Hahn echo period is added in order to refocus the signal after t_1 . The τ delay should be synchronized to be an integral number of rotor periods. By T_2' and T_2^* we note the effective and the apparent damping time constants during the τ – π – τ and the acquisition periods. (c) Pulse sequence for INADEQUATE-ce (see text for details)

Here we assumed that the chemical shift differences between the carbon nuclei are larger than the homonuclear J couplings, and thus only the truncated part of the Hamiltonian is effective. This is because the averaging of the chemical shift occurs over larger time scales than in the TOBSY scheme we analyze later.

The carbon–carbon homonuclear dipolar interactions, together with any anisotropies (chemical shift, or even J), are removed by fast MAS, and the isotropic chemical shift is refocused by the π pulse. The τ delay should be synchronized to be an integral number of rotor periods in order to average out completely the homonuclear carbon dipolar couplings. The heteronuclear dipolar and scalar interactions are averaged out by heteronuclear dipolar decoupling schemes, usually continuous wave (CW) decoupling, or the more efficient two-pulse phase modulation (TPPM) decoupling.³ The solid-state INADEQUATE experiment is particularly simple to implement, and can be performed at high spinning frequencies.

The double quantum coherence created by the first carbon 90° pulse evolves during t_1 , at a frequency which is the sum of the single-quantum frequencies of the two spins

$$\omega_{\text{DQ}} = \omega_{\text{SQ}}^A + \omega_{\text{SQ}}^B \quad (2)$$

and is converted back into antiphase coherence by the last 90° pulse. This sequence leads to anti-phase lineshapes which were previously considered to be impractical in ordinary solids due to the residual linewidth. Nevertheless, such experiments were shown to be practical on plastic crystals^{10,11} where the linewidth is only a few hertz, and, more recently, on crystalline organic compounds¹² where the linewidth in the one-dimensional carbon spectrum is comparable to the size of the scalar couplings.

The INADEQUATE experiment has been successfully applied to small molecules,¹² and an example of a two-dimensional spectrum is shown in Figure 3. Using fully labeled samples leads to a very good signal to noise ratio and, in this particular case, gradients were used to select the coherence transfer pathway in order to reduce the total experimental time (the spectrum was acquired with 10 mg of sample in 13 min). From the two-dimensional map, the atomic connectivity can be traced throughout the carbon skeleton in an unambiguous way. This experiment is sufficiently sensitive to obtain a spectrum of a powdered sample of *natural abundance* L-alanine with good signal to noise ratio over a weekend.¹²

Linewidths in *amorphous* solids can be much larger (hundreds of hertz) than those for the examples above and one might think that this would compromise the performance of the INADEQUATE experiment. However, the linewidth in solids arises from several different sources,¹³ such as:

- the degree of crystallinity of the sample, which yields a more or less broad chemical shift distribution;
- the local magnetic field inhomogeneity (B_0 inhomogeneity, magnetic susceptibility effects ...);
- dipolar couplings and higher order cross terms with chemical shift anisotropy (CSA) unaveraged by MAS;
- the incoherent effects of stochastically fluctuating local fields that yield T_2 relaxation.

These contributions can be divided into two categories depending on whether they are inhomogeneous or homogeneous.¹⁴ Inhomogeneously broadened lineshapes, resulting from such

Figure 3 Two-dimensional INADEQUATE spectrum of a fully ^{13}C labeled sample of L-tyrosine hydrochloride. The one-dimensional carbon spectrum is also shown. The spinning frequency was 20 kHz and the decoupling radio-frequency field strength was 120 kHz. Starting from the carbonyl carbon, we can trace out the whole carbon skeleton of the molecule, yielding an unambiguous assignment of the carbon backbone of the molecule. This spectrum was obtained by Dr S. Steuernagel (Bruker Analytik Germany) and is reproduced from Ref.⁵⁰ with permission. A 10-mg sample was used and the coherence transfer pathway was selected using gradients (shown in Figure 2a) and led to an experimental time of 13 mins

mechanisms as chemical shift distributions or field inhomogeneity, consist of a continuum of independent lines that can be manipulated individually whereas homogeneously broadened lines due to multispin dipolar couplings or T_2 relaxation, react to pulses as an indivisible entity. The refocused INADEQUATE sequence in Figure 2(b) can be applied successfully to disordered samples since it leads to in-phase lineshapes due to the last $\tau-\pi-\tau$ refocusing period.¹⁵ Assuming a short apparent relaxation time T_2^* , deduced from the linewidth, the efficiency of the refocused INADEQUATE experiment depends on the ratio T_2'/T_2^* , where T_2' is the transverse dephasing time measured in a spin echo experiment. We show where these respective damping constants are 'active' during the experiment in Figure 2. Another approach using composite refocusing (INADEQUATE-CR) was also introduced.¹⁶ The magnetization in this experiment is channeled into one line of the J structure (α or β) and this leads to single absorptive peaks. The pulse sequence is shown in Figure 2(c). As in the refocused INADEQUATE experiment, in the case of broad peaks, the efficiency of INADEQUATE-CR depends on the ratio between the homogeneous and the inhomogeneous linewidth.

Figure 4 shows the refocused INADEQUATE spectrum of a sample of 10% randomly carbon-13 labeled purified cellulose recorded in a total experiment time of 16 h (250 mg of

sample). As pointed out previously, in the two-dimensional map two directly bonded carbons share a common frequency in the double quantum dimension, and, provided that one carbon resonance can be identified a priori, assignment is quite straightforward. The cellulose spectrum contains resonances which have already been identified in previous studies, mainly by comparison with liquid spectra, and more recently by two-dimensional NMR.^{17,18} The assignment shown in Figure 4 differs from the ones obtained using spin diffusion experiments, i.e., dipolar interactions, which underlines the fact that data from dipolar correlation techniques must be interpreted with caution as they may yield incorrect assignments.

2.1.2 TOBSY

The INADEQUATE experiment in solids can be considered to play the role of COSY in liquids, by establishing one-bond connectivities. In liquids, COSY is often complemented by TOCSY, which correlates all the spins in a coupled spin system with each other. Originally proposed in the liquid state by Braunschweiler and Ernst,¹⁹ this experiment has been used extensively in liquids, together with COSY, INADEQUATE and NOESY, to provide assignment information for organic and biological molecules. Recently a solid-state version named TOBSY (for Total Through Bond Spectroscopy)

Figure 4 Two-dimensional refocused INADEQUATE spectrum of cellulose. The spectrum was obtained at 125 MHz on a Bruker DSX 500 spectrometer using a 7-mm double-tuned MAS probe. A total of 100 t_1 increments with 192 scans each were collected. The τ delay was set to 3 ms, and the contact time for cross polarization to 500 ms. The spinning speed was 6 kHz and the proton decoupling field strength was 100 kHz using continuous wave decoupling. The various connectivities between the directly bonded carbons are indicated by solid lines. The experimental one-dimensional spectrum is shown above the contour plot with a solid line. The homogeneous linewidth can be measured by a spin echo sequence, and from it we indicate the linewidths which are responsible for the damping during the two τ periods as a schematic spectrum as a thin line, for comparison, together with the measured linewidths. (Adapted from Lesage et al.¹⁵ with permission, © 1999 American Chemical Society)

has been originally proposed by Baldus and Meier²⁰ and further improved.^{21,22}

The correlation between nuclei is obtained by means of an isotropic Hamiltonian:

$$\mathcal{H} = 2\pi \sum_{i < j} J_{ij} \vec{I}_i \cdot \vec{I}_j \quad (3)$$

This Hamiltonian leads to a *net* polarization transfer as well as to antiphase signals¹⁹ in the resulting two-dimensional spectra. The *net* polarization transfer $I_{1x} \rightarrow I_{2x}$ gives positive in-phase cross peaks while the anti-phase signals (originating from the transfer $I_{1x} \rightarrow I_{1y}I_{2z} - I_{1x}I_{2y}$) lead to dispersion signals in the detection period. These anti-phase components do not contribute to the signal at $t_2 = 0$, but evolve into observable coherences under the influence of the J interaction. In solids where the J interaction is not resolved, these anti-phase components are not observable, especially in the case of homogeneously broadened spectra. Under these conditions, the TOBSY experiment leads to pure absorption lineshapes in the two-dimensional spectrum.

Figure 5 Two-dimensional TOBSY pulse scheme. During the t_1 evolution period, on-resonance high-power proton decoupling is used. The first 90° pulse on ^{13}C places magnetization along the z axis and then J -induced polarization transfer occurs during the mixing $\tau_{\text{mix}} = m\tau_{\text{MAS}}$ (where $m = 1, 2, 3, \dots$) under simultaneous homonuclear proton decoupling. In the original TOBSY experiments²⁰ the mixing scheme $R = \bar{2}4\bar{2}3\bar{1}$, is applied such that $k = 4$ or $k = 8$ cycles cover one rotor period τ_{MAS} . For detection during t_2 , high power on-resonance proton decoupling is applied. More recently the CN_n^v schemes were proposed in order to perform the J -induced polarization transfer.^{21,22} Usually cycles like WALTZ-4, POST-C7 and permuted WALTZ-4 can be used in order to improve the robustness of the pulse sequence with respect to rf field inhomogeneities. This pulse sequence can be easily adapted to cases where no proton nuclei are present (No proton channel in the above diagram)

To obtain an isotropic J mixing sequence (this means that the transfer does not depend on the initial condition of the magnetization), the Hamiltonian of equation (1) has to be crafted. The pulse sequence shown in Figure 5 achieves such an effective Hamiltonian. The philosophy of this pulse sequence is that MAS, together with rotor synchronized π pulses, can lead to a zeroth order average Hamiltonian that contains only the J couplings [see equation (3)]. The composite π pulses from the WALTZ decoupling scheme²³ have been used, and particular synchronization conditions have to be chosen in order to achieve pure J transfer.²⁰ The spin dynamics of rotor synchronized multiple pulse schemes is governed by the symmetry properties of the spin and space tensors of the interactions, and have been recently described at length using average Hamiltonian theory^{24,25} (see **Symmetry-Based Pulse Sequences in Magic-Angle Spinning Solid-State NMR**). Introducing pulse sequences having the generic symmetry CN_n^v , where N cycles C_p with $p = 0, \dots, N - 1$, occupy n rotor periods, one can prove that appropriate choice of N , v and n can be used to selectively average out given interactions. In fact the C9_3^1 symmetric class provides the basis for pure J magnetization transfer.²¹ Studies using such symmetric pulse schemes have led to improved magnetization transfer efficiencies, and have allowed these experiments to perform well under faster MAS frequencies.²² Heteronuclear dipolar decoupling of the protons is obtained using homonuclear proton decoupling in combination with MAS. We explain in detail how this works in the next section.

Experimental results using TOBSY are shown in Figure 6 for a powder sample of fully (^{13}C , ^{15}N)-labeled arginine. All one bond correlations are represented through cross peaks using a short mixing time, whereas long range connectivity coming from long-range and indirect couplings can be observed using a much longer mixing time.²⁰ The TOBSY spectrum of U- ^{13}C , ^{15}N bacteriochlorophyll *a* is presented in Figure 7 as another example of the applicability of the

Figure 6 TOBSY initial-rate spectrum from a fully ^{13}C , ^{15}N -labeled arginine powder sample after a mixing time of 3 ms. Only the aromatic and aliphatic regions of the total two-dimensional spectrum are shown. All one-bond correlations are represented through cross-peaks. The spinning frequency was set to 8.5 kHz, and four R cycles per MAS period were used. A total of 256 t_1 experiments averaging eight transients in the t_2 was performed. Contour levels between 5 and 15 of the maximum signal intensity are shown. (Reproduced from Baldus and Meier,²⁰ © 1996, with permission from Academic Press)

improved TOBSY sequences. Once again atomic connectivities along the carbon skeleton can be unambiguously determined.

2.2 Homonuclear Correlations for Other Nuclei

Up to now we have shown how homonuclear scalar couplings can be used for spectral assignment. Here we present an example in which J couplings can be used to probe geometric properties. In liquids, the well-known Karplus rule for the 3J proton couplings is a useful tool for the determination of dihedral angles⁷ (see **Vicinal Coupling Constants & Conformation of Biomolecules**, Volume 8). However, such couplings are not currently observable in solids. Homonuclear ^{31}P couplings have been used in order to determine bond angles in solid inorganic compounds.²⁶ The angle between two ^{31}P CSA tensors can be determined if polarization can be transferred between the two spins involved. By exploiting prior knowledge about the orientation of the CSA tensors relative to the molecular frame, bond angles can then be evaluated.

In many spin systems, such as SiP_2O_7 , the evaluation of the experimental sideband patterns using dipolar techniques becomes difficult because cross-peaks between all resonances appear and greatly reduce the individual cross-peak intensities. The partial overlap of cross-peaks makes a quantitative analysis of the cross-peak intensity even more difficult. Therefore,

Figure 7 Part of a scalar correlation spectrum of U- ^{13}C , ^{15}N bacteriochlorophyll *a* recorded using POST-C9 as the isotropic mixing sequence at a MAS rate of 13 kHz, a mixing time of 9 ms, an rf amplitude for proton decoupling of 140 kHz, carbon rf amplitude of 78 kHz during POST-C9 and 113 kHz for the $\pi/2$ pulse, spectral width 30 kHz in each dimension, acquisition time 34 ms, 165 t_1 increments. Eight contour levels between 1% and 20% of the maximum positive spectra intensity are plotted. (Reproduced from Heindrichs et al.,²¹ © 2001, with permission from Elsevier Science)

the scalar J couplings are used as the polarization transfer mechanism, and only two ^{31}P spins within the P–O–P unit exchange polarization through the $^2J_{\text{P-P}}$ scalar coupling. Thus, the relative orientation of each unit can be measured selectively.

In Figure 8(a) the two-dimensional scalar correlation spectrum of a powder sample of the cubic phase of SiP_2O_7 is shown together with its one-dimensional spectrum. Only the centerband and the first sideband regions are shown. The intensity of the cross-peaks between different sidebands of chemically inequivalent spins contains information about the P–O–P angles, which can be obtained by numerical fitting. The results of such a fitting procedure are shown in Figure 8(b) and show that three pairs of P–O–P groups are bent, while one is linear.²⁶ These NMR data suggest that the “linear” pyrophosphate groups in SiP_2O_7 are in fact linear on the NMR time scale ($\sim 100\ \mu\text{s}$). A static disorder of ‘normal’ bent units, postulated previously, is clearly excluded.²⁶

Other more exotic nuclei have also been investigated. One of the first examples of the application of INADEQUATE in the solid state was performed on the Sn nuclei.¹¹ ^{29}Si , whose natural abundance is 4.7%, has also been used to obtain scalar correlations. The 1J couplings are of the order of 50 Hz and the 2J couplings vary from 1 to 15 Hz. INADEQUATE helped find the correct structure of silanes in liquids. The technique was applied in the solid state by Benn et al.²⁷ to study very highly crystalline zeolites, where the linewidths are of the order of 1–20 Hz under proton decoupling. COSY-type experiments using $J_{\text{Si-Si}}$ couplings have also been reported on glasses^{28,29} (see **Silicon-29 NMR of Solid Silicates**, Volume 7).

Figure 8 (a) Rotor-synchronized two-dimensional ^{31}P TOBSY spectrum of the cubic phase of SiP_2O_7 recorded with a MAS frequency of 4.63 kHz at a static field of 9.4 T. Only the region showing the centerband and the +1 sideband is reproduced. The pulse sequence from Figure 5 was used. The mixing time period was set to 21 ms at a rf field strength of 111 kHz. The ^{31}P chemical shift scale is referenced externally to phosphoric acid. (b) Normalized root-mean-square deviation between the experimental cross-peak intensities (taken into account were cross-peaks of order $n - m = 0, \pm 1, \pm 2$) as a function of the angle β for four sets of P–O–P units in SiP_2O_7 . 3 USING HETERONUCLEAR J COUPLINGS

The key step in characterizing and assigning *natural abundance* organic solids is through *heteronuclear* proton–carbon correlations. Until recently heteronuclear correlations in solids were obtained exclusively by dipolar correlations.^{30–35} In the following, we review how heteronuclear coherence transfer can be obtained using scalar couplings leading to new sequences for spectral editing and heteronuclear J correlation.

3.1 How to Observe Heteronuclear Scalar Couplings: Homonuclear Proton Decoupling

The total Hamiltonian $\mathcal{H}$, under MAS and RF irradiation, is time dependent and can be written:

$$\mathcal{H}(t) = \mathcal{H}_I(t) + \mathcal{H}_S(t) + \mathcal{H}_{II}(t) + \mathcal{H}_{SS}(t) + \mathcal{H}_{IS}(t) + \mathcal{H}_{\text{RF}}(t) \quad (4)$$

where $\mathcal{H}_X(t)$ accounts for the time dependent CSA interactions for the spin species X , $\mathcal{H}_{XY}$ for the dipolar and scalar coupling interactions between the spin species X and Y , and $\mathcal{H}_{\text{RF}}(t)$ for the time dependent radio frequency fields that can be applied. In the following, we consider ordinary natural abundance organic solids (I refers to the ^1H nuclei and S refers to a rare nucleus such as ^{13}C or ^{15}N). Thus, it is reasonable to neglect the homonuclear Hamiltonian between rare spins $\mathcal{H}_{SS}(t)$.

To use the scalar couplings, one must first remove the dominant dipolar interactions (see **Average Hamiltonian Theory**, Volume 2, **Line Narrowing Methods in Solids**, Volume 4). Under homonuclear proton–proton decoupling (and assuming a fast radio-frequency averaging compared with the MAS time scale), the proton–proton dipolar interaction is, at least to first order, averaged to zero. The efficiency of the proton–proton decoupling depends on the decoupling sequence and many experimental parameters. Additionally, the proton chemical shift and the heteronuclear coupling interactions (dipolar and scalar) are scaled down by a scaling factor λ . In the absence of homonuclear interactions, the Hamiltonian becomes *inhomogeneous*^{14,36,37} allowing for the averaging to zero, to first order, of the heteronuclear dipolar interactions and the CSA under MAS. The homonuclear scalar coupling terms between I spins, which are relatively small, are neglected. This leads to a considerable simplification of the effective Hamiltonian under homonuclear decoupling and MAS conditions. This effective Hamiltonian in the doubly rotating frame, can be written

$$\mathcal{H}_{\text{eff}} = \lambda \sum_n \delta_n^I I_{nz} + \sum_m \delta_m^S S_{nz} + \lambda \pi \sum_{n,m} J_{nm}^{IS} 2I_{nz} S_{mz} \quad (5)$$

and is very similar to the ‘liquid state’ NMR Hamiltonian that contains only the isotropic interactions.

In Figure 9(a) we show the carbon-13 spectrum of a powder sample of L-alanine recorded under proton-homonuclear decoupling and MAS. Figure 9(b) shows the methyl resonance of a powder sample of $[2-^{13}\text{C}]$ sodium acetate recorded under the same conditions. Figure 9(c) shows the nitrogen-15 spectrum of a powder sample of glycine recorded under the same conditions. The frequency switched Lee–Goldburg (FSLG)^{4,38} decoupling scheme was used with a rf decoupling amplitude of 100 kHz, and the MAS spinning frequency was set to 12 kHz. Splittings are observable in these spectra corresponding to

Figure 9 Carbon-13 (a,b) and nitrogen-15 (c) NMR spectra of powdered organic compounds under MAS and homonuclear proton dipolar decoupling. The homonuclear dipolar couplings are averaged by the rf sequence and the heteronuclear dipolar couplings by MAS, leaving only the heteronuclear scalar couplings. (a) In the carbon spectrum of L-alanine we can distinguish the doublet of the α carbon and the quartet of the methyl carbon. (b) Carbon spectrum of a sample of sodium acetate enriched at the methyl position. Only the methyl resonance is shown. A quartet is expected for the CH_3 group, which appears as a doublet in the spectrum because of the poor resolution of the outer transitions. (c) The same ‘doublet’ appears in the nitrogen-15 spectrum of glycine and hides the fine structure of the 1:3:3:1 quartet. Note that the heteronuclear proton–nitrogen couplings are smaller than the proton–carbon couplings. In all spectra the scalar couplings are scaled by the scaling factor of the decoupling sequence. In these experiments the FSLG decoupling sequence was used but other decoupling sequences can be used as well

the multiplet fine structure due to the heteronuclear J couplings. The α -carbon in L-alanine gives a doublet, while the methyl carbon in alanine and in sodium acetate gives a ‘quartet’, which is poorly resolved and appears in the spectrum as a doublet. Even though the proton–nitrogen J interactions are smaller (~ 90 Hz) than the proton–carbon couplings (~ 130 Hz), they can also be resolved, as we can see from the ‘quartet’ present in the spectrum of glycine. It corresponds to the 1:3:3:1 fine structure of the NH_3^+ group.

3.2 Spectral Editing

One-dimensional spectral editing techniques such as INEPT, DEPT and APT, are very popular in the liquid state since they provide a quick and easy way of assigning carbon-13 resonances in many organic compounds (see **INEPT**, Volume 4, **Polarization Transfer Experiments via Scalar Coupling in Liquids**, Volume 6). They also constitute a first step towards the use of J couplings to perform heteronuclear correlation spectroscopy (see also **Heteronuclear Assignment Techniques**, Volume 4, **Spectral Editing Techniques: Hydrocarbon Solids**, Volume 7).

3.2.1 Solid-State APT

The attached proton test (APT) sequence is one of the simplest liquid-state spectral editing techniques,^{39–41} and it has been modified and used for the solid state by Lesage et al.⁴² The pulse sequence for the experiments is shown in Figure 10(a). Cross polarization is used to enhance the carbon polarization and homonuclear dipolar decoupling is introduced during the evolution periods to remove proton–proton dipolar couplings. As described above, under these conditions the inhomogeneous interactions, i.e., the chemical shift anisotropy and the heteronuclear dipolar couplings, are averaged out by rapid magic angle spinning, leaving only the isotropic chemical shift and the scalar J couplings. The π pulses applied simultaneously to proton and carbon in the center of the 2τ period, have the net effect of refocusing the carbon chemical shift evolution, while maintaining the evolution under the scaled scalar λJ_{IS} coupling. Thus, after cross polarization, carbon coherences evolve only under the effect of a scaled heteronuclear scalar coupling. The scaling factor λ varies according to the dipolar decoupling sequence that is used; for the FSLG sequence⁴ the theoretical scaling factor is $1/\sqrt{3}$.

If the dynamics can be described by the simple Hamiltonian of equation (5), the theoretical evolution of carbon signals can easily be calculated using product operator algebra⁴³ since all terms in the Hamiltonian commute with each other. This formalism proves to be very useful since all of the following sequences can be calculated, to first order at least, as if they were liquid-state sequences. In the case of the APT sequence, since the carbon and the proton chemical shift evolution is refocused, the effective Hamiltonian during the 2τ period is

$$\mathcal{H}_{\text{eff}}^{\text{APT}} = \lambda\pi \sum_{n,m} J_{nm}^{IS} 2I_{nz} S_{mz} \quad (6)$$

and the observable signal intensity is

$$I_{IS}^{\text{APT}}(2\tau) = \cos^n(2\pi J'\tau) \exp\left(\frac{-2\tau}{T_2'^{IS}}\right) I_{IS}^0 \quad (7)$$

where I^0 is the signal intensity after cross polarization and $T_2'^{IS}$ is the transverse relaxation (dephasing) time during the period 2τ (equal to $1/\pi\Delta$). For each CH_n group ($n = 0, 1, 2, 3$), the intensities are shown in Figure 11(a) as functions of the delay τ . The calculations are shown for two different values of the linewidth Δ (1 Hz and 130 Hz, respectively, for the left and right panel) and J coupling (and 50 Hz and 70 Hz, respectively), corresponding to the ‘ideal liquid state’ case, and to the equivalent solid-state case. Note that the linewidth Δ indicated in the figures is the full linewidth at half-height of the signals evolving during 2τ (i.e., the linewidth for a single component of the fine structure of the multiplet), and is different from the overall linewidth of the signals observed during acquisition. The calculations were done in the ideal case where all protonated carbon groups have the same heteronuclear scalar couplings; 130 Hz is a typical value for a one-bond J_{CH} coupling for an aliphatic carbon, and the value of 70 Hz corresponds approximately to a scaling factor $\lambda = 1/\sqrt{3}$, due to the homonuclear proton decoupling. A τ value of $1/(2J)$ will produce a spectrum in which the C and CH_2 carbon peaks will be positive in sign, while the CH and CH_3 peaks will be inverted. Note that the sign of the

Figure 10 (a) The pulse sequence suitable for the solid-state APT and the corresponding coherence transfer pathway. (b) Pulse sequence and coherence transfer pathways for the J -MQ-Filter experiment. In the experiments presented in Figure 12 we used the FSLG sequence as the homonuclear proton decoupling scheme, thus θ is 54.7° pulse. Other homonuclear decoupling sequences can also be used instead of FSLG, by appropriately fixing θ . The MQ-Filter block is given at the bottom of the figure. (Detailed information about the implementation of these sequences is given in Refs.^{42,44})

peaks is independent of the linewidth. Variations in linewidths will simply lead to a modulation of the amplitude of the signals but will not prevent discrimination between positive (CH_2) and negative (CH) signals. Note especially that, in cases where some groups are more flexible than others, partial averaging of the dipolar couplings through molecular motion will simply increase the signal amplitude (by decreasing the linewidth). Figure 11(b) shows a typical experimental example of this technique applied to L-histidine monohydrochloride monohydrate.

3.2.2 MAS-J-MQF

The APT sequence essentially serves as a parity test rather than removing resonances according to their multiplicity. An alternative sequence using the same principles but including a multiple-quantum filter block has been demonstrated to be capable of removing resonances from the spectrum according

to their multiplicity.⁴⁴ The sequence is shown in Figure 10(b). Note that this experiment is applicable even when a carbon chemical shift distribution leads to inhomogeneous line broadening, since the π pulse on the carbon channel refocuses this effect. Thus, this technique (and the others considered in this section) should be applicable even in amorphous solids. Figure 12 shows an example of this approach applied to a protected tripeptide sample.

3.3 Two-dimensional Techniques

Multidimensional heteronuclear correlation spectroscopy is the cornerstone for assignment and structure determination in the liquid-state.⁷ In analogy to liquid-state experiments (see **Two-Dimensional Carbon-Heteroelement Correlation**, Volume 8), the solid-state MAS- J -HMQC⁴⁵ and MAS- J -HSQC⁴⁶ sequences use heteronuclear multiple-quantum and heteronuclear single-quantum coherences, respectively, to

Figure 11 (a) Functional dependence of the observable signal as a function of the τ delay in the ATP sequence for the case of an ideal liquid and the solid-state. See text for details. A τ value of $1/(2J_{\text{CH}})$ will produce a spectrum in which the C and CH₂ carbon resonances will be positive in sign, while the CH and CH₃ resonances will be inverted. (b) One-dimensional CP/MAS spectrum (upper spectrum) and solid-state APT spectrum (lower spectrum) of L-histidine monohydrochloride monohydrate. A contact time of 1 ms was used and the spectra were recorded with 200 scans and 2048 scans, respectively. τ was set to 4 ms for the editing experiment. The spinning sidebands are marked with asterisks. (Reproduced from Lesage et al.⁴² with permission, © 1998 American Chemical Society)

provide chemical-shift correlations between pairs of directly bonded nuclei in powder samples. Long range heteronuclear J couplings can also be used to probe multiple bond correlations, leading to the MAS- J -HMBC experiment.⁴⁷

3.3.3 MAS- J -HMQC

This two-dimensional experiment is based on the polarization transfer techniques using scalar interactions that have been

described in the spectral editing paragraph. The only difference is that a t_1 evolution time is included during which the multiple spin multiple quantum coherences evolve under the isotropic chemical shifts of the proton nuclei. The sequence is shown in Figure 13(a) and leads to two-dimensional spectra containing correlations between rare nuclei (carbons, nitrogens) along ω_2 , and protons along ω_1 of the kind shown in Figure 14. The time τ is responsible for the polarization transfer, and it has been shown that for short τ evolutions only correlations from

Figure 12 *J*-MQ-Filtered solid-state NMR spectra of the tripeptide Boc-Ala-Ala-Pro-O-Bzl. (a) Standard CP/MAS spectrum of 20 mg of a powder sample of the tripeptide. The spinning frequency was set to 12.5 kHz and a 1-ms cross polarization contact time was used. TPPM heteronuclear decoupling ($\omega_1/2\pi = 100$ kHz) was applied during acquisition; 64 scans were recorded. (b) 1Q-Filtered spectrum. As predicted, signals from the CH, CH₂ and CH₃ groups are present; 128 scans were recorded. (c) 2Q-Filtered spectrum. Only signals from the CH₂ and CH₃ groups are present; 2560 scans were recorded. (d) 3Q-Filtered spectrum. Only signals from the CH₃ groups are present; 4800 scans were recorded. The evolution time τ was set to 3.2 ms (synchronized with the MAS) for (b) and (c) and to 7.0 ms for (d) in order to enhance 3Q coherence creation. Spectra (c) and (d) were acquired within 2 and 4 h, respectively. The signal to noise ratio relative to the CP/MAS experiment, corrected for the number of scans, is given next to the spectrum for each experiment. (Reproduced by permission from Sakellariou et al.,⁴⁴ © 2001, with permission from Academic Press)

directly bonded nuclei are obtained. For longer τ periods, long range correlations are observed, and, in the case of camphor, fit well when 2J and 3J are included in spin Hamiltonian. Such correlations are thus exploited to explore long range connectivities like the HMBC experiment in liquids.⁴⁷ In what follows, we concentrate on the possibility of obtaining the full assignment of medium-size organic molecules using these correlation techniques.

3.3.4 Complete Assignment Using Multiple-Bond Correlations

For an approach to the complete assignment of the ^{13}C spectrum, we start with the one-bond (^1H , ^{13}C) correlations. This approach has yielded the complete assignment of the protected tripeptide shown in Figure 15, and here we demonstrate the assignment protocol only for one of the residues.

As mentioned above, for short values of the evolution period τ (typically 2 ms), the carbon–proton magnetization transfer is highly selective, i.e., it leads to only one-bond chemical shift correlations. Figure 15(a) shows the one-bond MAS-*J*-HMQC spectrum of the tripeptide Boc-Ala-Ala-Pro-O-Bzl (the three amino acids are referred to in the text as

A1, A2 and P). Some resonance lines of the ^{13}C spectrum can be identified from this two-dimensional correlation map alone. We can readily identify the three carbon resonances at low field as well as the one around 77.3 ppm as quaternary carbons since they are not correlated with any proton in the ω_1 dimension. From carbon chemical shift considerations, the carbon resonance at 77.3 ppm can be assigned to the quaternary carbon of the ter-butyl group, and that at 137.3 ppm to the quaternary carbon of the benzyl group; the remaining two quaternary resonances must therefore correspond to the three amino acid carbonyl groups (171.9 ppm) and to the carbonyl carbon of the Boc group (155.7 ppm). The carbon peaks between 127 and 131 ppm yield correlations with protons at about 7 ppm, and are therefore likely to correspond to the protonated carbons of the benzyl group. From carbon peak intensity, the high-field resonance must correspond to the para carbon. A specific assignment of the two other aromatic resonances is not possible. In the high-field part of the spectrum, the three carbon resonances at 19.4, 20.3 and 29.6 ppm can be assigned to the three methyl groups since they correlate with protons around 1.5 ppm. Tentatively, from carbon chemical shifts and peak intensity, we assume that the peak at 29.6 ppm corresponds to the ter-butyl methyl groups,

Figure 13 (a) Pulse sequence for the MAS-*J*-HMQC experiment. θ is a prepulse whose flip angle depends on the homonuclear decoupling scheme (for FSLG $\theta = \theta_m$, i.e., the magic angle). After cross polarization from ^1H (I spins), the magnetization of the rare S spins evolves during the delay τ only under an isotropic scaled heteronuclear J coupling Hamiltonian. For a pair of covalently bonded ^1H - S spins, the carbon magnetization evolves from in-phase (S_x) into antiphase ($2I_z S_y$) coherence with respect to the attached proton. A 90° pulse applied on protons transforms the antiphase carbon coherence into a multiple-quantum heteronuclear coherence which evolves during t_1 only under the effect of the proton chemical shift. At the end of the t_1 evolution period, the MQ coherence is converted back into an antiphase carbon coherence by the second 90° proton pulse. During the second τ period this coherence evolves to become an in-phase observable carbon coherence. (b) Pulse sequence for the MAS-*J*-HSQC experiment. During the t_1 evolution period only single quantum proton coherence evolves under the isotropic proton chemical shift

and the other two, to the $\text{C}\beta$ of alanine residues. At this stage, however, it is not possible to determine to which alanine residue (A1 or A2) each methyl carbon resonance belongs. Of the remaining peaks, the two carbons at 25.7 and 30.8 ppm, which correlate with protons at around 2.5 ppm, are likely to correspond to the proline γ and β carbons, respectively. The remaining five peaks between 40 and 70 ppm therefore correspond to the proline α and δ carbons, to the two alanine α carbons, and to the $\text{O}-\text{CH}_2$ group.

Thus, multiple-bond proton–carbon correlations are required to lift this ambiguity. Geminal $^{13}\text{C}-^1\text{H}$ couplings ($^2J_{\text{CH}}$) and vicinal $^{13}\text{C}-^1\text{H}$ couplings ($^3J_{\text{CH}}$) are also active during the evolution periods, and thus contribute to the creation of heteronuclear multiple-quantum coherences. If the evolution periods τ are long enough, in theory of the order of $1/(2^n J_{\text{CH}})$, multiple-bond couplings may yield significant correlations. Note that, in this case, the MAS-*J*-HMQC experiment should rather be compared to the liquid-state

Figure 14 MAS-*J*-HMQC spectrum of Cyclosporin A. This spectrum was obtained at 500 MHz and shows one-bond carbon–proton correlations for the undecapeptide

heteronuclear multiple-bond correlation (HMBC) experiment. In organic compounds in the liquid-state, values between -10 and $+66$ Hz are usually found for $^2J_{CH}$ couplings, whereas the $^3J_{CH}$ couplings have values between 0 and 16 Hz.⁴⁸ In amino acids, the (CO–H α) coupling constants range from -4 to -7 Hz while (CO–H β) coupling constants range from 2 to 6 Hz.

The apparent carbon linewidths under FSLG decoupling are obviously much larger than these multiple-bond scalar interactions. However, the dephasing time constant which is effective for the creation of the heteronuclear MQ coherences (τ periods) is related to the refocused linewidth (or the homogeneous linewidth), for which all the inhomogeneous broadening is removed by the carbon π pulse. It was recently shown that, under CW decoupling, the carbon line broadening for crystalline organic compounds is mainly inhomogeneous,

and refocused linewidths as small as a few hertz on model organic samples have been measured.¹⁵ Under homonuclear proton decoupling, the homogeneous linewidth increases for protonated carbons. However, it remains about the same for nonprotonated carbons, i.e., of the order of a few hertz, thus rendering the observation of multiple-bond correlations feasible for these nuclei. Figure 15(b) shows the MAS-*J*-HMQC spectrum of the tripeptide recorded with an evolution period τ equal to 16 ms. Besides the one-bond connectivity (except for those corresponding to CH₂ groups, all of them are present), many additional through-bond ‘long-range’ correlation peaks are observed. As expected, all the nonprotonated carbons (four resonance lines in the carbon spectrum) yield multiple-bond connectivity. For example, the carbonyl carbon of the Boc group at 155.7 ppm is expected to correlate with the amide proton of the N-terminal alanine residue (A1), and also with

Figure 15 Carbon–proton two-dimensional MAS-*J*-HMQC spectra of the natural abundance tripeptide Boc-Ala-Ala-Pro-O-Bzl recorded with an evolution period (τ value) of (a) 1.6 ms, and (b) 16 ms. The one-dimensional CP/MAS ^{13}C spectrum is shown above the two-dimensional spectrum. The proton linewidths depend on the efficiency of the homonuclear decoupling scheme. Under our experimental conditions, we measured proton linewidths of about 200 Hz, 250 Hz and 400 Hz for the CH_3 , CH and CH_2 groups, respectively. However, for CH_2 groups, the proton resonance may correspond to two magnetically nonequivalent protons. Note that, despite the long evolution periods (16 ms) which are required for the excitation of the long-range MQ coherences, the multiple-bond experiment remains quite sensitive since, as pointed out in the text, the effective time constants which characterize the decay of carbon magnetization during the τ delays, are ‘refocused’ time constants and thus, are longer than the apparent relaxation times. (c) ^{15}N - ^1H two-dimensional MAS-*J*-HMQC spectra of the tripeptide. The spinning frequency was 12.5 kHz and τ was 4.32 ms. A total of 110 t_1 increments with 256 scans each were acquired. The other experimental conditions are the same as in (a) and (b). The one-dimensional CP/MAS ^{15}N spectrum is shown above the two-dimensional spectrum; 4 mm MAS probe ~ 20 mg, $\omega_{\text{IH}} = 100$ kHz. (Reproduced from Lesage et al.⁴⁷ with permission, © 2000 American Chemical Society)

the α proton of the same residue. Indeed, two cross-peaks, one very intense at 6.5 ppm and the other weaker at 4.25 ppm, are observed in the ω_1 dimension. From the proton chemical shifts, they must correspond respectively to the HN and $\text{H}\alpha$ protons of A1. In the one-bond (^1H , ^{13}C) MAS-*J*-HMQC spectrum, the

carbon resonance at 51.7 ppm is also correlated to the $\text{H}\alpha(\text{A1})$ proton, and can therefore be assigned to the $\text{C}\alpha(\text{A1})$. In addition to the quaternary carbons, the $\text{C}\beta$ carbons of the alanine residues (methyl groups) yield weak multiple-bond correlations with the neighboring α protons. As the $\text{H}\alpha(\text{A1})$ proton

could be previously assigned at 4.25 ppm from its correlation with the carbonyl carbon of the Boc group (at 155.7 ppm), the assignment of the methyl carbons is now straightforward: the carbon resonance at 20.3 ppm corresponds to the C β (A1) and, by deduction, the resonance at 19.4 ppm to the C β (A2). By continuing in this way, all the proton, carbon and nitrogen resonances in the spectrum can be assigned (the nitrogen-15 assignment being obtained simply from the natural abundance proton–nitrogen HMQC experiment shown in Figure 15(c)).

MAS-*J*-HMQC experiments constitute a powerful tool for the characterization of the NMR spectra of solid-state natural abundance organic molecules. Despite the small size of multiple-bond scalar couplings, it has been shown experimentally⁴⁷ that it is possible to observe long-range connectivities that can be assigned to through-bond correlations, which is an important step towards complete assignment of ¹³C CP/MAS spectra.

Note that it would be difficult to reliably identify multiple-through-bond correlations using dipolar based techniques, since, at long contact times, dipolar methods usually lead to a wide range of through-space interactions, often including inter-molecular contacts. In fact, long range dipolar and scalar experiments are complementary techniques, and differences in the correlation patterns could be very informative to identify, for example, effects such as hydrogen bonding in solids.

3.3.5 MAS-*J*-HSQC

The spin dynamics in the MAS-*J*-HMQC experiment can be very easily modified to have only a single quantum proton coherence evolution during the t_1 , leading to the MAS-*J*-HSQC experiment. At first sight there should not be a significant difference between the two experiments. In fact, for natural abundance compounds, the MAS-*J*-HMQC and

the MAS-*J*-HSQC experiments give about the same proton resolution in the indirect dimension, although the HSQC version is more prone to artifacts such as quadrature images or axial peaks, since there are more pulses in the sequence. On the other hand, for ¹³C enriched materials, substantially narrower proton linewidths are obtained with the MAS-*J*-HSQC experiment, since homonuclear carbon–carbon couplings have no influence on the evolution of the single quantum proton coherence. The pulse sequence of the MAS-*J*-HSQC experiment is shown in Figure 13(b). The comparison between the two approaches is discussed in detail in Ref.⁴⁶

3.3.6 *J*-WISE

The experiments discussed above are aimed at assigning complex spectra. However, controlled coherence transfer through scalar couplings can also be put to use in structural studies by comparing the results of polarization transfer using dipolar and scalar couplings. A striking example has recently been demonstrated for wideline proton (WISE) spectra in polymer systems to study hydration effects (see **Polymer Dynamics & Order from Multidimensional Solid State NMR**, Volume 6). Figure 16 shows a comparison between an ‘ordinary’ dipolar WISE spectrum,⁴⁹ recorded for a sample of partially rehydrated onion cell-wall material with a similar wideline spectrum where the proton–carbon correlation is obtained using a derivative of the MAS-*J*-HSQC experiment without applying decoupling during t_1 (dubbed *J*-WISE). Interestingly, all of the proton signals in the cell-wall material dipolar WISE spectra contain a broad signal split into spinning sidebands superimposed on a narrow component occurring at the centerband. By performing a *J*-WISE experiment, it was shown that the narrow line arises from water molecules close

Figure 16 Comparative study of onion cell-wall material using the standard WISE and *J*-WISE experiments. Proton signals arising from immobile regions of the molecule give the broad signal split into sidebands onto which is clearly superimposed a narrow center component in the dipolar spectra (a). In the *J*-WISE spectra (b) this narrow component is absent, indicating that it belongs to ‘bound water’. (Courtesy of Dr S. Hediger)

to the polysaccharides ('bound water'), since the narrow component disappears from the spectrum, indicating that there is no covalent connection between these protons and the carbon atoms of the polysaccharides. This is a particularly elegant demonstration of the complementarity between through-space and through-bond correlation techniques with which we conclude this entry.

Acknowledgements

We would particularly like to acknowledge the invaluable contribution of Anne Lesage to the work we review here, we simply regret that she was not available to write this entry with us. We would like to dedicate this article to Alix. We would also like to thank Sabine Hediger, Paul Hodgkinson, Stefano Caldarelli, Celine Auger, Patrick Charmont, Stefan Steuernagel and all the other members of our group who have contributed to this work. We thank Jamie Walls, Malgorzata Marjanska and Steven P. Brown for helpful discussions and criticisms on this manuscript.

École Normale Supérieure de Lyon, 1996, Ph.D., École Normale Supérieure de Lyon, France, 2000 under the direction of Lyndon Emsley, Fellow of the Lawrence Berkeley National Laboratory, UC Berkeley, currently working with Alex Pines. Current research interests focus on NMR.

Lyndon Emsley, *b* 1964. B.Sc. Imperial College, London, 1986, Ph.D., Université de Lausanne, Switzerland, 1991 under the direction of Geoffrey Bodenhausen. Fellow of the Miller Institute for Basic Research in Science, UC Berkeley, 1991–1993 (collaboration

with Alex Pines). Foreign member of the Institut Universitaire de France, 1994. Professor of Chemistry, École Normale Supérieure de Lyon 1995–present. Current research interests focus on fundamental aspects of NMR, with an emphasis on the solid state.

Vicinal $^1\text{H}, ^1\text{H}$ Coupling Constants in Cyclic π -Systems

Harald Günther

University of Siegen, Germany

1	Discussion	1

1 DISCUSSION

According to the Karplus theory of vicinal $^1\text{H}, ^1\text{H}$ coupling constants, i.e. $^3J(^1\text{H}, ^1\text{H})$, such parameters depend on the structural features of the corresponding HC–CH fragment (dihedral angle Φ , bond length R_{cc} , and HCC valence angles) as well as on the electronic effects of substituents.^{1,2} These results form the basis for numerous applications of ^1H NMR spectroscopy in organic, bio-organic, and organometallic chemistry.

While the dihedral angle dependence of $^3J(^1\text{H}, ^1\text{H})$ —the well-known *Karplus curve*—is one of the major tools in conformational analysis,³ structural research in the field of cyclic π -systems profits from the R_{cc} and valence angle dependence which dominates $^3J(^1\text{H}, ^1\text{H})$ values in planar unsaturated hydrocarbons, where $\Phi = 0^\circ$ for a *cis*-HC $_{\mu}$ –C $_{\nu}$ H arrangement and where substituents are absent. This aspect was first highlighted as a linear dependence between $^3J(^1\text{H}, ^1\text{H})_{\text{cis}}$ and the Hückel (HMO) π -bond order, $P_{\mu\nu}$, of the C $_{\mu}$ –C $_{\nu}$ bond was found for benzenoid aromatics⁴ and later extended to olefinic systems.^{5,6} At the same time, related correlations between $^3J(^1\text{H}, ^1\text{H})$ and the CC bond length $R_{\mu\nu}$ were established for aromatics⁷ and polyenes.⁸ An early application of $^3J(^1\text{H}, ^1\text{H})$ data for the analysis of the bonding situation in a cyclic π system was the detection of partial π -bond fixation in biphenylene (1),⁹ which in terms of resonance theory demonstrated the preference for Kekulé structures with exocyclic double bonds at the central four-membered ring. Later, the olefinic nature of tropone (2) was established from its $^3J(^1\text{H}, ^1\text{H})$ values,¹⁰ partial bond fixation in heterocyclic compounds was detected,^{11,12} and the characteristic $^3J(^1\text{H}, ^1\text{H})$ data measured for cyclic dienes and trienes were recognized as important tools for the structural analysis of cyclic diene–triene isomers like norcaradienes and cycloheptatrienes.¹³

(2)

A detailed investigation of the $^3J(^1\text{H}, ^1\text{H})_{\text{cis}}/R_{\mu\nu}$ and $P_{\mu\nu}$ relations in unsaturated six-membered rings of various

Figure 1 Dependence of $^3J(^1\text{H}, ^1\text{H})_{\text{cis}}$ on the CC bond length in the HC–CH fragment of six-membered rings [equation (1)]. (Reproduced with permission from H. Günther, ‘NMR Spectroscopy’, 2nd edn., Wiley, Chichester, 1995)

benzenoid aromatics and other hydrocarbons,^{14,15} where the magnitude of these constants ranges between 5 and 9 Hz (and—as for other $^3J(^1\text{H}, ^1\text{H})$ values—a positive sign is found¹⁶), finally led to equations (1) and (2) which can be used to derive bond length and π -bond order information from experimental $^3J(^1\text{H}, ^1\text{H})_{\text{cis}}$ data:

$$^3J(^1\text{H}, ^1\text{H})_{\text{cis}} = -351.0 R_{\mu\nu}(\text{nm}) + 56.65 \quad (1)$$

$$^3J(^1\text{H}, ^1\text{H})_{\text{cis}} = 12.47 P_{\mu\nu}(\text{HMO}) - 0.71 \quad (2)$$

The sensitivity of $^3J(^1\text{H}, ^1\text{H})_{\text{cis}}$ for bond length changes is high (Figure 1) and provides a valuable probe for the bonding situation in various cyclic π systems and annulenes. Steric compression and strain effects may cause deviations from equation (1) if changes of the HCC valence angles are induced.^{17,18} This becomes apparent if one compares the data for 1,4-di-*t*-butylnaphthalene¹⁸ with those of naphthalene¹⁵ or data for *o*-di-*t*-butylbenzene¹⁹ and the highly strained benzocyclopropene¹⁷ with those of the unstrained 9,10-dihydroanthracene¹⁷ (Figure 2).

Strain and steric compression are frequently encountered in fused ring systems where these factors cause a decrease in $^3J(1,2)$ and an increase in $^3J(2,3)$ if a small ring ($n < 6$) is fused to a large ring (3). The reverse trend—an increase of $^3J(1,2)$ and a decrease of $^3J(2,3)$ —is found if a larger ring is fused to a smaller one (4).²⁰

(3)

(4)

More drastic changes of the HCC valence angles are induced in π systems of different ring size and modified correlations have been derived for these cases:

Figure 2 The effect of steric compression and strain on $^3J(^1\text{H}, ^1\text{H})_{cis}$ values (in Hz) of various HC–CH fragments (a, b)

Table 1 The Ring Size Dependence of $^3J(^1\text{H}, ^1\text{H})_{cis}$ Values

Cycloalkene ring size	$^3J(\text{Hz})$
3 ²⁸	1.3
4 ²⁹	2.85
5 ²⁷	5.57
6 ²⁷	10.11
7 ²⁷	11.02
8 ²⁷	10.41

Five -membered rings:^{5,21}

$$^3J(^1\text{H}, ^1\text{H})_{cis} = -322.6R_{\mu\nu}(\text{nm}) + 48.45 \quad (3)$$

$$^3J(^1\text{H}, ^1\text{H})_{cis} = 7.12P_{\mu\nu}(\text{HMO}) - 1.18 \quad (4)$$

Seven-membered rings:^{20,22}

$$^3J(^1\text{H}, ^1\text{H})_{cis} = -367.4R_{\mu\nu}(\text{nm}) + 60.68 \quad (5)$$

$$^3J(^1\text{H}, ^1\text{H})_{cis} = 21.91P_{\mu\nu}(\text{HMO}) - 3.85 \quad (6)$$

The ring size dependence of the HCC valence angles is a consequence of the changes in internal CCC valence angles for the respective perimeters and a linear correlation of $\angle\text{CCC}$ with $^3J(^1\text{H}, ^1\text{H})_{cis}$ is thus not unexpected. Using five-, six-, seven-, and eight-membered ring systems, an increment of 0.29 Hz per degree was found after correcting for different π -bond orders.²³ Similar relations were established for the long-range $^1\text{H}, ^1\text{H}$ couplings 4J and 5J .²³ For isolated double bonds, the effect of HCC valence angle changes is most clearly seen by the ring size dependence of $^3J(^1\text{H}, ^1\text{H})_{cis}$ in cycloalkenes,^{24–27} as shown in Table 1.

A systematic study of $^3J(^1\text{H}, ^1\text{H})_{cis}$ for benzo-annelated annulenes³⁰ has shown that in addition to steric effects the electronic nature of the annulenes, i.e. the number of π electrons and the degree of delocalization, influences the $^3J(^1\text{H}, ^1\text{H})_{cis}$ data in the annelated benzene ring in a characteristic way. Thus, the π -electron structure of annulenes

can be monitored by the $^3J(^1\text{H}, ^1\text{H})_{cis}$ data for the benzene ring in the corresponding benzoannulene. The π -bond orders P_{12} and P_{23} are determined from the measured coupling constants according to equation (7), which is based on PPP–SCF π -electron calculations,^{31,32}

$$P_{\mu\nu}(\text{SCF}) = 0.104^3 J(^1\text{H}, ^1\text{H})_{cis} - 0.120 \quad (7)$$

a Q value being defined as $Q = P_{12}/P_{23}$. The magnitude of Q is related to the bonding situation in the annulene: $Q < 1.00$ for antiaromatic ($4n$) π systems, $Q > 1.10$ for aromatic ($4n + 2$) π systems, and $1.00 < Q < 1.10$ for olefinic systems. Typical examples are found with the benzotropylium ion (**5**)²³ and benzocycloheptatriene-id (**6**)³³ or the two dehydroannulenes (**7**) and (**8**).³⁴

Substituent effects have mostly been studied with substituted benzenes, where a careful determination of the $^3J(^1\text{H}, ^1\text{H})$ values³⁵ has established the effect of electronegativity: $^3J(\text{a,b})$ increases in the (X)C–CH_a–CH_b–CH_c–fragment if X is more electronegative than hydrogen, while a small decrease is found for the coupling $^3J(\text{b,c})$.

Vicinal $^1\text{H}, ^1\text{H}$ coupling via a *trans*-HC–CH fragment, $^3J(^1\text{H}, ^1\text{H})_{trans}$, is found only in larger annulene rings which tolerate *trans* double bonds. As a consequence of the different dihedral angle $\Phi = 180^\circ$, such couplings are larger than the *cis* values, as the data reported for [18]annulene [$^3J(^1\text{H}, ^1\text{H})_{cis} = 8.0$ and $^3J(^1\text{H}, ^1\text{H})_{trans} = 15.5$ Hz]³⁶ demonstrate. Other values have been collected in the literature,^{34,37} but a detailed analysis of these data was not attempted. For bridged annulenes, various steric requirements imposed on the perimeter geometry by the bridging group usually lead to a loss of coplanarity of all HC–CH fragments and the magnitude of the vicinal $^1\text{H}, ^1\text{H}$ coupling constants is subject to additional factors such as varying dihedral angles.^{38–40} Early theoretical calculations for $^3J(^1\text{H}, ^1\text{H})_{cis}$ have been reviewed.⁴¹

In conclusion, vicinal $^1\text{H}, ^1\text{H}$ coupling constants provide the basis for detailed insights into the electronic structure of annulenes and other cyclic π systems and complement the information obtained from shielding properties such as, for example, ring current effects.

1 INTRODUCTION

The discovery¹ that the vicinal (three-bond) proton–proton coupling constant, $^3J(\text{H,H})$, varies smoothly with the associated H–C–C–H torsion angle $\phi(\text{HH})$ in ethane had a profound impact on the acceptance of NMR as an indispensable tool in stereochemistry and conformational analysis. The well-known Karplus equation,^{1,2} also called the cosine-square rule [equation (1)], was derived from valence bond calculations on the unperturbed ethane molecule.

$$^3J(\text{H,H}) = C_0 + C_1 \cos(\phi_{\text{HH}}) + C_2 \cos(2\phi_{\text{HH}}) \quad (1a)$$

The Fourier series embodied in equation (1) is more often written as:

$$^3J(\text{H,H}) = A \cos^2(\phi_{\text{HH}}) + B \cos(\phi_{\text{HH}}) + C \quad (1b)$$

Of course, simple relationships exist between C_0 , C_1 , C_2 and A , B , C , respectively: $C_0 = 0.5A + C$, $C_1 = B$, $C_2 = 0.5A$. Karplus² predicted that $^3J(\text{H,H})$ depends on various other molecular parameters, such as the electronegativity of the substituents, bond lengths, and bond angles. In the same paper² he issued a caveat against the indiscriminate application of his equation and the theoretically derived parameters [coefficients in equation (1)] to ‘estimate torsion angles to an accuracy of one or two degrees’.

The general shape of the Karplus curve, large 3J at $\phi = 0^\circ$ (eclipsed, *sp*) and at or near $\phi = 180^\circ$ (*trans*, *anti* or *ap*), and decreasing to a minimum value ($^3J \approx 0 \text{ Hz}$) near $\phi = 90^\circ$, in the course of time was shown to be applicable to many molecular fragments, including $^3J(\text{H,H})$ with heteroatoms in the coupling path and also $^3J(\text{X,H})$ and $^3J(\text{X,Y})$ with X,Y NMR-active heteronuclei like ^{13}C , ^{15}N , and ^{31}P , for example $^3J(\text{H,C,O,H})$, $^3J(\text{H,N,C,H})$, $^3J(\text{N,C,C,H})$, $^3J(\text{C,C,C,H})$, $^3J(\text{H,C,O,P})$, $^3J(\text{C,C,O,P})$. Several of these more exotic vicinal couplings are useful in the conformational analysis of bio-molecules such as peptides, proteins, nucleic acids, and polysaccharides.

In suitable cases direct (1J) and geminal (2J) coupling constants provide additional structural information, albeit of a more qualitative nature. Long-range couplings (nJ , $n > 3$) are often highly useful, especially 4J couplings (planar W path). However, the present contribution focuses entirely on vicinal (3J) couplings.

The coupling constant $^3J(\text{H,C,C,H})$ with C saturated carbon is by far the best investigated and will be treated in depth in the present article. A selection of more simple Karplus equations involving heteroatoms will be presented and briefly discussed. Familiarity with the basic tenets and methods of conformational analysis is assumed. The multitude of techniques that are currently available to measure the coupling constants of interest remain outside the scope of the present contribution (see Section 7 for related articles). Clearly, the approaches that are found useful in the conformational analysis of biomolecules are applicable to many other molecular fragments in organic chemistry. The article concludes with some applications in the field of (poly)peptides and nucleic acids, and caveats are issued. The reader is advised to consult the selection of references given for further details and for references therein.

2 VICINAL PROTON–PROTON COUPLING CONSTANTS $^3J(\text{H,C,C,H})$

2.1 General Background

In the late 1950s experiments already showed³ that the *time-averaged* $^3J(\text{H,H})$ [equation (2)] in monosubstituted ethanes $\text{CH}_3\text{CH}_2\text{X}$ decreases more or less linearly with increasing electronegativity of the substituent X.

$$(^3J(\text{H,H})) = [J(60) + J(180) + J(300)]/3 \quad (2)$$

Studies carried out in the early 1960s^{4,5} confirmed these findings. Perhaps unfortunately, the (erroneous) notion that $^3J(\text{H,H})$ in all situations decreases with increasing electronegativity became firmly lodged in the minds of NMR spectroscopists. A second, also erroneous, assumption was generally accepted and that is the linear additivity of (relative) electronegativities $\Delta\chi_1 = \chi_i - \chi_{\text{H}}$. In other words, the general validity of equation (3) was accepted without question, although proper analysis of the experimental data on monosubstituted ethanes and 2-substituted propanes, already available in the early 1960s, could have shown differently.

$$^3J(\text{H,H}) = f(\phi) + a \sum_i \Delta\chi_i \quad (3a)$$

or alternatively:

$$^3J(\text{H,H}) = f(\phi)[1 - a(\sum_i \Delta\chi_i)/f(\phi)] \quad (3b)$$

where $f(\phi)$ denotes a Karplus function of ϕ_{HH} ; $a/f(\phi)$ is usually written as k .

In the case of coupling to the fast-rotating methyl protons, for example in substituted ethanes and 2-substituted propanes [equation (2)], the ϕ -dependent terms in equation (1a) vanish and $f(\phi)$ reduces to the ‘constant’ C_0 . The following comparison is obtained (Hz):

$$\begin{aligned}\text{CH}_3\text{CH}_2\text{X} :^3 C_0 = 7.5, a = -0.4 \\ \text{CH}_3\text{CH}_2\text{X} :^4 C_0 = 7.9, a = -0.7 \\ \text{CH}_3\text{CHXCH}_3 :^3 C_0 = 7.0, a = -0.55 \\ \text{Combined} :^5 C_0 = 7.7, a = -0.80\end{aligned}$$

In the remainder of this article the slope (a) will be denoted C_{01} . The ‘goodness of fit’ of these least-squares regressions (± 0.3 Hz) is disappointing, moreover, several workers^{4,5} noted a breakdown of linearity in cases where X and Y in CH_3CHXY represent highly electronegative substituents like fluorine or oxygen. It should be noted that the measured coupling to methyl cannot yield the electronegativity dependence of the ‘constants’ C_1 and C_2 in equation (1); it was simply assumed that these dependences were all equal.

In 1965 Booth⁶ noted that an electronegative substituent located on the C–C fragment constituting the coupling path and in antiparallel (*ap*) position relative to one of the two coupling *gauche* (*sc*) protons causes an ‘extra’ diminution of their mutual coupling constant (Booth’s rule). In hindsight it is easy to see that this observation implies a breakdown of the symmetry inherent to a Fourier series with cosine terms only, e.g., equation (1a), but it was not so interpreted at the time. On the contrary, one might say, and for a long time the Durette–Horton equation⁷ [equation (4)], was popular in the field.

$$^3J(\text{H,H}) = [C_0 + C_1 \cos(\phi) + C_2 \cos(2\phi)](1 - k \sum_i \Delta\chi_i) \quad (4)$$

Equation (4) is simply a combination of equations (1a) and (3b), rewritten here in terms of cosine Fourier coefficients C ; ϕ denotes the torsion angle between the coupling nuclei indicated in parentheses on the left-hand side of equation (4), $\Delta\chi_i$ are relative electronegativities of substituents according to either the Pauling⁸ or the Huggins⁹ scale.

Unfortunately, equation (4) embodies at least four questionable or even erroneous assumptions:

1. The orientation of any electronegative substituent with respect to the coupling protons is unimportant (in negation of Booth’s rule).
2. Coefficients C_0 , C_1 , C_2 have the same electronegativity dependence.
3. Substituent effects are linearly additive.
4. The standard atomic electronegativity scales^{8,9} can be applied to polyvalent substituents, regardless of the remaining atoms or groups attached.

At this point it should be mentioned that many workers in the field of stereochemistry in a way circumvented assumptions 2, 3, and 4 by the calibration of Karplus parameters for given classes of molecules of interest with the aid of model compounds with known or estimated torsion angles. Even today this approach often remains the only sensible course of action available in the case of couplings to heteronuclei, e.g., $^3J(\text{C,H})$, $^3J(\text{N,H})$, $^3J(\text{P,H})$, $^3J(\text{P,C})$, vide infra. More refined approaches are now possible in the case of $^3J(\text{H,H})$ in $\text{sp}^3\text{--sp}^3$ H–C–C–H fragments.

2.2 Substituent-Induced Asymmetry in the Karplus Curve

The first systematic investigation into the orientational effects of substituents on $^3J(\text{H,H})$ was carried out by Abraham

Figure 1 Newman projections along the central bond of a $\text{H}_\text{A}\text{--C--C--H}_\text{B}$ fragment, H_A and H_B are mutually coupled. (a) Situation pertaining to Booth’s rule (strong decrease of $^3J(\text{H,H})$ for an electronegative substituent S); (b) situation pertaining to Abraham’s rule [weak increase of $^3J(\text{H,H})$]; (c) situation where Abraham’s rule applies twice. This configuration occurs, for example, in cyclohexanes with H_A , H_B diequatorial and the S substituents diaxial

and Gatti¹⁰ with the aid of a series of 1,2-disubstituted ethanes $\text{CH}_2\text{X--CH}_2\text{Y}$. Their results are summarized in Figure 1.

For most practical purposes one needs to distinguish three different situations:

- (a) *Gauche* (*sc*) protons, J_g , with X in an *anti* orientation X_t : J_g decreases strongly with increasing electronegativity of X (Booth’s rule);
- (b) *Gauche* (*sc*) protons, J_g , and a substituent X in a *gauche* orientation with respect to its vicinal coupling proton, X_g : J_g increases with increasing electronegativity of X (Abraham’s rule);
- (c) *Anti* or *trans* (*ap*) protons, J_t , with X necessarily in a *gauche* position (not shown in Figure 1): J_t decreases with increasing electronegativity of X.

For X = oxygen in conformationally rigid pyranose sugars, a statistical analysis¹¹ of a large set of couplings indicated the following changes of 3J from X = H: situation (a) -1.8 Hz; (b) $+0.5$ Hz; (c) -1.45 Hz. This example clearly illustrates the fact that *gauche* (*sc*) couplings do not obey the simple cosinesquare rule. The various effects are additive to a good approximation, 24 additivity constants (eight different substituent types) gave an rms error of only 0.29 Hz for a test set consisting of 305 couplings.

Extended Hückel molecular orbital theory (EHT) calculations of $^3J(\text{H,H})$, carried out by Pachler^{12,13} on $\text{CH}_3\text{CH}_2\text{X}$ (X = H, CH_3 , NH_2 , OH, F), CH_3CHF_2 , and $\text{CH}_2\text{FCH}_2\text{F}$, indicated that an X substituent (or the C–X bond) induces an asymmetry in the Karplus curve. More refined EHT calculations^{14,15} confirmed this important finding and showed¹⁵ that mutual interaction between substituents cannot be neglected. Pachler^{12,13} described the calculated influence of the X substituent in terms of the summation of two effects: (1) an attenuation of the Fourier coefficients, i.e., as in equation (4) but with different k values for C_0 , C_1 , and C_2 ; (2) a phase shift, assumed to be proportional to the electronegativity of the substituent (Figure 2).

A phase shift can be formulated in several ways, for example by the introduction of sine terms.^{12,13} This leads to equation (5).

$$\begin{aligned}^3J(\text{H,H}) = C_0 + C_1 \cos(\phi) + C_2 \cos(2\phi) \\ + S_1 \sin(\phi) + S_2 \sin(2\phi)\end{aligned} \quad (5a)$$

with

$$C_m = C_{m0} + C_{m1} \sum_i \Delta\chi_i \quad \text{and} \quad S_m = S_{m1} \sum_i s_i \Delta\chi_i \quad (5b)$$

Figure 2 The calculated coupling constants (EHT method¹⁴) for ethane (solid line) and fluoroethane (dashed line) as a function of the HH torsion angle ϕ ; the positive direction of ϕ is defined according to IUPAC,¹⁷ the F atom occupies the S_1 substituent position shown in Figure 3 (sign factor $s_i = +1$). (Reproduced with permission from Elsevier Science Ltd., Kidlington, UK, from K. G. R. Pachler, *Tetrahedron*, 1971, **27**, 187)

In equation (5) the original Pachler equation^{12,13} is recast into a general Fourier expression.¹⁵ Moreover, the use of a separate and cumbersome proton-substituent torsion angle $\cdot\Phi_{\text{HX}}$ ^{12,13} is avoided by the introduction of the 'sign' factor s_i for each substituent S_i , s_i is +1 or -1 according to the definition by Haasnoot et al.¹⁶ (see Figure 3). (In this paper, as well as in others,¹⁵ the sign factor S_i was denoted ξ_i .)

It is important to keep in mind that the sign factors s_i of the substituents S_1 and S_2 (not to be confused with the Fourier coefficients S_1 and S_2) depend exclusively upon their stereochemical position with respect to their 'own' geminal coupling proton H_A . The following recipe applies: choose a Newman projection along the coupling path in such a manner that the chosen coupling proton H_A is located on the front side (Figure 3): S_1 is found at 120° and S_2 at -120° (positive angle defined as clockwise). Repeat the procedure with H_B up front, S_3 is at 120° and S_4 at -120° . The sign factors ($s_i = +1$ for substituents S_1 and S_3 , $s_i = -1$ for S_2 and S_4) are thus uniquely defined and are *independent* of the actual value of the torsion angle ϕ_{AB} . It goes without saying that in the case of a CH_2 group ($\text{CH}_{A1}\text{H}_{A2}$) one has to take care to select the proper H_A (interchange of H_{A1} and H_{A2} means a change of sign factor for the remaining substituent). Equation (6) simplifies the computer programming:

$$\sum_i s_i \Delta\chi_i = \Delta\chi_1 - \Delta\chi_2 + \Delta\chi_3 - \Delta\chi_4 \quad (6)$$

It is easily appreciated that the sine terms vanish in all cases where equivalent substituents (same $\Delta\chi_i$) occupy a +1 and a -1 position at the same time, for example in $-\text{CH}_2-\text{CHX}_2$ and the +, - coupling in the $-\text{CHX}-\text{CH}_2\text{X}$ molecular fragment. The above sign factor definition is associated with the definition of the positive direction of ϕ_{AB} according to IUPAC rules:¹⁷ positive when H_B rotates clockwise away from H_A , with the H_A, H_B eclipsed position taken as zero angle. Since the sine terms change sign at $\phi_{AB} = 0^\circ$ a change of substituent position from +1 to -1 can be depicted as a mirroring of the ΔJ curve (Figure 4). Equation (5) is invariant under electronegativity scale changes,¹⁵ aside from changes in the values of the coefficients C_m and S_m . It is a valid procedure to choose the relative electronegativity of hydrogen as zero and to fix $\Delta\chi$ of one other substituent. For practical reasons, a value $\lambda_{\text{OR}} = 1.40$ was selected, vide infra.

Figure 3 Definition of substituents with positive (S_1 and S_3) and negative (S_2 and S_4) sign factors s_i . Note that with each coupling nucleus in an sp^3-sp^3 fragment two geminal substituents with opposite sign factors are associated. The result of rotation of H_B with respect to H_A in the $-\phi$ direction is mathematically equivalent to the result of a $+\phi$ rotation with concomitant interchange of S_1 and S_2 . (Reproduced with permission of Elsevier Science Ltd., Kidlington, UK, from C. A. G. Haasnoot, F. A. A. M. de Leeuw, and C. Altona, *Tetrahedron*, 1980, **36**, 2783)

Haasnoot et al.¹⁶ also sought to describe the generalized Karplus equation by superimposing a phase shift upon the symmetrical ethane curve [equation (7) and Figure 4].

$$^3J(\text{H,H}) = P_1 \cos^2(\phi) + P_2 \cos(\phi) + P_3 + \sum_i \Delta\chi_i [P_4 + P_5 \cos^2(s_i(\phi) + P_6 | \Delta\chi_i |)] \quad (7)$$

Comparison with equation (5) shows that C_{11} and S_{11} have been set to zero, and that in the $\cos(2\phi)$ and $\sin(2\phi)$ terms

Figure 4 The calculated difference curve $\Delta J = J(\text{CH}_3\text{CH}_2\text{S}) - J(\text{CH}_3\text{CH}_3)$ for a substituent S with a positive sign factor, showing the rationale behind the phase-shift parameters P_4 , P_5 , and P_6 in the Haasnoot equation (7)¹⁶

both a constraint (through a common parameter P_5) and a nonlinear $\Delta\chi_i$ dependence have been introduced. The invariance property (vide supra) does not hold for equation (7). The parameters P_1 – P_6 were empirically determined with the aid of a test set containing 315 couplings and corresponding ϕ_{HH} values.¹⁶ Each substituent was assigned a $\Delta\chi_i$ value according to Huggins,⁹ but empirically modified to account for the moderation of the electronegativity of the α substituent by attached atoms or groups (β substituents), other than hydrogen. A least-squares regression (J_{calc} versus J_{obs}) showed an rms error of 0.48 Hz and a correlation coefficient R of 0.992, in contrast to a similar regression using three parameters only, equation 1(a) (rms = 1.20 Hz, R = 0.947).¹⁶

2.3 Group Electronegativities and Nonadditivity Effects

Analysis¹⁵ of the results of a systematic series of calculations of $^3J(\text{H},\text{H})$ in a variety of mono-, di-, tri-, and tetrasubstituted ethanes by means of the EHT method (1404 J values) suggested that: (a) the use of standard relative electronegativities $\Delta\chi_i$ should perhaps be abandoned in favor of ‘best values’ of substituent constants λ_i derived from the data set at hand; (b) the nonadditivity effect (interaction between substituents) can be well described by the introduction of cross terms involving products $\Delta\chi_i\Delta\chi_j$ or $\lambda_i\lambda_j$. Díez et al.¹⁸ allowed the coefficients of equation (5b) to be quadratically dependent upon λ . It was shown that only certain combinations of cross terms can survive in such an expansion because of symmetry. Neglecting interactions between more than two substituents, one obtains equation (8), which is in fact an extension of equation (5).

$$C_m = C_{m0} + C_{m1}\sum_i\lambda_i + C_{m11}\sum_i\lambda_i^2 + C_{m12}(\lambda_1\lambda_2 + \lambda_3\lambda_4) + C_{m13}(\lambda_1\lambda_3 + \lambda_2\lambda_4) + C_{m14}(\lambda_1\lambda_4 + \lambda_2\lambda_3) \quad (8a)$$

$$S_m = S_{m1}\sum_i s_i\lambda_i + S_{m11}\sum_i s_i\lambda_i^2 + S_{m13}(\lambda_1\lambda_3 + \lambda_2\lambda_4) \quad (8b)$$

How can we determine the ‘substituent constants’ or ‘group electronegativities’ λ_i (which may contain other factors beside electronegativity)? Which of the cross terms in equation (8) are important and which can be neglected safely? In an attempt to answer these questions a combined empirical and theoretical approach was taken.

First, a large body of accurate (± 0.02 Hz) coupling data from mono- and 1,1-disubstituted ethanes was measured and analyzed.¹⁹ Because of torsional averaging, one isolates the ‘constant’ C_0 in equation (8a), $m = 0$. Excluding the self-quadratic term C_{011} from consideration,¹⁵ we obtain equation (9).

$$\langle^3J(\text{H},\text{H})\rangle = C_{00} + C_{01}(\lambda_1 + \lambda_2) + C_{012}(\lambda_1\lambda_2) \quad (9)$$

Not only were the coefficients C_{00} , C_{01} , and C_{012} optimized, but also the λ_i values. As explained above, parameter redundancies were removed by fixing the λ values of two different substituents present in the set: $\lambda_{\text{H}} = 0.00$ and $\lambda_{\text{OR}} = 1.40$ (measurements in solvent CDCl_3). The ‘best’ least-squares regression¹⁹ yielded equation (10):

$$\langle^3J(\text{H},\text{H})\rangle = 7.836 - 0.594(\lambda_1 + \lambda_2) - 0.423(\lambda_1 \cdot \lambda_2) \quad (10)$$

and in addition 50 λ_i values¹⁹ from 84 couplings; rms deviation = 0.018 Hz, maximum deviation = 0.06 Hz. A similar regression with the use of Huggins’s relative electronegativities yielded a 10-times larger rms deviation;¹⁹ however, this

Table 1 Substituent Parameters λ_i (Relative Group Electronegativities) Deduced from $\langle^3J\rangle$ of Various Mono- and 1,1-Disubstituted Ethanes in CDCl_3 and in D_2O , Equation (10). More Detailed Data are Given Elsewhere.^{19,20,24} R Signifies Carbon, Usually Alkyl; Z Signifies any Substituent, Except Hydrogen and Halogens.¹⁹ Fixed Points are Indicated by an Asterisk; 90% Confidence Limits ($\times 100$) are Shown in Parentheses. ^a λ_i range 0.60–0.62; for Z = halogen: Cl 0.85, Br 0.92, I 1.02.

^b λ_i range 0.65–0.78; for Z = halogen: F 0.65, Cl 0.82, Br 0.92, I 0.99.

regression also underlined the importance of the $\lambda_1\lambda_2$ cross term, at least for coupling to methyl protons.

Equation (10) proved to be highly useful for determining λ_i values of substituents not present in the original data set. Recently, special attention²⁰ was paid to solvent effects, in particular to the influence of the solvent D_2O in cases where the α substituent carries at least one nonconjugated lone pair of electrons that can readily act as a hydrogen bond acceptor. The vicinal coupling constants (and thus λ values) measured in common organic solvents (like acetone- d_6 , CD_3CN , and DMSO) hardly differ from those established in CDCl_3 . Table 1 presents a selection of λ_i values of substituents that are of particular value in the analysis of couplings measured in biomolecules.

Second, the least-squares analysis of the set of 1404 J values indicated¹⁵ that only two more cross terms (besides C_{012}) are probably important for use in equation (8a): C_{214} and either S_{211} or S_{213} .

Table 2 Final rms Deviations Obtained for $^3J(\text{H,H})$ with the Aid of the 299 J Test Set in the Various Approximations^a

Approximations	rms($\Delta\chi_i$) ^b (Hz)	rms(λ_i) ^c (Hz)	N^d

^eEquation (1a).

^fEquation (5), C coefficients only.

^gEquation (5), S_2 added (the rms error does not change when C_{11} and S_{11} are also added).

^hEquation (7), the coefficients (based on λ_i) are shown in equation (11).

ⁱEquation (8): C_{00} , C_{01} , C_{10} , C_{20} , C_{21} , S_{211} used, the coefficients (based on λ_i) are shown in equation (12).

^jEquation (8): C_{00} , C_{01} , C_{012} , C_{10} , C_{20} , C_{21} , C_{214} , S_{211} used.

^kEquation (8), as in footnote ^j, but C_{01} fixed on the 'ethane' value, and C_3 added ($C_3 = 0.1$ taken as the fixed value); the coefficients (based on λ_i) are shown in equation (13).

2.4 Parameter Optimizations

In order to test the ideas developed in the previous sections, an empirical approach was again taken. The original data set (315 J set)¹⁶ was first reduced to 299 J values (299 J set) by the deletion of norbornane- and norbornene-like structures [equations (5) and (7) do not contain correction terms for through-space effects,²¹ nor for deviations of CCH bond angles from the tetrahedral value, see Section 5]. Group electronegativities λ_i were selected for the various substituents present in the data set. The corresponding torsion angles were recalculated with the aid of the MM2-85 force field.²²

A series of least-squares parameter optimizations were carried out (see Table 2). It is of interest to watch the successive improvement, as judged by the drop in rms deviation, as we start (entry 1) from the original three-parameter Karplus equation [equation (1a)], and successively add (entry 2) an electronegativity dependence of the C_0 and C_2 coefficients, add (entry 3) the sine terms of the modified Pachler equation [equation (5)], use (entry 4) the Haasnoot approximation [equation (7)], and finally the Díez–Donders equation [equation (8)], the latter in three forms: (1) (entry 5), all cross terms zero, except the $S_{211} \sum_i S_i \lambda_i^2$; (2) (entry 6) as (1) but $C_{012} (\lambda_1 \lambda_2 + \lambda_3 \lambda_4)$ and $C_{214} (\lambda_1 \lambda_4 + \lambda_2 \lambda_3) \cos(2\phi)$ added; (3) (entry 7) as (2) plus a small threefold term $C_3 \cos(3\phi)$ added. In the latter parameter optimization, the C_{01} parameter was kept fixed on the value obtained from the 'ethane set' [equation (10)]; C_3 was fixed at -0.10 , a value close to that suggested by ab initio calculations.²³

The current parameters are shown in equations (11)–(13), with reference to the entries in Table 2.

Entry 4, Haasnoot:

$$^3J(\text{H,H}) = 14.64 \cos^2(\phi) - 0.78 \cos(\phi) + 0.58 \\ + \sum_i \lambda_i [0.34 - 2.31 \cos^2(s_i(\phi) + 18.40|\lambda_i|)] \quad (11)$$

Entry 5, Díez–Donders:

$$^3J(\text{H,H}) = (7.82 - 0.79 \sum_i \lambda_i) - 0.78 \cos(\phi) \\ + (6.54 - 0.64 \sum_i \lambda_i) \cos(2\phi) \\ + (0.70 \sum_i S_i \lambda_i^2) \sin(2\phi) \quad (12)$$

Entry 7, Díez–Donders:

$$^3J(\text{H,H}) = [7.41 - 0.59 \sum_i \lambda_i - 0.27 \sum_i (\lambda_1 \lambda_2 + \lambda_3 \lambda_4)] - 0.85 \cos(\phi) \\ + [6.84 - 0.87 \sum_i \lambda_i + 0.29 (\lambda_1 \lambda_4 + \lambda_2 \lambda_3)] \cos(2\phi) \\ - 0.10 \cos(3\phi) + (0.71 \sum_i S_i \lambda_i^2) \sin(2\phi) \quad (13)$$

The coefficients of equation (13) differ from previous ones²⁴ mainly because a constraint is now laid upon the $\cos(3\phi)$ coefficient, vide supra.

2.5 Summary of Results

1. In previous work the unsatisfactory rms deviation (0.48 Hz) obtained with the use of equation (7) and the full 315 J calibration set, prompted Haasnoot et al.¹⁶ to propose a division of the set into three parts. In other words, separate parameters were presented for ethane-like fragments which contained two, three, and four substituents, i.e. for $\text{CH}_2\text{--CH}_2$, CH--CH_2 , and CH--CH moieties, respectively. In contrast, all of the parameter optimizations reported in Table 2 were carried out on the full 299 J test set and it was found that a single optimization suffices to reach an acceptable rms deviation (0.37 Hz). Presumably, the improved agreement between J_{obs} and J_{calc} is at least, in part, the result of an improvement in calculated ϕ_{HH} values in the present calibration set.
2. The extended five-parameter Karplus equation [terms up to $\cos(2\phi)$ and linear electronegativity dependence of the Fourier coefficients C_0 and C_2] gives a 'best' rms deviation of only 0.70 Hz. Introduction of the asymmetry effect induced by a substituent diminishes the rms error in a dramatic way to less than 0.4 Hz. Systematic theoretical and experimental investigations into the effect of asymmetry on other types of vicinal couplings: $^3J(\text{C,H})$, $^3J(\text{N,H})$, $^3J(\text{P,H})$, $^3J(\text{P,C})$, unfortunately appear to be lacking, but see Section 3.2.
3. The Pachler Fourier series equation, equation (5), postulates a linear electronegativity dependence of the asymmetric part, expressed as $S_{21} \sum_i S_i \Delta\chi_i \sin(2\phi)$ or in the present work also as $S_{21} \sum_i S_i \lambda_i \sin(2\phi)$. The Haasnoot¹⁶ formulation, equation (7), implicitly contains $\Delta\chi_i^2 \cos(2\phi)$ and $\Delta\chi_i^2 \sin(2\phi)$ terms. The Díez–Donders equation, equation (8), explicitly uses an $S_{211} \sum_i S_i \lambda_i^2 \sin(2\phi)$ term. This term alone, in combination with the use of empirical group electronegativities λ_i , is responsible for a substantial decrease in the rms deviation compared with the linear Fourier: 0.33 Hz versus 0.39 Hz, compare entries 5 and 3 in Table 2.

- The introduction of two more cross terms (C_{012} and C_{214}) in the Díez–Donders formulation is only slightly effective, compare entries 5 and 6. This result comes as a surprise in view of the importance of the C_{012} term in the ethane/2-propane series [equation (10)].
- The use of a Pauling/Huggins-type electronegativity scale appears perfectly justified up to a certain level of approximation.

3 VICINAL COUPLING CONSTANTS INVOLVING HETEROATOMS

3.1 General Background

Measurement of heteronuclear coupling constants is an essential factor in the conformational analysis of biomolecules.^{25–28} Over the past three decades much effort has been invested into the delineation of Karplus-type relations for couplings involving one or more heteronuclei, either as coupling partner or contained in the coupling path. Unfortunately, there exists no firmly established quantitative correlation between $^3J(\text{H,C,C,H})$ and corresponding couplings to heteronuclei [$^3J(\text{X,C,C,H})$, $\text{X} = ^{13}\text{C}$, ^{15}N , ^{31}P], nor simple rules that predict the behavior of a vicinal coupling when a carbon atom in the coupling path is replaced by a heteroatom. In short, for each different combination of nuclei and coupling path, a Karplus-type equation must be parameterized from scratch, preferably on the basis of a large number of experimental couplings (calibration points). Semiempirical calculations of vicinal couplings cannot predict 3J with an accuracy desired by NMR spectroscopists, but such calculations, especially when carried out for a series of related molecular fragments,²⁵ may reveal details that would otherwise not be considered.

Thus far, the proposed parameterizations, resulting in a set of Karplus coefficients, rarely appear to have gone beyond the level of the three-parameter equation (1b). The problem of substituent effects on the A , B , and C coefficients is usually circumvented by the use of model compounds that contain the same (or at least similar) substituents as the compounds that one is interested in. The torsion angles necessary for such a parameterization are either estimated from molecular models, calculated by means of force-field methods, or taken from X-ray studies. Thus, one may hope to work effectively on the level of the five-parameter Karplus expression. It should be remembered that in the case of $^3J(\text{H,C,C,H})$ this level yields an rms deviation of 0.7 Hz (299 experimental calibration points); inclusion of an asymmetry term causes the rms deviation to drop to less than 0.4 Hz, vide supra.

A selection of coefficients for use in equation (1b) that are currently used in structural and conformational studies of proteins (Table 3) and nucleic acids (Table 4) is presented here. Some parameterizations have been carried out solely on the basis of semiempirical MO calculations in various approximations and these should perhaps be taken only as a rough guide. The coefficients for $^3J(\text{C,C,C,H})$ in Table 3 were determined from measurements³³ in norbornanes and are not necessarily representative for this coupling in open-chain compounds.

The most important asset that these coefficients presently offer is *not* their overall reliability (statistically tested in a small minority of cases) but the opportunities that are provided to remove ambiguities. For example, a single coupling constant $^3J(\text{H,H})$, measured along a given bond in an open-chain molecule, in the general case (single conformer assumed) corresponds to any one out of four torsion angles ϕ_{HH} . The situation is even more complex in the case of a conformational mixture. Modern NMR techniques allow us to measure accurately one or more $^3J(\text{X,H})$ and sometimes $^3J(\text{X,Y})$ along the same bond. The various Karplus curves are phase-shifted with respect to one another, because the X and/or Y nuclei are shifted by $\pm 120^\circ$ (sp^3) or 180° (sp^2). Thus, comparison of the various couplings often solves an assignment problem, always acute when dealing with diaster-eotopic nuclei, and/or may result in the selection of only one conformation that fits all the data.³⁸ Other applications are discussed in Section 4.

3.2 Vicinal Carbon–Proton Couplings $^3J(\text{C,C,C,H})$

This particular coupling constant appears to have resisted³⁹ all attempts to formulate satisfyingly simple and general trigonometric relationships similar to those developed for $^3J(\text{H,C,C,H})$. Although early MO calculations⁴⁰ on $^3J(\text{C,H})$ in substituted propanes already indicated that these couplings indeed obey a Karplus-type equation, in practice severe complications arose and progress remains slow. The present situation concerning $^3J(\text{C,H})$, Figure 5, can be summarized as follows:

- The ratio $^3J(\text{C,H})/^3J(\text{H,H})$ in molecular fragments where C replaces a corresponding H varies from 0.50 to 0.85 (mean 0.61 ± 0.065).²⁷ Thus, this ratio cannot be used with confidence to scale $^3J(\text{H,H})$ couplings or Karplus coefficients to fit $^3J(\text{C,H})$ data.
- The influence of electronegative substituents on rotationally averaged ($^3J(\text{C,H})$) in *t*-butyl derivatives correlates well with $^3J(\text{H,H})$, with the former slightly more sensitive to the electronegativity effect.⁴¹ More recently, an analysis of $^3J(\text{C,H})$ in carbohydrates⁴² suggested that oxygen (and carbon) substituents require a different set of coefficients [including the $\sin(2\phi)$ term] when moved from the β position to the γ position with respect to the coupling carbon nucleus, Figure 5. This implies that the minimum number of Karplus coefficients could be twice as large compared with the six that suffice to describe $^3J(\text{H,H})$.
- When the coupling ^{13}C nucleus itself carries one or more substituents besides hydrogen, matters are even more complicated. It has long been known that the nature of the X substituent has a profound influence on the magnitude of the rotationally averaged $^3J(\text{C,H})$ in $(\text{CH}_3)_3^{13}\text{CX}$ compounds.⁴³ Other factors besides electronegativity appear to be operative here. Moreover, MO calculations of $^3J(\text{C,H})$ in 1-fluoropropane⁴⁰ (Figure 5,

Figure 5 Torsion angles ϕ and ψ and atomic numbering for $^3J(\text{C,C,C,H})$. The coupling nuclei are marked with an asterisk

$X = F$) predicted that this coupling is substantially larger when ψ_{FC} is set at 180° than when it is set at 60° . In a recent MO study⁴⁴ on a series of 1-substituted propanes (Figure 5, $X = H, CH_3, NH_2, OH$, and F) both ϕ and ψ were varied from 0° to 360° in 30° steps. The rotation of ψ indeed appears to have a profound effect on $^3J(C,H)$. For example, for $\phi_{CH} = 180^\circ$ the calculated $^3J(C,H)(X = F)$ varies from 8.0 Hz ($\psi_{FC} = 0^\circ$) to 12.0 Hz ($\psi_{FC} = 150^\circ$). These predictions were experimentally verified by measurements on *cis*- and *trans*-4-*t*-butylcyclohexanols, where the effect is even larger than predicted for $X = OH$.⁴⁴ In the same paper⁴⁴ the set of 340 calculated $^{13}C-H$ couplings was fitted (rms = 0.27 Hz) with the aid of a nine-coefficient Karplus-type

expression. A 15-coefficient approximation was used to fit 39 experimental $^3J(C,H)$ values of cycloalkanols and pyranose sugars (rms = 0.30 Hz).⁴²

In summary, much work has to be done before $^3J(C,H)$ can be used to calculate torsion angles. In the meantime, it appears safe to apply the general rule: $^3J_{ap} \gg ^3J_{sc}$.

3.3 Vicinal Proton–Proton Couplings $^3J(H,N,C,H)$

This coupling, usually denoted $^3J_{HN\alpha}$, deserves some attention because it can be measured with precision in proteins and affords important information concerning the

Figure 6 Schematic representation of the main-chain torsion angles ϕ , ψ , and ω in polypeptides and proteins. The χ_1 angle is defined as the torsion angle $\text{N}-\text{C}^\alpha-\text{C}^\beta-\text{X}$; in many amino acids $\text{X} = \text{C}'$

Figure 7 Newman projection along the $\text{N}-\text{C}^\alpha$ bond of a peptide backbone showing three important vicinal coupling constants that supply information about the ϕ torsion angle

local backbone geometry along the ϕ angle (Figures 6 and 7). It should be noted here that in protein chemistry the torsion angle between coupling nuclei is denoted as θ ; for θ_{HNCH} one uses the relationship $\theta = \phi - 60^\circ$ (Figure 7).

Independent calibrations in terms of A , B , and C [equation (1b)], were carried out by Pardi et al.³⁰ (37 data points, rms = 0.87 Hz) and by Ludvigsen et al.²⁹ (112 data points, rms = 1.01 Hz), Table 3, on the basis of known X-ray structures. Inspection of the plots given suggests that corrections for differences in electronegativity of the various side chains might improve the rms deviation, especially for θ_{HNCH} near 180° and near 0° . The Karplus coefficients proposed by Bystrov²⁵ predict $J(180) = 10.9 \text{ Hz}$ and $J(0) = 8.7 \text{ Hz}$, the latter value is probably too large by about 1.5–2.0 Hz.

3.4 Vicinal ^1H and ^{13}C Couplings to ^{31}P in Phosphate Diesters

The vicinal couplings $^3J(\text{P},\text{O},\text{C},\text{H})$ and $^3J(\text{P},\text{O},\text{C},\text{C})$, taken in combination, yield important conformational information concerning two backbone torsion angles in nucleic acids: β (angle $\text{PO}_5'\text{C}5'\text{C}4'$) and ϵ (angle $\text{C}4'\text{C}3'\text{O}3'\text{P}$), (Figure 8). The Karplus coefficients that describe the angular dependence of $^3J(\text{P},\text{H})$ and $^3J(\text{P},\text{C})$ are relatively large. This fact contributed to the success of a different approach taken in the parameterization,⁴⁵ necessitated by the knowledge that phosphates (and sulfates) often display ‘nonclassical’ torsion angles, i.e. large deviations from ‘classical’ 180° and 60° angles. Moreover, it is desirable to avoid the use of crystallographic information which in individual cases can

Figure 8 Newman projections along the main-chain torsion angle ϵ and β in nucleic acids. The negative charge on the phosphate group is omitted. These angles are monitored by $^3J(\text{P},\text{O},\text{C},\text{H})$ and $^3J(\text{P},\text{O},\text{C},\text{C})$. (Reproduced by permission of Adenine Press from P. P. Lankhorst, C. A. G. Haasnoot, C. Erkelens, and C. Altona, *J. Biomol. Struct. Dyn.*, 1984, 1, 1387)

be biased by crystal-packing effects. Instead, the unknown backbone angle (ϵ) can be determined simultaneously with the Karplus coefficients, provided that several different couplings along the same central bond are available and that conformational purity along this bond can be attained. In the case discussed here, six Karplus coefficients and four torsion angles were determined from 17 experimental couplings in RNA compounds (rms = 0.2 Hz). As it turned out, the *mean* NMR value of ϵ_{ap} in the RNA molecules in the stacked form (219°) corresponded well with the *mean* of crystallographic determinations in similar RNAs (218°). The same Karplus coefficients (Table 4) are transferable to DNA molecules.⁴⁶

4 SELECTED APPLICATIONS OF 3J IN THE FIELD OF BIOMOLECULES

4.1 General Remarks

For more than a decade the conformational situation (‘structure’) of biopolymers, such as proteins and nucleic acids, was judged from characteristic NOEs. More recently, interatomic distances or NOEs were introduced as constraints in MD (molecular dynamics calculations) trajectories. However, without additional information, it is very difficult to judge whether or not conformational homogeneity exists along each chemical bond of interest. This is especially true in cases where a given conformer predominates; minor forms may then escape detection altogether. Contradictory NOEs certainly point to the simultaneous existence of various rotamers, but these are not easily quantified from NOE information. With the advent of more powerful NMR spectrometers and techniques, investigators are becoming more and more aware that homo- and heteronuclear coupling constants offer a rich source of the additional information that is required.

An important recent application^{48,49} of the Karplus coefficients involves the introduction of coupling constant restraints into molecular dynamics calculations. Defining $\Delta J = J_{\text{obs}} -$

J_{calc} , one adds a penalty function in the form of a pseudoenergy term $\frac{1}{2}k_i\Delta J_i^2$ to the force field for each conformational constraint along given torsion angles, in addition to the usual distance constraints obtained from NOEs. One of the advantages of this approach, when applied to multiple couplings along a chosen bond, is that conformational equilibria, which occur on a short timescale, can be handled with more confidence. Of course, the k_i 'force constants' should be weighed according to the reliability of J_{obs} and J_{calc} , but to date such information on J_{calc} is limited to a few types of vicinal couplings, see Sections 3.2–3.5. It was also proposed to incorporate time-averaged J values⁵⁰ as constraints; this idea was successfully tested on a cyclic peptide, antamanide ($^3J_{\text{HN}\alpha}$). Extension to multiple couplings about certain bonds undoubtedly will follow soon.

4.2 Amino Acids, Peptides, and Proteins

4.2.1 Main Chain Torsion Angles in Polypeptides and Proteins

The main chain in an amino acid sequence is characterized by three sequential torsion angles: ϕ , ψ , ω (Table 3 and Figure 6). For several reasons most attention was and still is focused on ϕ . This particular angle is correlated with the local shape of the sequence (α -helix, β -sheet, and various turns). In principle, ϕ can be monitored by the use of six different coupling constants (Table 3). Of these, $^3J(\text{H}, \text{N}, \text{C}^\alpha, \text{H}^\alpha)$ is the easiest one to measure, even in large proteins, followed by $^3J(\text{H}, \text{N}, \text{C}^\alpha, \text{C}^\beta)$.³⁸ Coupling to carbonyl carbon requires more effort and is difficult to obtain when the coupling is small. Nevertheless, a qualitative insight into the magnitude of two more ϕ couplings can be gained, at least in small cyclic peptides, from natural abundance NMR spectra; $^3J(\text{C}^\alpha, \text{C}^\beta, \text{N}, \text{H})$ and $^3J(\text{C}^\beta, \text{N}, \text{C}^\alpha, \text{H}^\alpha)$.^{38,51} Now that $^{13}\text{C}^{15}\text{N}$ isotopically-enriched proteins are becoming available, 3D and 4D NMR techniques offer new possibilities for measuring previously 'unmeasurable' couplings in large proteins, e.g., $^3J(\text{H}, \text{N}, \text{C}^\alpha, \text{C}^\beta)$.⁵² The ψ angle remains elusive. For $^3J(\text{H}^\alpha, \text{C}^\alpha, \text{C}^\beta, \text{N})$ and $^3J(\text{C}^\beta, \text{C}^\alpha, \text{C}^\beta, \text{N})$ very little reference material is available at present. A similar remark applies to $^3J(\text{C}^\alpha, \text{C}^\beta, \text{N}, \text{H})$, which coupling monitors the ω angle. In rigid domains, both ψ and ω can be determined from NOEs, however.

4.2.2 Side-Chain Conformations of Amino Acid Residues

The heteronuclear $^3J(\text{C}^\beta, \text{C}^\alpha, \text{C}^\beta, \text{H}^\beta)$ and $^3J(\text{N}, \text{C}^\alpha, \text{C}^\beta, \text{H}^\beta)$ couplings along with the two homonuclear $^3J(\text{H}^\alpha, \text{C}^\alpha, \text{C}^\beta, \text{H}^\beta)$ couplings allow the unambiguous diastereotopic assignment of the two β -methylene protons of the side chain of amino acid residues.^{51,53} Given the correct assignment of H^β (pro-*R*) and H^β (pro-*S*) (Figure 9), the conformational populations of the equilibrating three rotameric species can be calculated from the two $^3J(\text{H}^\alpha, \text{C}^\alpha, \text{C}^\beta, \text{H}^\beta)$ couplings when the limiting values ($^3J_{\text{ap}}$ and $^3J_{\text{sc}}$) are known. The Pachler⁵⁴ values $^3J_{\text{ap}} = 13.6\text{ Hz}$ and $^3J_{\text{sc}} = 2.6\text{ Hz}$ are still widely used in the literature, although Abraham et al.⁵⁵ in 1977 already pointed out that differentiation according to the electronegativity of the side chain as well as the inclusion of substituent orientation was called for. In that work⁵⁵ a simple additivity scheme of substituent constants for the prediction of $^3J_{\text{sc}}$ was proposed. For example, for $\text{X} = \text{carbon}$, the two $^3J_{\text{sc}}$ values predicted

Figure 9 Newman projections of the three staggered χ_1 side-chain conformations in an amino acid with two H- β protons. The three rotamers are designated I, II, and III for $\chi_1 = -60^\circ$, 180° , and 60° , respectively. For the sake of clarity pro-*R* and pro-*S* are abbreviated as *R* and *S*, respectively

were 3.4 Hz and 4.2 Hz, for $\text{X} = \text{oxygen}$, values of 2.2 Hz and 4.9 Hz were proposed. A more refined, but similar, approach is now possible through the use of equations (11), (12) or (13) in conjunction with the experimental group electronegativities λ_i . It appears best to distinguish three different groups of side chains A through C according to the respective λ_i values given in Table 1.

A: $\lambda_i = 0.42$ (Asn, Asp, His, Phe, Trp, Tyr)

B: $\lambda_i = 0.60$ – 0.75 (Arg, Cys, Gln, Glu, Leu, Lys, Met)

C: $\lambda_i = 1.25$ (Ser in D_2O), $\lambda_i = 1.33$ (Ser in CDCl_3)

The predicted $\text{H}^\alpha\text{H}^\beta$ limiting coupling constants for each of the three rotamers along χ_1 in peptides and proteins (idealized staggered geometry assumed), differentiated according to the electronegativity of the side chain, are shown in Table 5. The nature of the solvent plays a role only in the cases of free amino acids and N-terminal residues, because $\lambda(\text{NH}_2) > \lambda(\text{NH}_3^+)$ (Table 1).

Some examples of $\text{H}^\alpha\text{H}^\beta$ coupling constants and rotamer populations are displayed in Table 6. For purposes of comparison, the populations calculated with standard values⁵⁴ are also given. The differences between the new and the old population values are usually $\leq 7\%$, except for Ser ($\leq 10\%$). It is concluded that the trends recorded in the literature thus far remain valid. For future work requiring high precision, the new values are recommended. It is noted in passing that application of equations (11), (12), or (13) allows us to predict safely couplings pertaining to any deviation from ideal staggered geometries. A good example of nonstaggered situations occurs in proline residues. An analysis of the 10 coupling constants of proline and of 12 model compounds⁵⁹ with the aid of the Haasnoot equation [equation (7)]¹⁶ in conjunction with the pseudorotation model for five-membered rings⁶⁰ showed that the unsubstituted proline ring occurs in a practically 1:1 conformational equilibrium between N-type and S-type forms (see Section 4.3.1 for a discussion of N- and S-conformers). Recently, Karplus and co-workers⁶¹ successfully used the Haasnoot equation [equation (7)] to probe the motional characteristics of the four proline residues in the cyclic decapeptide antamanide on a picosecond time scale.

4.3 Nucleic Acids

The structural properties and current nomenclature rules¹⁷ of nucleic acid conformations have been treated by Wüthrich²⁸ and by Saenger.⁶² The conformational analysis of oligonucleotides with the aid of coupling constants has been reviewed by Altona,⁶³ backbone torsion angles are shown in Figures 8, 10, and 12.

Table 5 Predicted Limiting $H^\alpha H^\beta$ Coupling Constants (Hz) [Equation (13)] for Each of the Three Rotamers Along $C^\alpha C^\beta$ in Peptides and Proteins. Idealized Staggered Models Assumed. Three Classes of Amino Acid Residues A–C (See Text) are Differentiated According to the Group Electronegativity λ_i of the Side-Chain Substituent X, Figure 9. Because $\lambda(\text{NH}_2) > \lambda(\text{NH}_3^+) \approx \lambda[\text{NHC}(=\text{O})\text{R}]$ (Table 1) N-Terminal Residues are Further Differentiated According to Solvent Conditions

AcSer ⁵⁷	7.5	6.2	3.8	42(32)	9(11)	49(57)
Cyclosporin A ⁵⁸ MeLeu ⁴	CDCl ₃	12.0	4.5	91(85)	12(17)	-3(-2)
Cyclosporin A ⁵⁸ MeLeu ⁶	CDCl ₃	6.0	10.5	24(31)	77(72)	-1(-3)
Cyclohexapeptide ⁵⁸ Phe ⁷	DMSO	4.5	9.0	11(17)	59(58)	30(25)
Cyclohexapeptide ⁵⁸ Trp ⁸	DMSO	10.9	4.2	79(75)	11(15)	10(10)
Cyclohexapeptide ⁵⁸ Phe ¹¹	DMSO	11.5	3.1	86(80)	2(5)	12(15)

^aThe rotamer populations are computed from three equations with three unknowns using standard matrix methods; for the sake of clarity pro-R and pro-S are abbreviated as R and S, respectively:

$$J_{\text{obs}(R)} = p_I J_{I(R)} + p_{II} J_{II(R)} + p_{III} J_{III(R)}$$

$$J_{\text{obs}(S)} = p_I J_{I(S)} + p_{II} J_{II(S)} + p_{III} J_{III(S)}$$

$$p_I + p_{II} + p_{III} = 1$$

The computation is simpler when it is assumed that all J_{sc} values are equal.⁵⁴

4.3.1 The Furanose Ring

The flexible five-membered sugar ring plays a pivotal role in nucleic acid structure and dynamic behavior. Structural differences between A-, B-, and Z-type duplexes are intimately correlated with specific conformational ranges of individual sugars. Within the B-DNA family each sugar responds to its

Figure 10 Conformational notation of the torsion angles of the backbone and χ of the base in nucleic acids¹⁷

surroundings (e.g., the base-stacking pattern) by an appropriate adaptation of its geometry. Careful analysis of sets of $^3J(\text{H,H})$ values reveals intimate details on the ‘atomic level’ that cannot be obtained from NOEs.^{64,65} Various reviews are available^{24,63–65} and only a brief outline of the coupling constant approach is sketched here.

Two distinct D-ribose conformations (better: conformational ranges) occur in nucleic acids, N-type (North, roughly C-3'-endo) and S-type (South, roughly C-2'-endo), Figure 11, which occur in fast equilibrium unless the stereochemical requirements of the helix impose restraints. For example, an RNA double helix consists of an N–N–N sequence of sugars, Z DNA of an S–N–S–N alternation. In B DNA the duplex structure allows the sugars some mobility to flip from S to N and vice versa. Pyrimidine sequences are relatively more mobile ($78 \pm 13\%$ S) than are purine sequences ($90 \pm 7\%$ S).²⁴ One always measures time-averaged couplings and shifts under ‘fast-exchange’ conditions. Nevertheless, it remains possible to extract quantitative information on geometry and conformational population from the couplings thanks to the fact that the five endocyclic torsion angles ν_i are mutually dependent via the two-parameter equation (14).

$$\nu_j = \phi_m \cos\{P + 0.8\pi(j - 2)\}, j = 0 - 4 \quad (14)$$

Figure 11 Schematic composite representation of the furanose conformations in nucleic acids: S-type (C-2'-endo/C-3'-exo) (left) and N-type (C-2'-exo/C-3'-endo) (right). in which ϕ_m represents the amplitude of pucker and P the phase angle of pseudorotation.⁶⁰ The torsion angles are numbered clockwise, starting with $\nu_0(\text{C}4'-\text{O}4'-\text{C}1'-\text{C}2')$. In D-sugars, N-type conformers are characterized by a positive sign of ν_3 , S-type forms by a negative sign of ν_3 . The (exocyclic) proton–proton torsion angles ϕ_{HH} are related to the ν_j -values via the pseudorotation parameters ϕ_m and P [equation (15)].⁶⁶

$$\phi_{\text{HH}} = a + b\phi_m \cos(P + \text{phase shift}) \quad (15)$$

where, in the idealized approximation, $b = 1$ and $a = 0^\circ$ for *cis* protons and $\pm 120^\circ$ for *trans* protons. Empirically established values for the parameters a and b in equation (15) for deoxyribose, ribose, arabinose, lyxose, and xylose are available.^{66,67} Equations (14) and (15) and the extended Karplus equation [equation (13)] are employed in the iterative least-squares program PSEUROT.⁶⁸ Given a complete set of experimental proton–proton couplings $J(1',2')$, $J(2',3')$, and $J(3',4')$ for riboses and, in addition, $J(1',2'')$ and $J(2'',3')$ for deoxyriboses, the program minimizes the functional $R = \sum (J_{\text{exp}} - J_{\text{calc}})^2$ and yields the pseudorotation parameters of the two stable furanose conformers and the mole fractions. The accuracy of the procedure is greatly enhanced when the conformational equilibrium displays a strong shift with temperature. Version 4.0 of the PSEUROT program is in the public domain (*Quantum Chemistry Program Exchange No. 463*, Indiana State University, 1983); this version employs equation (7) and the original coefficients.¹⁶ Later versions (PC, IBM compatible) 5.4 and 6.0 (see text) are available under licence from the author. Note that the PSEUROT programs are designed to yield the conformational characteristics of any saturated five-membered ring, provided that the appropriate vicinal ^1H – ^1H couplings are input.

In NMR practice it is not always feasible to carry out the laborious spectral simulations that are required to obtain the individual coupling constants. Often, the sums of couplings to given protons are easily available, however, and these contain much the same information.^{24,69} In the case of DNA we define:

$$\Sigma 1' = J(1', 2') + J(1', 2'') \quad (16a)$$

$$\Sigma 2' = J(1', 2') + J(2', 3') + J(2', 2'') \quad (16b)$$

$$\Sigma 2'' = J(1', 2'') + J(2'', 3') + J(2'', 2') \quad (16c)$$

$$\Sigma 3' \{^3\text{P}\} = J(2', 3') + J(2'', 3') + J(3', 4) \quad (16d)$$

The $\Sigma 2'$ and $\Sigma 2''$ terms include the absolute value of $^2J(2', 2'')$ (approximately 14 Hz in deoxyribofuranose). A

graphical method, based on the theory employed in PSEUROT, successfully utilizes graphs of $\sum J$ versus P and $\sum J$ versus populations to solve the conformational problems.^{24,69} Recently, the graphical procedure was automated in program PSEUROT, Version 6.0.⁶⁸

4.3.2 Orientation of the Nucleic Acid Base

The glycosyl torsion angle χ (not shown) defines the orientation of the base with respect to the sugar ring.⁶² Two major orientations are known: *anti* and *syn*. In the more common *anti* form, the C-8-H-8 and C-6-H-6 vectors of the purine and the pyrimidine bases point roughly in the direction of the C-1'–O-4' bond and are antiparallel to the C-1'–H-1' bond. From pyrimidine model compounds the Karplus coefficients for $^3J(\text{C-6, N-1, C-1', H-1'})$ and $^3J(\text{C-2, N-1, C-1', H-1'})$ were determined⁴⁷ (Table 4) and from these values one predicts the following (very approximate) characteristics:

$$\text{antibase} : ^3J(\text{C-6, H-1'}) \approx 9\text{Hz}, ^3J(\text{C-2, H-1'}) \approx 3\text{Hz}$$

$$\text{synbase} : ^3J(\text{C-6, H-1'}) \approx 4\text{Hz}, ^3J(\text{C-2, H-1'}) \approx 7\text{Hz}$$

In a regular B-DNA structure with *anti* bases, the angle χ is well defined ($\pm 10^\circ$) from three NOE contacts: H-6/H-8–H-2', H-6/H-8–H-2'', H-6/H-8–H-3', but in exceptional cases where the base enjoys more conformational freedom measurement of $^3J(\text{C,H})$ may well supply valuable additional information.

4.3.3 Backbone Conformations of RNA and DNA

The six torsion angles along the nucleic acid backbone are denoted α – ζ , starting with P–O-5' as the central bond for α , Figure 10. NMR spectroscopy provides no direct grip upon the important phosphate diester torsions ζ and α ; these are usually determined from NOE-constrained MD trajectories. The remaining backbone angles β , γ , δ , and ϵ are monitored by various vicinal coupling constants. Because X-ray crystallography⁶² has made it clear that important deviations from pure staggered geometries (180° , 60°) in double-helical structures commonly occur, it is the task of the NMR spectroscopist to deduce at the same time values for the backbone angles as well as conformational populations. This is possible in principle because Nature has conveniently provided a sufficient number of coupling nuclei along the backbone that can be put into use.

It is often helpful to study the behavior of sums of couplings versus rotation about a given torsion angle. As an aid to the discussion, Table 7 has been prepared. The Karplus coefficients used to calculate the $^3J(\text{P,H})$ and $^3J(\text{P,C})$ values in Table 7 are taken from Table 4.

Torsion angle β (P–O5'–C5'–C4'), Figure 8. In 5'-mononucleotides of RNA and DNA, the $\beta^t(\text{ap})$ rotamer is invariably preferred ($>70\%$). In stacked oligonucleotides, the β^t angle is confined to a small range of values ($176 \pm 4^\circ$). Under the additional assumption that in unstacked ('melted') states an equilibrium exists between two or three rotamers (β^t , 175° ; β^+ , 60° ; β^- , 300°), a sum rule is easily derived [equation (17)]:

$$p(\beta^t) = (25.4 - \Sigma')/20.5 \quad (17)$$

where p stands for the fractional population and $\Sigma' = J(5', \text{P}) + J(5'', \text{P})$. Stereospecific assignments of H-5' and H-5'' are not

Table 7 Backbone Angles β , γ , and ϵ (°) of Nucleic Acids in the Most Populated Ranges and Corresponding Calculated Vicinal Coupling Constants (Hz) (See Text)

β^t	170	175	180	185	190

$J(\text{P,C} - 2')$	6.6	7.4	8.1	8.8	9.5
$J(\text{P,C} - 4')$	2.0	1.5	1.1	0.7	0.5

necessary at this stage. Unfortunately, we have no information concerning the true values of the β^+ and β^- angles, but it can be verified that nonclassical β_{sc} rotamers (e.g. β_{sc} , $\pm 90^\circ$) would introduce less than 2% error in the $p(\beta^t)$ value calculated from equation (17). The C-4',P coupling can be used as an independent check on the β^t population [equation (18)]:

$$p(\beta^t) = [^3J(\text{C-4}', \text{P}) - 0.7]/10.2 \quad (18)$$

Assuming that the H-5' and H-5'' resonances are assigned stereospecifically from NOEs, approximate values of the minor populations $p\beta^+$ and $p\beta^-$ are derived from $J(5',\text{P})$ and $J(5'',\text{P})$. Preference for β^+ was found to occur locally in a minihairpin loop.⁷⁰

Torsion angle γ (O5'-C5'-C4'-C3'), Figure 12. Nucleosides and mononucleotides in the solid state display a preference for γ^+ (76%), followed by γ^t (18%) and γ^- (6%). This rotamer distribution in the crystalline state is mirrored by the distribution found in aqueous solution at ambient temperatures. Crystallographic data reveal trends toward nonclassical angles: γ^+ , 53° ; γ^t , 180° ; γ^- , 290° . The right-handed helix requires a pure γ^+ rotamer; upon melting, conformational mobility is regained. The population γ^+ again follows from a sum rule

**Figure 12** Newman projections of the three γ rotamers in nucleosides. In nucleotides the OH group is replaced by an O- PO_3^- group

[equation (19)]:

$$p(\gamma^+) = (13.6 - \Sigma)/10.0 \quad (19)$$

where $\Sigma = J_{4'5'} + J_{4'5''}$. A pure or almost pure γ^t form is adopted by dG residues in Z DNA⁶² and at the 5'-3' loop stem junction in small hairpin loops in DNA, i.e. at the position of the local sharp turn of the backbone.⁷⁰ Such a turn is revealed by a large (>9 Hz) value of $^3J_{4'5'}$.

Torsion angle δ (C5'-C4'-C3'-O3'): This torsion angle is directly related to the pseudorotation parameters P and ϕ_m of

the D-(deoxy)ribose sugar by equation (20).⁶³

$$\delta = 120.6 + 1.1\phi_m \cos(P + 145.2) \quad (20)$$

Torsion angle ϵ (C4'-C3'-O3'-P), Figure 8. The study of the conformational behavior of this backbone angle is virtually impossible without the aid of vicinal ^{13}C - ^{13}P couplings because only a single $^3J(\text{P},\text{H})$ value is measured for each residue. The ϵ^+ rotamer is sterically 'forbidden'⁶³ and need not be considered. The two allowed conformational ranges, ϵ' and ϵ^- , are more or less symmetrically disposed with respect to H-3' and, without further information, $^3J(\text{P},\text{H})$ can give few clues concerning the ϵ'/ϵ^- rotamer population distribution. It is known, however, that $^3J(\text{P},\text{H}-3')$ of single-stranded RNA oligomers increases with increasing population of stacked (single-helical) conformer to a maximum of about 9 Hz, whereas $^3J(\text{P},\text{H}-3')$ in similar DNA compounds decreases to a minimum of about 4 Hz when fully stacked. This difference in behavior was quantitatively interpreted with the aid of ^{13}C NMR data.^{45,46,71} It turned out that there exists a strong correlation between the conformation of the sugar ring and the ϵ' angle. In RNA the stacked state strongly biases the sugar towards the N-type form [$\epsilon'_\text{N} = 219^\circ$; $^3J(\text{P},\text{C}-4') \approx 8$ Hz; $^3J(\text{P},\text{H}-3') \approx 9$ Hz], whereas in DNA the sugar mainly occupies the S-type range [$\epsilon'_\text{S} = 192^\circ$; $^3J(\text{P},\text{C}-4') \approx 10.7$ Hz; $^3J(\text{P},\text{H}-3') \approx 4.5$ Hz]. The ϵ^-_N combination appeared 'forbidden', whereas $\epsilon^-_\text{S} = 266^\circ$, corresponding with $^3J(\text{P},\text{C}-2') \approx 8.3$ Hz, remains allowed. The latter combination must be considered important, because X-ray crystallography has shown that it occurs in various residues throughout the double helix (BII form). We expect that the BII form will be studied in solution as soon as ^{13}C -enriched synthetic DNAs become available. Finally, it should be mentioned that ϵ'_N in DNA (212°) is smaller than ϵ'_N in RNA (219°).⁷¹

5 CAVEATS

The original optimism that arose among stereochemists when Karplus's first paper¹ on $^3J(\text{H},\text{H})$ in ethane appeared in 1959 soon gave way to grave scepticism in the course of the 1960s.² Nevertheless, the Karplus-type relationships are by now firmly rooted in stereochemical thinking. Perhaps unfortunately, not all the known ramifications are widely appreciated. Moreover, even in the situation of the best-known coupling, $^3J(\text{H},\text{C},\text{C},\text{H})$ along sp^3 - sp^3 C-C bonds, some influences that affect couplings have not been taken into consideration in the present contribution. At least three of these (perhaps not unrelated) influences are known, but as yet not understood to the extent that quantitative corrections to calculated couplings can be brought into play: (a) the β effect, the orientation of a β substituent appears to affect $^3J(\text{H},\text{C},\text{C},\text{H})$, an increase of about 0.5 Hz is noted for $^3J_{\text{ap}}$ when a C-O bond occurs in the *ap* position with respect to one of the coupling protons;¹¹ (b) the through-space (Barfield) transmission effect,^{72,73} first noted in norbornane-like structures but not necessarily limited to highly strained compounds; (c) bond angle deformations, semiempirical calculations^{2,74} predict that vicinal couplings depend significantly on the bond angles HCC' and CC'H' of the HCC'H' fragment. The effect would be maximal for $^3J_{\text{ap}}$ and $^3J_{\text{sp}}$. At this point a dilemma arises. Assuming that reliable

empirical corrections for influences (a)-(c) can be established, it would be necessary to introduce much detailed structural information concerning the molecular fragment under study into play before a measured coupling can be interpreted quantitatively in terms of the same structure. Undoubtedly, in the future this will be done for selected fragments which are of vital interest to researchers. However, we may also expect that for times to come present-day knowledge will suffice to solve stereochemical problems routinely along the lines pioneered by Karplus in 1959.¹

Conceptually, cryogenic NMR probes are not a new idea. Early work demonstrated that considerable gains in sensitivity could be obtained by cooling the probe rf coils and associated electronics.^{1–4} More recently, there have been poster presentations at various NMR meetings showing applications of cryogenic NMR probe technology.^{5–9} Reports in the primary literature have begun to appear dealing with applications to both proteins^{10,11} and small molecules.^{12–15}

For small molecules, cryogenic NMR probes open the possibility of acquiring both direct and long-range heteronuclear shift correlation data for a variety of scarce samples, e.g., rare natural products and impurities, degradation products, and metabolites of pharmaceuticals. Cryogenic NMR probe technology should also make it feasible to characterize unstable compounds prior to their degradation, which have heretofore been difficult to characterize.¹⁶ This technology will have an impact on the application of relatively insensitive NMR experiments in structure characterization studies. Examples will likely include the acquisition of long-range heteronuclear shift correlation data on very small samples that are beyond the detection limits with conventional 3 or 1.7 mm NMR probes; the more routine acquisition of ¹³C–¹³C INADEQUATE spectra;¹³ and the acquisition of HSQC-TOCSY data. It is also likely that cryogenic NMR probes will make the utilization of long-range ¹H–¹⁵N two-dimensional NMR experiments, which have recently been reviewed,¹⁷ a routine tool in structural characterization studies.

To illustrate the significant improvement in performance offered by cryogenic NMR probe technology relative to conventional NMR probes, comparative long-range ¹H–¹⁵N 2D NMR spectra of a 2 mg sample of the oxazolidinone antibiotic eperezolid (**1**) in 150 μL d₃-acetonitrile in a 3-mm NMR tube are shown in Figure 1.¹⁵ The cryogenic NMR probe data were acquired using a Varian INOVA 500 MHz NMR spectrometer equipped with a 5 mm gradient triple resonance Chili-probe[™] in which the 3 mm sample tube was run coaxially. The data acquired conventionally employed a Varian INOVA 500 MHz NMR spectrometer equipped with a Nalorac 3-mm gradient triple resonance micro NMR probe. The cryogenic NMR probe data shown in Figure 1(a) were recorded in a total of 26 min and gave a *S/N* ratio in the projection of 101:1. To acquire comparable *S/N* data (112:1) using a conventional 3-mm NMR probe required >17 h (Figure 1b).

The considerable sensitivity advantage offered by cryogenic NMR probe technology can be expected to open numerous new avenues of structural chemistry investigation in the areas of small or unstable samples, and in the application of relatively insensitive NMR experiments on a routine basis. Comparable gains will undoubtedly be enjoyed for hyphenated techniques such as LC-NMR when cryogenic probe technology is applied in this area.

Figure 1 Comparison long-range ^1H - ^{15}N GHMBC spectra of a 2 mg sample of the oxazolidinone antibiotic eperezolid (**1**) dissolved in $150\text{ }\mu\text{L}$ d_3 -acetonitrile in a 3-mm NMR tube.¹⁵ The data shown in panel A were acquired in 26 min using a Varian INOVA 500 MHz NMR spectrometer equipped with a Varian 5-mm gradient inverse triple resonance cryogenic Chili-probeTM. Data shown in panel (B) were acquired in >17 h using a Varian INOVA 500 MHz NMR spectrometer equipped with a Nalorac MIDTG-500-3 3 mm gradient inverse triple resonance micro NMR probe. Both spectra were acquired using a CIGAR-HMBC experiment optimized for 5–10 Hz.^{18,19} Both data sets were taken using 64 increments of the evolution time. Spectral widths were 4248 Hz in F_2 and 4561 Hz in F_1 in both experiments. For the Cryo-Q probe, 90° pulse lengths were $9\text{ }\mu\text{s}$ for ^1H at a power of 3 watts and $18\text{ }\mu\text{s}$ for ^{15}N at a power of 140 watts. Wurst-8 shaped gradients were employed with the Cryo-Q probe pulses applied in the ratio of 5:5:1 ($12:12:2.43\text{ G cm}^{-1}$) with an eight-step phase cycle. A total of eight transients were accumulated/ t_1 increment. In comparison, the data acquired in the conventional 3-mm NMR probe required 1024 transients/ t_1 increment to achieve comparable S/N .

1 INTRODUCTION

Pulsed magnetic field gradients can be used in NMR to suppress unwanted magnetization, or to encode space, motion, and coherence order. These applications, which are central elements of in vivo magnetic resonance, can also be used to enhance high-resolution NMR spectroscopy. There are several ways in which a conventional NMR experiment can benefit from pulsed field gradients. Coherence pathway selection using field gradient pulses instead of phase cycling can minimize data collection time, reduce artifacts, and avoid signal loss associated with traditional water elimination methods. Differences in the rates of molecular motion between solvent and macromolecules can be exploited to achieve linewidth and lineshape independent water suppression. The consequences of poor homogeneity can be reduced using spatially selective excitation, and spoiler gradients can be used to selectively eliminate unwanted magnetization. The present article describes the development and application of B_0 pulse field gradients in high resolution NMR spectroscopy. For a description of B_1 gradient applications see *Radiofrequency Gradient Pulses*.

2 EARLY APPLICATIONS

The first report of using pulsed field gradients was published in 1955 and described the potential of magnetic resonance for information storage.¹ This work detailed the use of gradient pulses in multipulse, multiecho NMR to eliminate selectively unwanted signal. In this paper, bracketing a 180° refocusing pulse with a symmetric gradient pair was introduced as an efficient way to avoid spurious echoes. Further, the application of a gradient pulse during a z axis storage interval was introduced as a way to select for stimulated echoes. These early

pulsed gradient applications are still used in contemporary NMR, especially in imaging and localized spectroscopy, where they have taken on names such as primer–crusher pairs, crushers, and spoiler gradients. These concepts are also important for the application of pulsed gradients in high-resolution NMR spectroscopy.

The use of pulsed field gradients to measure molecular diffusion was introduced in 1965 by Stejskal and Tanner.² This approach overcame severe bandwidth limitations associated with earlier static gradient measurements. In this method, transverse magnetization is encoded with spatially dependent phase by application of an initial gradient pulse, allowed to stay encoded for a fixed period of time, and then rephased by a second gradient pulse. The loss of recoverable signal due to the movement of spins is related to the diffusion coefficient by the Stejskal–Tanner equation:

$$\ln(S/S_0) = -\gamma^2 g^2 \tau^2 (\Delta - 1/3\tau) D \quad (1)$$

where γ is the magnetogyric ratio, g is the strength and τ the duration of the gradient pulse pair, Δ is the time between gradient pulses, and D is the diffusion coefficient (see also *Diffusion Measurements by Magnetic Field Gradient Methods*). The large difference in D for macromolecules relative to solvent water provides the basis for the use of diffusion gradients in spectroscopy.

In 1968, Vold and co-workers³ used a spoiler gradient to overcome imperfect 180° inversion in a T_1 recovery sequence. Shortly thereafter, the benefits of using spoiler gradients, or homospoil pulses, as they sometimes became to be known, were reported by a number of groups. One of the best known applications has been as a mix time spoiler in the NOESY experiment (see also *NOESY*).

Even spatial resolution has shown potential value in high-resolution spectroscopy. As will be discussed later in this article, slice selection can be used to reduce end effects from sample and coil, and field maps may provide a way to optimize homogeneity. For a description of the development of spatial applications of pulsed field gradients see *Magnetic Resonance Imaging: A Historical Overview*.

In 1977, Wokaun and Ernst⁴ described the relationship between coherence order and the effect of a gradient pulse. The idea of using gradients for coherence pathway selection was further developed by the studies of several groups.^{5–8}

3 GRADIENT HARDWARE CONSIDERATIONS

3.1 Eddy Current Compensation

In early studies, potential benefits of using pulsed gradients were often overshadowed by drawbacks such as long gradient recovery times, increased phase instability, peak shape distortion, and, for high-resolution applications, disturbance of the field/frequency lock system. The problem is with the induced eddy currents generated in conductive materials by the switched gradient field. This may include such items as the magnet cryoshields, the bore tube, and the coil itself. The transient fields generated by eddy currents have a variety of decay times which may be of the order of milliseconds, or can persist for seconds. To reduce this problem, the gradient

amplifier can be overdriven to compensate for these undesirable fields. This approach, referred to as preemphasis, is in common use on almost all modern gradient systems, but does not completely overcome the problem (*Eddy Currents and Their Control*).

3.2 Gradient Amplifier Noise

With the incorporation of strong ($>200 \text{ mT m}^{-1}$) pulsed gradient systems into the NMR experiment, it is important to consider the dynamic range of the gradient amplifier. For example, a 1 T m^{-1} gradient is capable of producing $425\,800\,2\pi$ radians s^{-1} gradient across a 1 cm sample. The tolerance of most experiments requires that any variation of the amplifier quiescent state (the noise floor) be significantly less than 10^{-7} of this peak value. For many experiments, especially those in which a nonrectangular gradient wave form is used, 16-bit control of the gradient amplitude is also desirable.

3.3 Actively Shielded Gradients

One of the most important improvements in gradient technology for NMR has been the introduction of actively shielded gradients (see *Gradient Coil Systems*). The basic idea is to provide a second coil of opposite polarity outside the primary gradient coil, which is then driven to buck the stray field generated outside the primary coil. In practice the combination of active shielding and preemphasis gives the best performance.

Phase error can also come from movement of the coil during sharp gradient transitions. This is the source of the characteristic sound made by gradient pulses, sometimes referred to as the speaker-coil effect. It is often desirable to attenuate the amplitude and ring down time of this vibration. Reduced mechanical noise from the gradients is usually accomplished by potting the coils in a nonconductive material such as concrete or epoxy. These coils must also be designed to dissipate the significant heat that can be generated by gradient experiments.

3.4 Single-Axis versus Three-Axis Gradients

In any experiment which consists of multiple rf and multiple gradient pulses, care must be taken to avoid recovering unwanted signal dephased earlier in the pulse sequence. This is relatively straightforward, and can be achieved by prudent choice of sign, amplitudes, or durations of the gradient pulses. If multiple axes are available, gradient cycling has been shown to be effective.⁹ In practice, single z axis gradient coils have been more widely available for high-resolution applications, and have proven sufficient to provide improvements over conventional phase cycled methods. Unfortunately, in some cases the static gradients generated by the homogeneity shims can create a problem. Although weak in comparison to the applied gradient pulses, these static gradients may have over 1 s (e.g. acquisition time) to rephase the effect of a 1 ms or shorter gradient interval.

In 1971, Redfield and Gupta¹⁰ commented on the formation of unwanted gradient echoes when using spoiler gradients. The

misadjustment of shims, in the same direction as the applied gradient, is suggested as a way to prevent this accidental rephasing by the static shim gradients during acquisition. Misadjustment of shims, however, is rarely desirable. Further, in the case of high order z shims, the rephased signal may be from a small part of the NMR sample. An effective approach to reducing this problem is to avoid application of a pure z pulsed gradient, using additional x and/or y gradients to provide an off z axis distribution of phase.¹¹

3.5 Sample Spinning and Field Frequency Locking

Although the effect of a gradient pulse on a deuterium field/frequency lock system is reduced relative to protons by $\gamma_{\text{D}}/\gamma_{\text{H}}$, lock blanking during the gradient pulse can be valuable. Recovery of the steady-state lock signal is determined primarily by the sensitivity of the lock as reflected in the M_{xy}/M_z of the deuterium spins, and by the T_2 relaxation rates of the deuterium solvent. Lock recovery rates can be very favorable for strong lock solvents such as the 5–10% D_2O commonly used for biochemical studies.

Sample spinning is only compatible with z axis gradient application, and even there care must be taken to avoid vortexing of the sample. Any increased mixing leads to signal loss in both diffusion weighted and in gradient coherence selection methods. Also, in practice, sample spinning has been observed to reintroduce t_1 noise, partially negating one of the benefits of using gradients in the first place. Fortunately, full performance can be achieved nonspin for most biochemical samples.

4 THE EFFECT OF MAGNETIC FIELD GRADIENTS

4.1 Dephasing

The application of a pulsed field gradient generates a reversible distribution of phase

$$\phi_r = \gamma(g\tau)rp \quad (2)$$

where γ is the magnetogyric ratio, g is the gradient strength, τ is the gradient duration, r is the distance from gradient isocenter, and p is the coherence order. This effect can be visualized by mapping the effect of gradient pulse on a phase sensitive proton image as shown in Figure 1. As expected the application of a rectangular, 10 mT m^{-1} gradient of 1 ms in duration generates approximately three 2π cycles of phase along the z axis of a 1.5 cm long water sample. If not resolved in space, the signal from the volume of spins self-cancels. The effectiveness of cancellation increases with gradient integral $g\tau$.

The amount of gradient needed for complete signal dephasing is variable and depends strongly on factors such as B_1 homogeneity and bulk magnetic susceptibility shifts. Although these would appear to be well controlled in a typical high-resolution NMR experiment, small deviations can make a significant difference when the amount of unwanted signal is large, as it is for most dilute biochemical samples in 90–95% H_2O . The largest variations in B_1 are in the transition bands, at the ends of the rf coil, where B_1 goes from maximum to zero. Short samples and bubbles can lead to localized frequency shifts, which also lead to inefficiency in self-cancellation.

Figure 1 Phase sensitive image of a water sample in a standard 5 mm NMR tube. The effect of a 1 ms 10 mT m^{-1} rectangular z gradient pulse is recorded. The height of the detected volume is about 1.5 cm. As illustrated by the image and accompanying profile, the expected phase distribution is encoded by the applied gradient pulse. The curvature at the ends of the sample is the fall-off of x gradient strength as a function of z

5 COHERENCE PATHWAY SELECTION

Coherence selection using gradients takes advantage of the field dependence of coherence order. This dependence is described in terms of the phase generated by an applied gradient as shown in equation (2). In its simplest form, a sequence of rf pulses and delays generate multiple coherence pathways. A particular pathway can be selected, for example, by application of a gradient pulse to coherence order label the spins during an evolution or mixing delay interval, followed by the application of a read gradient just prior to data acquisition to rephase the desired pathway. This assumes that the chosen pathway will have zero net phase gradient and that the unwanted pathways will have a net distribution of phase, and therefore self-cancel. In general, signal will only be observed from pathways in which

$$\sum_i G_i p_i = 0 \quad (3)$$

where G_i represents the integral ($g\tau$, for a rectangular gradient pulse) of each gradient interval, i , and p_i is the coherence order during each interval, i .

5.1 Density Operator Description

The effect of a pulsed magnetic field gradient on the nuclear spin can be understood by describing the state of the spin system in terms of density operators. Many different formalisms express the density operator in matrix elements of appropriate sets of operators in a Cartesian or spherical basis.

A detailed description of the effect of magnetic field gradients on the magnetization or coherence component is given by Counsell et al.⁸

For the purpose of describing the effects of magnetic field gradients, it is convenient to classify the density operator $\rho(t)$ of the spin system at any time t according to its various coherence orders or components:

$$\rho(t) = \sum_p \rho^p(t) \quad (4)$$

where p and ρ^p represent a particular coherence order and the density operator component corresponding to that coherence order. The spin coherences undergo precession during a gradient pulse, and the extent of precession depends on the spatial coordinate r of the spin, and the coherence order p of that particular component. Hence the Hamiltonian of the spin system during the gradient pulse is predominantly from Zeeman contributions. The Zeeman fields experienced by the various spins in the sample vary according to their spatial coordinates. The precession or rotation can be represented by $\exp\{-i\omega_z(r)F_z\tau\}$, where $\omega_z(r)$ is the precession frequency at a spatial position r , and τ is the duration of the field gradient pulse, and F_z is the z component of the total angular momentum. Classification of the density operator into the various coherence order components is convenient, since the effect of the field gradient pulse can be written as

$$\rho^p(t-) \xrightarrow{\exp\{i\omega_z(r)F_z\tau\}} \exp\{-ip\omega_z(r)\tau\}\rho^p(t+) \quad (5)$$

which describes the transformation of the p th component of the density operator ρ . $\rho(t-)$ and $\rho(t+)$ are used to label the density operator before and after the gradient pulse. As the right hand side shows, the effect of the gradient pulse is to modulate the density operator component by a complex phase factor. This phase factor depends on the coherence order of the component and on the integral of the gradient pulse. In other words, the phase of each magnetization component is modified by a factor which depends on the coherence order of the component, spatial position of that particular spin and also on the duration and amplitude of the applied field gradient. If we consider heteronuclear spins, the phase factor would also take into account the magnetogyric ratio of the nuclear spin. Essentially, the effect of the gradient pulse is to defocus the coherence by a controlled amount. Each of the coherence pathways can be thought to be coherence order labeled by the gradient pulse. Selection of a particular pathway or decoding is then accomplished by applying a rephasing gradient pulse with amplitude and duration $\omega_z^R(r)\tau^R$, which transforms the density operator described by

$$\sum_k C_k \rho^{(-1)} \exp\{-i\phi_k\} \quad (6)$$

where k is the index for a particular coherence pathway in the experiment, ϕ_k is the cumulative phase dispersal for that particular pathway, C_k denotes all of the time dependence and $\rho^{(-1)}$ denotes the observable component of the density operator, corresponding to coherence order $p = -1$. This can

4 FIELD GRADIENTS AND THEIR APPLICATION

be written as

$$\sum_k C_k \rho^{(-1)} \xrightarrow{\exp\{-i\omega_z^R(r)F_z\tau^R\}} C_1 \rho^{(-1)} + \sum_{k \neq 1} C_k \rho^{(-1)} \exp\{-i(\phi_k + \omega_z^R(r)\tau^R)\} \quad (7)$$

where 1 denotes the desired coherence pathway in the experiment. The first term on the right hand side $k = 1$, corresponds to the pathway which has been exactly decoded, and hence observed since

$$\phi_k = -\omega_z^R(r)\tau^R \quad (8)$$

The second term denotes all the other pathways which are still defocused and are not observable. Equation (5) describes the most important feature of all coherence transfer selection schemes, including rf phase cycling, B_0 and B_1 gradient methods. In conventional rf phase cycling methods, each coherence component accumulates phase factors during the various cycles of the phase cycle. The receiver phase cycle is then determined such that only the desired pathways yield a signal (see also **Phase Cycling**). In the case of pulsed field gradients, each of the gradient pulses contributes to the cumulative phase factors of the various coherence components. The desired pathway is then selected by choosing the appropriate rephasing gradient integral (the product of amplitude and duration for rectangular gradient pulses) prior to data acquisition. A major feature of gradient selection of coherence pathways is that the selection is accomplished in a single acquisition, unlike rf phase cycling, where multiple acquisitions are required. It can be thought of as phase cycling in space rather than time. Also, the major limitation of gradient pathway selection has been the loss of all but a single pathway, resulting in lower sensitivity.

5.2 Coherence Pathway Diagrams

Coherence pathway diagrams^{12,13} are a convenient way to visualize the use of gradients. This is illustrated with the homonuclear correlation experiment, COSY, in Figure 2. The spin system starts at thermal equilibrium with $p = 0$ and is detected in quadrature with $p = -1$. For this rf sequence there are two coherence pathways, $p = (0, -1, -1)$ and $p = (0, +1, -1)$. According to equation (3), a pathway will be selected only if $p_1 G_1 + p_2 G_2 = 0$. For the first pathway, where p_1 and p_2 are of the same sign, the gradient integral G_2 must be the negative of G_1 . For the second pathway, where $p_2 = -p_1$, G_1 and G_2 must be identical. In a similar way, a pair of identical gradient pulses eliminates spurious signals in a spin echo experiment by selecting for a sign change in coherence order (e.g. $p = +1$ to -1 and $p = -1$ to $+1$). Unwanted signal excited by an imperfect 180° pulse will be dephased, $p_2 G_2 \neq 0$.

For the multiple quantum experiments a third rf pulse adds another coherence transfer interval, and adds the possibility of using DQ coherence levels $p = \pm 2$. For the double quantum filtered correlations (DQF) COSY sequence illustrated in Figure 3, a gradient ratio, $G_1:G_2:G_3$ of 1:1:3, selects for one of the four DQ coherence pathways $(0, +1, +2, -1)$.

Figure 2 Pulse sequence and coherence pathway diagrams for the incorporation of pulse field gradients in COSY. P type $(0, -1, -1)$ COSY is selected when $G_2 = G_1$ and N type $(0, +1, -1)$ is selected when $G_2 = -G_1$

6 HOMONUCLEAR APPLICATIONS

For small organic molecule NMR, the major use of pulse field gradients is speed and reduction of artifacts in simple 2D NMR. For aqueous based proton NMR, gradient selection of multiple quantum pathways to discriminate against water, is an important application.

The uncoupled spins of water cannot generate $p = \pm 2$ coherence order, and can easily be left dephased during the detection period. This has been an advantage for in

Figure 4 Noise floor contour plot of 400 MHz GE DQF COSY spectrum of 8 mM angiotensin II in H₂O. An 800-fold vertical expansion of the reference one-pulse spectrum is shown above the contour plot. 2D data were collected at 4 Hz resolution in ω_1 and ω_2 without phase cycling. A transmitter zero-frequency artifact, not residual water, is responsible for the intensity at 4.6 ppm. (Adapted by permission of Academic Press from Hurd¹⁵)

vivo detection of lactate.¹⁴ The single-shot selection process avoids the motion related subtraction errors that can be a problem in vivo. The further addition of rf selective coherence transfer provides extraordinary discrimination between the lactate methyl signal and the overlapping lipid CH₂ in a 2D DQ sequence.¹¹ Success of the in vivo results obtained using actively shielded gradients led to experiments with this technology on high-resolution NMR systems. Not surprisingly, one of the first experiments was gradient enhanced GE DQF COSY.¹⁵ As illustrated by the noise floor contour plot shown in Figure 4, this approach to solvent suppression does not perturb signals close to or at the water chemical shift. It is also apparent that the nonsubtractive nature of gradient coherence pathway selection reduces the problem of t_1 noise.

7 PROTON DETECTED HETERONUCLEAR APPLICATIONS

7.1 GE HMQC

Proton detection of low γ nuclei is a good example of a method in which the desired signal is but a small part of the overall proton magnetization. As such, this type of experiment lends itself well to the application of gradients. The pulse sequence and modified coherence pathway diagram for a gradient enhanced version of a heteronuclear correlation experiment GE HMQC¹⁶ are shown in Figure 5. In this diagram, shared coherence levels are drawn using a γ_H normalized coherence order

$$p' = p(^1\text{H}) + p(\text{X})\gamma_X/\gamma_H \quad (9)$$

Since phase distribution is proportional to the product of p' and gradient integral G , signal will only be observed for transverse magnetization from pathways for which the sum of the effects from all of the individual gradient pulses goes to zero:

$$\sum p'[i]G[i] = 0 \quad (10)$$

For $^1\text{H}/^{13}\text{C}$ experiments, $\gamma_X/\gamma_H = 0.25$. This means, for example, that $^1\text{H}[+1]^{13}\text{C}[-1]$ zero-quantum coherence will have a normalized order $p' = 0.75$. A gradient, G_1 , applied during such an interval will cause a coherence pathway through this zero quantum level to be encoded with a distribution of phase, $\phi = 0.75G_1$. To select for this pathway, a read ($p' = -1$) gradient, G_3 must be set to $0.75G_1$. This pathway, $\text{H}[0]\text{C}[0] \rightarrow \text{H}[+1]\text{C}[0] \rightarrow \text{H}[+1]\text{C}[-1] \rightarrow \text{H}[-1]\text{C}[-1] \rightarrow \text{H}[-1]$, can also be selected using alternate ratios of gradients $G_1:G_2:G_3$. These sequences can be optimized for best use of available gradient strength for dephasing (2:2:1) or can be optimized to avoid certain artifacts.¹⁷

In natural-abundance carbon experiments, more than 99% of the signal must be subtracted out to reveal the protons attached to the 1% abundant ^{13}C nuclei. With gradient selection, protons attached to ^{12}C and from solvents such as water are not detected, thus avoiding subtraction and dynamic range limitations. The effectiveness of this suppression is illustrated in Figure 6 by a noise floor contour plot of a single acquisition

Figure 5 Pulse sequence and coherence pathway diagram for GE HMQC

per block $^1\text{H}[\text{natural abundance } ^{13}\text{C}]$ GE HMQC spectrum of sucrose in water. In this example, without broadband ^{13}C decoupling, the correlations are observed as ^{13}CH doublets. The absence of signal at the ^{12}C proton chemical shifts and at the water chemical shift in this spectrum demonstrate the complete cancellation of signal from protons not attached to ^{13}C . Another good application is in the long range heteronuclear multiple bond correlation (HMBC) experiment where t_1 noise from the uncoupled protons may obscure weak long range $^{13}\text{C}-^1\text{H}$ correlations in a conventional experiment.

7.2 3D and 4D Applications

It was recognized from early on that the reduction in the phase cycle requirement and the concomitant reduction in total data collection time would be a significant reason to use pulse field gradients in 3D and 4D applications. These experiments usually require large numbers of acquisitions just to achieve adequate resolution in the evolution domains. In fact, in some cases, it is the phase cycle and not the signal-to-noise ratio (S/N) which dictates the length of data collection time. A number of multidimensional methods have been developed to take advantage of the reduced data collection time, water suppression characteristics, and fewer artifacts.^{18–23} Others have taken advantage of reduced phase cycle to increase resolution in the evolution dimensions.²⁴

One of the first 3D gradient sequences was a modification of HMQC-COSY. The GE HMQC-COSY sequence¹⁸ is a combination of a gradient-enhanced HMQC experiment, in which heteronuclear zero quantum magnetization is coherence order labeled and then selectively rephased via a 4:–3 gradient pair surrounding the final carbon 90° pulse, and a gradient-enhanced COSY experiment in which quadrature in the COSY dimension is selected with a 1:1 gradient pair around the final 90° pulse. The resulting gradient integrals are 4:–2:1. The asymmetry of this gradient pulse scheme leaves protons which are not at least indirectly connected to ^{13}C dephased and unobserved. This method provides editing, simple pattern

Figure 6 Noise floor contour plot of a 2 min total acquisition time $^1\text{H}[^{13}\text{C}$ natural abundance] GE HMQC spectrum of sucrose in water shows complete elimination of ^{12}C protons and solvent water

Figure 7 C-6 plane from a $512 \times 128 \times 128$ GE HMQC-COSY spectrum of menthol collected in less than 7 h. Simple correlation patterns are observed for direct and remotely coupled protons. (Reproduced by permission of Academic Press from Hurd and John¹⁸)

recognition features, and in some cases additional resolution. Without the need for phase cycling, a moderate resolution $512 \times 128 \times 128$ spectrum can be obtained in just a few hours. As illustrated by the C-6 plane of menthol, shown in Figure 7, protons directly attached to carbon are observed as $J(\text{C,H})$ doublets along the $\omega_3 = \omega_2$ diagonal. A proton attached to a directly adjacent carbon (^{12}C) is observed at its ^{12}C proton chemical shift in ω_3 , and at the frequencies of the directly (^{13}C) attached proton in ω_2 (see, for example, the H-6b,H-1 correlation). Proton connectivities from two carbon bonds away are observed as single correlations at the ^{12}C proton chemical shift in ω_3 and at the ^{12}C proton chemical shift of the intermediary proton in ω_2 (see, for example, H-6,H-10). The inequivalent CH_2 protons of C-6 (H-a,H-b and H-b,H-a correlations) remain coupled in both ω_2 and ω_3 to give a parallel squares pattern. This occurs because both protons are attached to the same ^{13}C nuclei.

Proton detected 3D SQ-DQ COSY of ^{13}C enriched sugars has been reported to be more useful with the incorporation of pulse field gradients, yielding ‘unsurpassed’ resolution plus better overall artifact suppression.²⁴

7.3 Protein NMR Applications

The analysis of protein structure by NMR has been a driving force in the development of proton-detected multidimensional methods. The success of these applications often depends on the ability to identify, assign, and obtain distance information from C- α ,H resonances. The proximity of these signals to the water chemical shift can be a problem in some cases. Traditional methods of water suppression often exhibit an inherent disadvantage. Selective excitation often results in the loss or attenuation of desired signals near the water resonance and, when presaturation is used, magnetization transfer and proton exchange can lead to a loss of signal intensity throughout the spectrum. Although these issues can be managed, in part, by compromises in solvent conditions and temperature, gradient based coherence selection offers an alternative. GE HMQC-TOCSY and GE HMQC-NOESY give full unobscured C- α ,H correlations at water chemical shift.¹⁹ These experiments were also among the first gradient coherence selection experiments run using a field/frequency lock and variable temperature; these are key requirements for routine use of gradients.

8 WATER ELIMINATION

Removal of the large unwanted water signal without perturbing the desired signal has been one of the great technical challenges of biomolecular proton NMR. Potential difficulties include exchangeable protons, a crowded water chemical shift region, and correlation times which allow signal loss via magnetization transfer. Gradients have had an increasingly important role in this area. The advantage relative to presaturation has been quantitatively measured using gradient versions of the heteronuclear single quantum correlation (HSQC) experiment.^{25,26} As illustrated in Figure 8, the retention of signal is most significant for proteins in the physiologically important pH range of 6.5–7.5.²⁶ Elimination of the presaturation effect reveals the smaller loss of signal due to a ‘short’ recycle delay. This second effect is presumably due to an increased rate of exchange with long T_1 water protons at higher pH. In addition to multiple quantum coherence pathway selection, there are several other gradient based methods which can be used for water suppression. Spoiler gradients can be used in combination with selective rf excitation as an effective replacement of conventional presaturation, gradient pairs can be used to improve selective spin echo methods, and diffusion weighted methods can provide lineshape independent water reduction (*Water Signal Suppression in NMR of Biomolecules*).

8.1 CHESS

In a method sometimes referred to as a *chemical shift selective* (CHESS)²⁷ pulse, water is selectively excited and

Figure 8 1D ^{15}N - ^1H PFG HSQC spectra showing saturation transfer between solvent H_2O and the ^{15}N -labeled amide protons of 0.8 mM Ac-L-Asn-L-Pro-L- ^{15}N Tyr-NHMe at various pH values and a temperature of 30 °C. (A) PGF HSQC spectra recorded with 1.3 s of water presaturation and total recycle time of 3.3 s. (B) PFG HSQC spectra recorded without presaturation and with a total recycle time of 3.3 s. (C) PFG HSQC spectra recorded without presaturation and with a total recycle time of 15.3 s. (Reproduced by permission of Academic Press from Li and Montelione²⁶)

then spoiled by application of a pulsed field gradient. For optimum elimination the tip angle of the excitation pulse must be adjusted for water T_1 relaxation which occurs during the excitation-dephase intervals. For high-resolution applications, this delay period can be increased to allow for recovery of shorter T_1 signals of interest at the water chemical shift.²⁸ When used for in vivo applications, where the volume of interest usually has multiple water T_1 values, a series of intervals (usually three) is used to provide the optimum water elimination. In practice, multiple CHESS pulses also improve water elimination in high-resolution NMR applications. This is likely due to B_1 rather than T_1 heterogeneity. In the case of multiple CHESS pulses, care must be taken to avoid the rephasing of water. This can be accomplished by using spoiler gradients with different intensities, durations, or axes. This method is not only dependent on gradient performance, but also on selective rf pulse design. Desirable features of these rf pulses are minimum out-of-band excitation and sharp transition bands. Since the water signal is to be dephased anyway, the phase in the excitation band is unimportant and can be sacrificed in pulse design.²⁸

8.2 Spin Echoes and Gradient Pairs

Elimination of the unwanted signals generated by the non- π character of selective time reversal pulses is an important application of pulse field gradients. A pair of gradients placed on either side of a 180° pulse to avoid spurious signal, one of the first applications of pulse field gradients, can provide significant improvement in modern high-resolution NMR. Placed on either side of a nonselective 180° refocusing pulse, a gradient pair eliminates unwanted signal from imperfections in B_1 that would ordinarily have to be eliminated by phase cycling. This effect can be even more dramatic with frequency selective π pulse methods. Figure 9 illustrates the benefit of a gradient pair in the performance of gradient enhanced spin echo water suppression (GE SEWS), a selective 1-1 spin echo experiment.

8.2.1 WATERGATE

In a related experiment dubbed WATERGATE,²⁹ water suppression by gradient-tailored excitation is also accomplished using a gradient pair to improve a frequency selective spin echo. In this case, the frequency selectivity is achieved using a nonselective 180° pulse/water selective $180^\circ(-x)$ pulse combination. This has the advantage that peaks away from the water signal see only a nonselective spin echo. The disadvantage of these frequency selective methods is that they give up the chemical shift region near water.

8.3 Diffusion Weighted Water Suppression

The difference between the translational diffusion of a large solute molecule such as a protein and that of solvent water is the basis of the DRYCLEAN water suppression method.³⁰ DRYCLEAN comes from *diffusion-reduced* water signals in spectroscopy of molecules moving *slower than* water. The idea is that water will move far enough in the time between the encode and the decode gradient pulses to remain dephased, while the large solute molecule will not move very far and will be largely rephased. According to equation (1), for a modest 20-fold difference in diffusion constant, D , a gradient pair could be selected to preserve over 70% of solute signal, while suppressing water by 1000-fold.

9 PHASE SENSITIVE METHODS

Modern multidimensional spectra are almost always recorded in pure absorption mode. The primary reasons are improved resolution and lineshape, and an increase of root-2 (about 40%) in S/N compared with magnitude mode. Absorption mode spectra are also phase sensitive.

Typically, pure absorption phase is obtained by amplitude modulation of the signal as a function of the evolution period t_1 , in contrast to phase modulation in the magnitude methods. Amplitude modulation yields separable phases (separable to absorption and dispersion), but loses the ability to discriminate between positive and negative frequencies. Frequency discrimination can be obtained by independent collection of the real and imaginary parts in t_1 (quadrature

Figure 9 GE SEWS: comparison of spin echo water suppression (a, c) without and (b, d) with a gradient pair bracketing the semiselective 1–1 refocusing pulse. Suppression is shown for the 90% H₂O in a 2.6 mM sample of ¹⁵N-enriched bovine pancreas trypsin inhibitor (BPTI). A single acquisition without gradient pair shown in (a) reduces water only by a factor of 50 and thereby limits optimization of receiver gain and ultimate SNR. In (b) complete suppression is obtained in a single acquisition using the gradient method allowing optimum setting of receiver gain. Although phase cycling improves the water suppression in the method without gradients (c), neither suppression or S/N matches the level achieved using the gradient pair (d). (Reproduced by permission of GE NMR Instruments)

data in t_1). Complex Fourier transformation of these data in t_1 produces spectra with quadrature detection in ω_1 . By acquiring mirror image pathways (+1) and (–1) in t_1 , this approach provides pure absorption shapes for the correlation peaks, and quadrature detection in the evolution dimension(s).

In the case of phase sensitive detection in gradient spectroscopy, there can exist a fundamental limitation. The single-shot selection of a unique coherence pathway precludes the acquisition of the mirror image pathways of (+1) and (–1). If both pathways are not acquired, mixed phase (absorption and dispersion components mixed in an inseparable manner) results for the correlation peaks. Hence the earlier gradient spectroscopy experiments were carried out in the magnitude mode. The requirement for selection of mirror image pathways for pure absorption mode can be at odds with that for improved dynamic range performance which requires selection of a unique pathway in a single acquisition.

The methods developed for pure absorption spectra in gradient spectroscopy adopted a compromise approach. The

techniques can be broadly classed as: (a) those which acquire both the mirror image coherence pathways simultaneously by not applying a field gradient during the evolution dimension, albeit, using gradients elsewhere in the pulse sequence; (b) those which acquire both mirror image coherence pathways (+1) and (–1) in the evolution dimension, independently, and then combine both of these signal components in the time domain or in the frequency domain, to yield pure absorption spectra; (c) methods which use gradients as spoilers only and not for coherence pathway selection; and (d) methods which switch between the signals from the two mirror image pathways during the acquisition time.

9.1 Phase Sensitive GE DQF COSY

The DQF COSY experiment proposed by Davis et al.³¹ falls into category (a). In this experiment, gradients are used to select DQ coherence transfer. However, gradients are not

Figure 10 Pulse sequence and coherence pathway diagram for phase sensitive GE DQF COSY as described by Davis and co-workers³¹

applied during the evolution period. With this modification, both mirror image coherence pathways are allowed during t_1 and pure absorption lineshapes can be obtained in the 2D spectrum. This work also addresses the problem of time dependent phase errors associated with chemical shift precession during the gradient pulse. In this pulse sequence as shown in Figure 10, these phase errors are refocused by the addition of a 180° rf pulse. The DQ selection is made using a pair of gradients G_1 and G_2 about the read pulse with a ratio of 1:2. The gradient sequence selects two of the four possible DQ pathways and hence the S/N of the experiments is root-2 (40%) lower than that of conventional phase cycled DQF COSY. Some of the loss can be avoided by use of an optimized tip angle for the read pulse. Frequency discrimination in t_1 is obtained in the normal manner.

The addition of a CHESS pulse (water selective excitation–gradient dephase interval), as described in the previous section, allows reduced gradient coherence selection intervals, and makes this an attractive approach for the study of biomolecules in water.

9.2 Phase Sensitive GE HMQC and GE HSQC

There are a variety of methods which belong in category (b), where the mirror image components corresponding to (+1) and (−1) coherence orders are acquired separately and then recombined in the time or frequency domain. Most of the proposed methods for gradient enhanced proton detected heteronuclear correlation^{32–36} fall into this category. One example is the phase sensitive ^1H – ^{13}C HMQC experiment described by Tolman et al.³³ The sequence consists of a HMQC sequence with three gradients G_1 , G_2 , and G_3 , as shown in Figure 11. G_1 and G_2 are applied during the multiple quantum period on either side of the central proton 180° . Additional 180° pulses on both ^1H and ^{13}C are applied to refocus chemical shift precession that has occurred during the gradient intervals. The final gradient G_3 is applied after the last ^{13}C 90° . The sign of the final gradient is changed to retrieve the mirror image pathway. These two pathways correspond to mirror images in t_1 , and are collected separately and subtracted to produce the real part of t_1 and are added to produce the imaginary part of

Figure 11 Pulse sequence and modified coherence pathway diagram for phase sensitive pulse field gradient HMQC described by Tolman et al.³³

Figure 12 Phase sensitive ^{15}N – ^1H GE HMQC spectrum of 100 μM ketosteroid isomerase (KSI) (27 kDa dimer) in 90% H_2O at 37°C obtained at 500 MHz. (Sample provided by courtesy of M. Summers, University of Maryland)

t_1 . Ross et al.³⁶ avoid the use of additional refocusing pulses by back-prediction of the t_1 domain. The method described by Tolman et al.³³ was used to collect the phase sensitive GE HMQC spectrum of the dilute (100 μM in 90% H_2O) protein sample shown in Figure 12. Here again, the addition of a CHESS pulse interval allows the use of shorter coherence selection intervals and allows for the study of larger, more dilute molecules. The unmatched level of water suppression is characteristic of the coherence selective B_0 gradient methods.

9.3 Heteronuclear zz Filters

The most compelling benefit arising from the use of gradient coherence pathway selection in proton detected heteronuclear correlation experiments is the nearly complete elimination of signal from protons not attached to the

heteronuclear spins. This advantage is especially important for the suppression of water protons since conventional methods such as presaturation and most of the selective excitation methods can lead to loss of desired signal. Unfortunately, some of the benefits of these experiments are offset by the loss of a factor of root-2 in the S/N that results from the selection of a single or limited number of coherence pathways. On the other hand, the suppression of protons not attached to the X nucleus, and of the solvent proton resonance, can be a challenging task in the conventional, phase cycled methods. One approach to reduce this problem, which belongs in category (c) above, was described by Brühwiler and Wagner.³⁷ This approach takes advantage of the heteronuclear longitudinal spin order (described by the density operator $I_z S_z$, and also termed heteronuclear zz magnetization) which is formed by the sequence fragment $90_x(^1\text{H})-\tau-180_x(^1\text{H}, \text{X})-\tau-90_y(^1\text{H})$ where τ is $1/4J(\text{X}, \text{H})$. In this method, referred to here as the heteronuclear zz filter, protons not attached to the X spins remain in the transverse plane following this interval and are eliminated by application of a spoiler gradient. Although this method maintains full sensitivity, it is not overly effective at eliminating magnetization from protons that are not attached to the X nucleus, and especially those for H_2O solvent.

This approach has been successfully applied in combination with other suppression schemes.^{38–43} The symmetry of the HSQC sequence allows for incorporation of two zz filters.⁴⁰ This approach maintains full sensitivity and pure absorption peak shapes, since all the necessary coherence pathways are selected. A HSQC sequence with gradient zz filters is shown in Figure 13. The gradient G_3 dephases the transverse magnetization while the desired components are stored along the z axis. As in the conventional HSQC experiment, X chemical shift labeling occurs in the evolution time, t_1 , between the two $90^\circ(\text{X})$ pulses, and the application of the $180^\circ(^1\text{H})$ pulse in the center of the evolution time removes the $J(\text{X}, \text{H})$ coupling from the evolution dimension. The frequency labeled magnetization is transferred back into heteronuclear longitudinal zz order by the second $90^\circ(\text{X})$ pulse, and the spoiler gradient G_4 is applied further to eliminate unwanted

signals. To improve the suppression of the water signal, a pair of CHESS pulses can be applied at the beginning of the sequence. As described previously, the water resonance can be partially inverted allowing for recovery of desired signal at the water chemical shift. In the implementation shown here, spoiler gradients, G_1 and G_2 , are applied along the x and y axes, respectively, while the G_3 and G_4 gradients are applied along the x , y , and z axes simultaneously to minimize any residual water signal that may arise from accidental gradient rephasing.

This approach provides an optimum S/N and peak shapes but is inferior in performance to gradient coherence selection techniques for water elimination.

9.4 Gradient-Enhanced z Filter

To improve on the HSQC with zz filters, a gradient form of the z filter was developed and added to the sequence as shown in Figure 13.⁴⁰ This filter consists of two $90^\circ(^1\text{H})$ pulses with a gradient in between. The first pulse of the filter, $90^\circ_y(^1\text{H})$, rotates the in-phase magnetization (i.e. protons coupled to X) to the z axis. The unwanted magnetization is left in the transverse plane, which is then dephased by the spoiler gradient G_5 . The desirable component of the magnetization, which is aligned along the z axes is then read by the final $90^\circ(^1\text{H})$ pulse. This filter resembles a conventional z filter,⁴⁵ but has the advantage of full sensitivity, since the desired magnetization that enters the filter is completely aligned along a single axis. Unlike conventional z filters which use multiple delays and hence require multiple acquisitions, the gradient z filter accomplishes the filtering in a single acquisition. As illustrated in Figure 14, this method yields full sensitivity, pure absorption peak shapes, and good elimination of water. Furthermore, loss of signal associated with conventional water suppression and the requirement for additional phase cycling to improve suppression is avoided. This method, applied without the CHESS pulse and with z axis only gradients, was found to outperform nongradient methods in terms of solvent and artifact suppression, based on a comparable recording time.⁴²

Figure 13 Pulse sequence for gradient-enhanced z -filtered (GEZ) HSQC. This sequence contains two gradient zz filters G_3 and G_4 and one gradient-enhanced z filter G_5 . Additional water elimination can be achieved via the two CHESS pulses (G_1 and G_2) which precede the sequence. (Reproduced by permission of Academic Press from John et al.⁴⁰)

Gradient z and zz units have also been used to improve ^{13}C resolution in an HSQC–NOESY experiment.⁴⁴

9.5 SWAT Gradients

In the *switched acquisition time* (SWAT) gradient method,⁴⁵ the N type (0, +1, ..., −1) and P type (0, −1, ..., +1) coherence pathway signals are alternately and individually acquired on alternate sampling points of the digitizer. Since the signals from the N type and P type pathways are in an easily separable format, pure phase 2D spectra with quadrature detection in both dimensions can be reconstructed from a single acquisition. The basic idea of the SWAT gradient method is to sample at twice the Nyquist frequency, inserting appropriate gradient pulses between digitizer sampling points, to rephase alternatively the desired coherence. Ordinarily, in a gradient COSY spectrum, either the N type or the P type coherence pathway would remain dephased and unobserved during the acquisition period. The data can be processed to yield pure absorption lineshapes in a number of ways. Although, the SWAT method is quite demanding on gradient switching time, it is the only method which achieves pure phase fully quadrature multidimensional data in a single acquisition per t_1 frame.

10 SPATIAL TOOLS

The rf coils used in high resolution NMR are designed to produce a homogeneous B_1 magnetic field. In practice, homogeneous B_1 fields are achievable in the transverse plane of sample volume and over most the detectable volume along

the z axis. Normally, the transition band, the region of sample volume in which the B_1 field strength goes from its maximum value to zero, is responsible for the B_1 inhomogeneity that can lead to artifacts in multiple pulse NMR experiments. A separate problem that can occur at the coil extremes is that the lineshape of the NMR signal can be distorted by bulk magnetic susceptibility effects from the ends of the sample volume and the end of the NMR sample tube. Like B_1 inhomogeneity, this lineshape distortion can be a problem, especially for observation of protons in aqueous solutions where the water signal must be eliminated or reduced. The principle of slice selection can be applied to eliminate this B_1 inhomogeneous signal in high-resolution NMR.

10.1 B_1 Inhomogeneity and Transition Band Suppression

Gross rf coil inhomogeneity can be visualized via spatial projections along the z axis (so-called z profiles). A z profile of a 180° pulse generated by a typical rf coil is shown in Figure 15(a). Comparison with the 90° pulse z profile from the same coil [Figure 15(b)] illustrates the gradient of B_1 field (transition bands) that occurs at the top and bottom of the coil. In the 180° pulse profile, signal is not detected where a 180° rotation of

Figure 15 z profiles of an (a) 180° rf pulse, (b) 90° rf pulse, (c) composite 90° rf pulse, (d) 90° rf pulse following transition band suppression (TBS), and (e) composite 90° rf pulse following TBS

spins has occurred, but is detected in the sample volume which does not experience a 180° flip. These transition band regions can be reduced slightly by employing a composite 90° pulse as illustrated by the z profile in Figure 15(c). In the transition band suppression (TBS) method,⁴⁶ signals from these regions of coil volume are selectively excited and then eliminated by gradient dephasing. Slice selection is achieved by application of one or more frequency selective pulses during a constant z gradient. In practice, multiple pulses work better because of the differences in B_1 of the region to be suppressed. While this effectively eliminates signal from these unwanted regions of the coil volume, care must be exercised in choice of pulse design to avoid excitation of the spins within the region of homogeneous B_1 . Figure 15(d) shows a 90° pulse profile of the sample following application of TBS, and Figure 15(e) shows the combined effect of TBS and a composite 90° pulse.

10.2 Improvements in WEFT and Reduction of Susceptibility Artifacts

One application of TBS is the reduction in the susceptibility water hump which is often observed in a very short samples. In essence, this is the slice selective version of a matched susceptibility plug.

Spatial differences in both B_0 and B_1 homogeneity also limit the effectiveness of water suppression by T_1 inversion recovery methods such as WEFT. A water elimination technique was described earlier using gradient dephasing in which the duration of the relaxation delay is used to recover the biopolymer spins at the water chemical shift. The TBS approach can be used to limit the effects of B_1 inhomogeneity and significantly reduce the amount of signal left at the water 'null'.

The first practical test of TBS was its incorporation into the phase sensitive version of gradient enhanced DQF COSY. The pulse sequence is shown in Figure 16. Water is first selectively excited using a crafted rf pulse and dephased by application of an x gradient. The residual water spins are then partially inverted and transverse magnetization dephased by application of a y gradient pulse. This is followed by a recovery period

during which the inverted water spins relax to a 'null'. During this recovery period, typically 200 ms, the transition band slices are excited and dephased using a z slice gradient. The water elimination is followed by a phase sensitive gradient enhanced DQF COSY sequence. Coherence is selected using a 1:–2 ratio of gradients applied simultaneously along the x , y , and z axes. The careful choice of gradient axes during the water elimination period and for coherence selection is important to avoid unwanted rephasing of water signal. This approach was tested on a 1 mM sample of ubiquitin in 90% H_2O . As demonstrated by the contour plots of these data shown in Figure 17, water is nearly eliminated and correlations are observed unperturbed, even at or near the water chemical shift.

10.3 Field Maps and Shimming

One advantage of gradients is that you can make images with them. 3D phase or frequency maps are in effect images of the inhomogeneity experienced by the sample. Shim coil fields can also be directly characterized by measurement of a set of field maps with known shim current offsets. The foregoing information should be sufficient to determine in a noniterative way, the optimum corrected field. This approach to shimming, common to in vivo NMR, may become a significant advantage for three-axis gradient systems in high resolution NMR (*Shimming of Superconducting Magnets*).

11 SUMMARY

By effectively replacing the functions of phase cycling with a single-step, pulse field gradients are used to suppress artifacts, extend resolution in the evolution domains of multidimensional NMR and, where S/N allows, reduce total data collection time. Further, B_0 field gradients provide unmatched levels of water elimination, with reduced dependence on the effects of lineshape, magnetization transfer, and dynamic range. With continued improvements in performance and availability, gradients are likely to become a routine part of high-resolution NMR.

1 INTRODUCTION

NMR spectrometers have been commercially available for just over 40 years. The first spectrometers were based on the CW NMR method, and spectrometer design did not change dramatically until the late 1960s, when pulsed spectrometers were introduced. After superconducting magnets became the norm in high resolution NMR, commercial instrument makers engaged in competition, which has resulted in NMR spectrometers becoming ever more complex and expensive. Now, only the most well funded laboratories can afford to purchase a state-of-the-art NMR spectrometer at the highest frequencies available.

This would seem to lock the young NMR spectroscopist into a situation where he or she has to work at a large, well funded institution in order to practise his or her technology. However, the advent of the microprocessor based personal computer has provided the possibility for anyone to build a near state-of-the-art, and relatively inexpensive, NMR spectrometer, mostly from commercial components. The sources of the components used in the spectrometer described below are referenced as an aid to the reader.

There are only a few components of a modern pulsed NMR spectrometer that are not commercially available at a cost within the budget limitations of most small companies or even individuals. The first thing one must realize is that NMR was originally developed at frequencies of 60 MHz and lower, so a lot of good NMR was done at lower frequencies. If one can find an old CW system with a good magnet, and there are hundreds around universities and other large institutions, one can follow the simple procedures outlined in this article and construct a good pulsed NMR spectrometer at a reasonable cost.

The home built spectrometers described below are pulsed wide-line instruments. But there is no reason why one could not obtain a used high-resolution magnet and add the features needed for high-resolution work such as a field/frequency lock and a decoupler.

With the availability of the new pulse programmer/modulator system discussed here, one need not be an electronics engineer or a computer programmer to build an NMR spectrometer. Most of the components needed for an NMR spectrometer are commercially available at reasonable cost if one is willing to stay at relatively low fields, i.e. 60 MHz or less. This includes powerful software packages that can act as both the operating and data reduction systems for an NMR spectrometer. We discuss two of these, the Asyst software, and that sold by National Instruments.

In many ways the pulse programmer/modulator is the heart of a pulsed NMR spectrometer. Until now this has been the hardest component part of an NMR spectrometer to either make or buy at a price an individual or small company can afford. The pulse programmer/modulator described here can be purchased either as a kit, or assembled, at reasonable cost. (Tri-Valley Research, 3590 Churchill Court, Pleasanton, CA 94588). This system fits in two expansion slots of an IBM-compatible personal computer (PC). It will deliver a 1 V peak-to-peak (p-p) rf pulse, of any pulse sequence desired, into a 50 Ω load. The pulse programmer portion of this system is based on logic cell arrays (LCAs) (Xilinx, Santa Clara, CA) that can be programmed to produce any pulse sequence needed for NMR. The modulator contains a direct digital synthesizer (DDS) that can produce a wide range of rf frequencies.

One can purchase rf amplifiers that will amplify this signal up to any level needed for NMR from a number of companies. This pulse then goes to the probe, which can be home built.¹ The NMR signal then goes to the receiver, which is commercially available (Tri-Valley Research, 3590 Churchill Court, Pleasanton, CA 94588) or can be made from any number of designs published in the literature.

The receiver delivers the detected NMR signal to a commercial analog-to-digital (A/D) converter located in the PC. The spectrum ends up on the computer hard drive ready for data reduction by a commercial software package. The whole system less the magnet can be built at a cost of below \$20 000.

2 GETTING STARTED

Before starting to build an NMR spectrometer it is advisable to obtain a few books. One possibility is 'Experimental Pulse NMR, A Nuts and Bolts Approach', written by Fukushima and Roeder and published by Addison-Wesley in 1981. Also, it is recommended that a copy of 'The AARL Handbook' is obtained.² You will also need some test equipment. Besides an inexpensive multimeter, you will need an oscilloscope, both of which can now be purchased, at reasonable cost, from any good electronics store. For the spectrometer described here, a 20 MHz scope is adequate. One possibility is a BK Precision model 2120 made by the Dynascan Corp.

An important aspect of the fabrication of a home built NMR spectrometer is the knowledge of how to make a quarter-wavelength coaxial cable tuned to the frequency of the spectrometer. A quarter-wavelength coaxial cable at a given frequency behaves as an infinite resistance when shorted to ground. A practical way to fabricate a quarter-wavelength cable is by using a frequency sweep generator. The Wavetek Model 1062 (5808 Churchman, PO Box 190, Beech Grove, IN 46107) will work well. You will also need either a

reflection bridge, such as those furnished by Bruker (based in Germany) to people who purchase their spectrometers, or a three-port coupler, such as made by Mini-Circuits. A Mini-Circuits coupler model ZDC-10-1 serves this purpose, and can be purchased at an electronics supply house. By grounding one side of the quarter-wavelength cable and comparing the other side to an infinite resistance one can observe on the oscilloscope the quarter-wavelength frequency for a specific cable length.

Several rf attenuators will be needed, which can be built from plans in 'The ARRL Handbook'. Both a step low-power resistive attenuator³ covering a range of attenuation, and two heavier 20 db π network attenuators⁴ can be built by placing 10 W resistors in a small die cast box which can be purchased at any electronics store. These attenuators are used to measure the output of the high power transmitter and its driver.

Most people who will want to build an NMR spectrometer at home will have some experience in this field and will know how to use this test equipment or will have access to an NMR laboratory that employs people who will know the technology. A detailed set of instructions on the use of this equipment can also be obtained (Tri-Valley Research, 3590 Churchill Court, Pleasanton, CA 94588).

3 A HOME BUILT NMR SPECTROMETER

Figure 1 is a photograph of the NMR spectrometer built by the authors in Pleasanton, CA. This spectrometer was built under a contract from the Strategic Highway Research Program to study the use of NMR spectroscopy to measure the amount of asphalt in hot mix as it is prepared and used in the field.

Space does not permit a detailed description of how this spectrometer was built or the NMR studies conducted with it. However, an outline of this work is given below, and the details are available on request (Tri-Valley Research, 3590 Churchill Court, Pleasanton, CA 94588). There were two basic design concepts used in the development of this spectrometer. The first was to place as much of the digital electronics as possible on the bus of a personal computer. The second was to use as many commercially available components as possible. The latter concept makes it possible to buy much of the spectrometer from large companies with well developed and supported products. This is especially true for the high power

Figure 1 Home built NMR spectrometer

Figure 2 Block diagram of the home built NMR spectrometer. (Reproduced from Job et al.⁵)

rf amplifier and the data reduction software. Figure 2 shows a block diagram of this spectrometer.

The system described here is flexible enough to accommodate a wide variety of NMR experiments. For example, the block diagram shows the pulse programmer/modulator boards and the A/D board all in one computer. This is the normal configuration. Examination of Figure 1 shows the system contains two computers, the small Everex 286 placed under the oscilloscope on the middle Tuffy cart, and the large 486 under the keyboard and monitor on the right-hand Tuffy cart (purchased from K-Log Education Division, PO Box 5, Zion, IL 60099-0005). The small Everex 286 contains the pulse programmer/modulator system, and the 486 contains the A/D board and does the data reduction. The use of one computer for spectrometer control and another for data reduction is common practice for large NMR systems. This makes it easier to accommodate the special software requirements of some of the components of the spectrometer. This is discussed in the software section later in this article.

3.1 The Pulse Programmer/Modulator System

This is the most difficult component part of the NMR spectrometer to obtain commercially. Both National Instruments (6504 Bridge Point Parkway, Austin, TX 78730) and Keithley/Metrabyte Instruments (12440 Myles Standish Boulevard, Tauton, MA 02780) sell boards which could in theory produce trains of dc pulses, or at least square waves. The system described here is modestly priced and fits into two expansion slots of a PC and produces any desired sequence of rf pulses at any frequency or phase relationship between pulses. This system has been used in computers ranging from a 10 MHz XT to a 33 MHz 486 with an ESIA bus. This system is shown in Figure 3.

Block diagrams of the pulse programmer and modulator boards are shown in Figures 4 and 5, the working details of which have been published.⁵

3.2 The High Power rf Amplifier

The pulse programmer/modulator system in the PC produces a 1 V rf pulse into a 50 Ω load. This pulse sequence is sent to a

Figure 3 Pulse programmer/modulator system. These two boards hook together with a flat band cable and occupy two slots on the PC bus. (Reproduced from Job et al.⁵)

driver for the high power amplifier that amplifies the rf pulses to about 200 V p-p (100 W). (Table 35–37 in ‘The ARRL Handbook’ lists the conversion of p-p voltages to power for a 50 Ω system. This conversion can also be made by dividing the square of the p-p voltage by 400.)

A Henry KD Standard Amplifier (Henry Radio, 2050 South Bundy Drive, Los Angeles, CA 90025) is driven with this signal. The output of this amplifier delivers about 1 kW to the probe. This system appears to function well, being almost trouble free. Henry Radio makes a range of reasonably priced amplifiers for the amateur radio market.

3.3 The Probe

The probes used in both the 10 MHz Halbach magnet and the 20 MHz H magnet all have the same general configuration as shown in Figure 6. A general treatment of probe design is available.²

The inductor coils are usually wound from magnet wire. Almost any weight wire can be used. In fact, some constructors prefer to use ordinary copper tubing purchased at a hardware store for larger sized probes. Copper tubing of $\frac{1}{8}$ " (3 mm) diameter works well. Simply wrap the wire or tubing around the glass tube to be used as an insert in the probe to hold the coil. Care must be used in wrapping coils of copper tubing or noninsulated wire to make sure that there is enough space between the coils so that arcing does not occur. Arcing is not so much a problem between the wraps of the coils as it is between the leads or between the leads and the probe body.

The position of the coil is at the point where, when the probe is in the magnet, the coil will be in the area of highest homogeneity of the magnetic field. The number of turns needed depends on the frequency of the system being built. One needs to balance the circuit using a sweep generator and reflection bridge or coupler. With the Mini-Circuits coupler the output of the probe is hooked to the BNC connector marked ‘in’ on the coupler, the rf output of the sweeper is connected to the ‘out’ BNC connector of the coupler, and the ‘Demod in’ connector of the sweeper is connected to the BNC connector

marked ‘CPL’ of the coupler. The sweeper is then hooked up to the scope in the XY mode and a proper swept signal applied to the system. A dip will be seen on the scope display. This will be at the frequency the probe balances to 50 Ω . The capacitance of the probe circuit or the inductance of the coil must then be adjusted so that the probe balances to 50 Ω at the required frequency. In the spectrometer described, 1000 V ceramic disk capacitors were used. Obtain a collection of these capacitors in the low picofarad range, take an afternoon off, and learn how to balance a probe. You will find that after a few attempts it becomes easy. Any good machine shop can make the probe body. Thin wall aluminum tubing is available in a wide range of sizes, so this type of probe can be made for almost any magnet.

3.4 The Magnet

The spectrometer built for the Strategic Highway Research Program, shown in Figure 1, was designed to determine the proton NMR wideline spectrum of a 4" (100 mm) highway core. The magnet required for this large a sample needed to have at least a 5" (125 mm) free bore in order to hold an NMR probe large enough to accommodate this sample. A standard H-type permanent magnet would have been large and very heavy. Therefore, a Halbach dipole was used for this application.

Halbach dipoles⁶ were first proposed as focusing magnets for particle accelerators. A Halbach dipole is essentially a tube of magnetic material which has been segmented in such a way so as to create a dipole magnet with the axis of the magnetic material transverse to the bore of the magnet. This is ideal for NMR use because it allows one to use a solenoid as the NMR coil rather than a saddle coil. It is essentially a permanent magnet that uses its own magnetic material, in this case neodymium–iron–boron (NdFeB), as a carrier for the flux return lines. This eliminates a heavy steel yoke. The magnet used in the spectrometer described here has a 5.5" (140 mm) free bore and weighs 300 lb (136 kg). We also have a standard H magnet that was part of an IBM NR-02 NMR spectrometer.

Although the Halbach dipole functioned well in the asphalt application, its use is not recommended for any but the most experienced NMR spectroscopist. It needs more work before it should be considered for use on a routine basis. A number of magnet makers can furnish excellent H-type dipole magnets for low field NMR work.

Any magnet used in an NMR spectrometer needs field stabilization. Permanent magnet materials change field strength with temperature, and NdFeB is particularly difficult in this regard. This has always been a problem with commercially available small NMR spectrometers. We have solved this problem by placing the magnet in an aluminum tank and circulating a temperature controlled antifreeze solution through the tank. The temperature of the solution in our spectrometer is controlled by a Cole-Parmer Circulator Bath (catalog number L-10267-62; Cole-Parmer Instrument Company, 7425 North Oak Park Avenue, Chicago, IL 60648).

3.5 The Receiver

Figure 7 is a block diagram of the commercially available¹ receiver used for the system described herein.

Figure 4 Block diagram of the pulse programmer board. (Reproduced from Job et al.⁵)

Figure 5 Block diagram of the modulator board. (Reproduced from Job et al.⁵)

The preamplifier is protected from the high power rf pulse by placing a pair of 914A crossed diodes between the input and ground. The output of the probe is connected to the preamplifier with a quarter-wavelength coaxial cable. Such a cable shorted to ground is an infinite resistance in an rf circuit. The rf pulse will open the diodes at the input of the preamplifier and create a shorted quarter-wavelength cable to ground. This protects the preamplifier. You can also place a T connector on the input to the probe and place the transmitter line to one side of the connector, with a grounded quarter-wavelength cable on the other side. The quarter-wavelength cable will pass all rf frequencies other than the transmitter frequency to ground, i.e. act as a filter.

3.6 The Analog-to-Digital Converter

Good analog-to-digital (A/D) converters suitable for use in an NMR spectrometer are now available. There are several A/D converters on the market that can be used in an NMR spectrometer. However, an A/D converter must be chosen which is compatible with the data reduction software to be used. There must either be a driver written to allow the software to communicate with the A/D board in the computer, or the A/D board must be able to place the data on the computer hard drive so that the software can address it. The simplest

Figure 6 NMR probe. (Reproduced from Job et al.⁵)

Figure 7 Block diagram of the receiver

solution to this problem is to use an A/D board compatible with the software, i.e. one that has a software driver.

There are at least two companies that furnish 1 MHz, 12-bit A/D converters and software suitable for use in data reduction on an NMR spectrometer. These are Keithley Instruments and National Instruments (addresses given above). Keithley Instruments has also written a driver for a Markenrich

(Markenrich Corp., 1812 Flower Avenue, Duarte, CA 91010) Waag I A/D board. This board has only 8-bit resolution, but it has conversion rates of up to 20 MHz. Both boards have been found to function well with the Keithley software.

The National Instruments A/D board has been designed for an EISA bus computer and does not have on-board memory. The National Instruments software system will work with a

PC, Apple Macintosh, or work station. It also operates under Windows.

3.7 The Data Reduction Software

Our own experience has been limited to the Keithley 'Asyst' package. The complete Asyst is a large software package designed to allow an end user to write an overlay program that will work with the underlying Asyst software to perform any experiment the end user would like to carry out. Two problems with this package are that it requires almost the whole of the computer memory under 640 kilobytes to load, and that it is made to work with expanded memory rather than extended memory. Expanded memory presents a problem in that it requires a page swapping segment in the PC memory above 640 kilobytes and below 1 megabyte. The Markenrich A/D board requires segment E000 of this memory. The pulse programmer software is written for a VGA monitor, which takes the first three memory segments above 640 kilobytes. When the driver for the Markenrich board is loaded and a VGA monitor used, there is no memory left for an expanded memory page swapping segment, as required by the Asyst software. This is not a problem if one uses both a control computer and a data reduction computer in the system as shown in Figure 1.

The overlay program needed for data reduction of NMR spectra is not difficult to write. Although there is a 'C' compiler with Asyst, we prepared our overlay in 'Fourth', which is the usual language used with Asyst. Fourth is not hard to learn and is a good language for instrument control and data reduction software. The Asyst software was found to be very flexible and powerful.

4 SOME APPLICATIONS OF A HOME BUILT SPECTROMETER

Beside the asphalt application for Strategic Highway Research Program our work has mostly been in the development of quantitative methods for moisture determination

in the agricultural/food processing industries. These methods use free induction decays, Carr-Purcell-Meiboom-Gill (CPMG) relaxation time measurements, and off-resonance FIDs with subsequent Fourier transformation to obtain a frequency domain spectrum.

Recently we have developed, in addition to the asphalt in hot mix method, qualitative methods to determine the concentration of solids in whole onions and the solids/fat ratio in edible oils. These methods were all developed on the system described in this article. These methods all used our large Halbach magnet and CPMG pulse sequences to determine changes in relaxation times which are related to the parameters of interest. These methods, and others, are available on request (Tri-Valley Research, 3590 Churchill Court, Pleasanton, CA 94588).

Figure 8 illustrates a typical NMR FID obtained with our spectrometer. This spectrum was plotted on a standard printer connected to the data reduction computer. It was done with

the Asyst software. Figure 9 shows the data from a CPMG experiment and illustrates the ability of this pulse sequence to average out magnet inhomogeneities. Figure 10 shows the expanded spectrum of the first few echoes and illustrates one of the features of the Asyst software. The use of this spectrometer in the agricultural field has been described.⁷

1 INTRODUCTION

Nuclear magnetic resonance or NMR has become the cornerstone of modern chemical structure elucidation. The technique is unparalleled in its ability to determine chemical structures by tracking atom-to-atom connectivity. Experiments are now available that allow one to determine homonuclear (^1H – ^1H and ^{13}C – ^{13}C) and heteronuclear (^1H – X where $\text{X} = ^{13}\text{C}$, ^{15}N , ^{19}F and ^{31}P among other heteronuclear pairs) connectivity information that is invaluable in assembling unknown chemical structures. Despite the considerable power of NMR methods, the technique unfortunately suffers from inherently low sensitivity when compared to other analytical spectroscopic methods such as mass spectrometry. This rather stringent limitation has prompted very considerable effort in the development of small volume, high sensitivity NMR probe designs. In part, these efforts have been necessary as it is not always possible to isolate additional sample for analysis.

The earliest detailed description of NMR spectroscopy using small rf coils that the author is aware of is found in the work of Odelblad in 1966.¹ In this study, solenoidal microcoils were used in conjunction with continuous wave (CW) NMR methods to study human cervical mucous secretions. The study examined ^1H chemical shifts and spin-lattice (T_1) relaxation behavior of the secretions. From that study, there was a gap of more than a decade before the pioneering work of Shoolery in 1979.² Shoolery's work focused on the use of 1.7 mm capillary NMR probes for direct observe ^{13}C NMR measurements. Shoolery demonstrated that it was possible to substantially reduce data acquisition times, acquiring decoupled ^{13}C NMR spectra for samples as small as 1 mg of cholesterol in 16 h. Corresponding gains were reported for ^1H spectra, with data acquired for a 1 μg sample of cortisone acetate.

These early studies set the stage for the development of 3 mm micro NMR probes that started in 1991 in a collaboration

between the author, colleagues and staff at Nalorac Corporation. The first report utilizing 3 mm micro NMR probe technology appeared in 1992.³ Using the simple indoloquinoline alkaloid cryptolepine (**1**) as a model compound for the study, the authors reported the acquisition of inverse-detected direct heteronuclear shift correlation HMQC data⁴ using a 12 μg (0.05 μMole) sample of the alkaloid dissolved in 145 μl of d_6 -DMSO in 16 h. These data are shown in Figure 1. Long-range heteronuclear correlations were measured using the substantially less sensitive HMBC experiment⁵ on a 35 μg sample (0.15 μMole) of the alkaloid in 145 μl of d_6 -DMSO in 21 h. These studies ushered in new capabilities for the characterization of small samples by NMR spectroscopy. It would have been necessary to isolate substantially larger samples than those reported for characterization using conventional 5 mm NMR probeheads.

Later in 1992, a direct comparison of the performance of 3 mm and 5 mm inverse-detection NMR probes for the acquisition of heteronuclear shift correlation data was reported.⁶ Using 1 μMole samples of the alkaloid harmaline (**2**) prepared in appropriate volumes for the two probe formats, HMQC spectra were acquired with identical s/n (signal-to-noise) ratios. It took four times as long to acquire comparable s/n data in a 5 mm probe with an identical quantity of sample as for the same data in a 3 mm micro inverse NMR probe design (Figure 2). Clearly, for structural characterization problems when limited quantities of sample are available, there is a significant time advantage to acquiring the data using a 3 mm rather than 5 mm probehead.

Several years after the introduction of the 3 mm micro NMR probes, another innovation appeared in the form of the Varian Nano-probe™.^{7–9} Shoolery, the driving force behind this probe technology, had the vision of having 100% of the sample within the confines of the rf coils of the probe. Obviously, however, this would result in considerable inhomogeneity over the sample due to the discontinuity of the magnetic susceptibility at the cell boundary. To circumvent this problem, the sample cell was oriented at the magic angle, 54.7° , and spun at high speed ($>1\text{ kHz}$) to average all of the magnetic dipoles to zero. The small volume of the nano-cell, 40 μl , makes it well suited to small samples. Nano-probe technology has made it possible to acquire ^1H spectra on samples of an aromatic alkaloid, **1**, as small as 75 ng (32 picomoles)

Figure 1 HMQC spectrum of a 12 μg (0.05 μmole) sample of the alkaloid cryptolepine (**1**) acquired overnight using a 3 mm micro inverse-detection NMR probe. The projection of the 2D data matrix through the proton frequency domain (F_2) is shown immediately above the contour plot; the ^1H reference spectrum is shown at the top

and COSY spectra overnight on an 85 picomole (200 ng) sample of the same model alkaloid.¹⁰ The ^1H spectrum of an 32 picomole sample of cryptolepine (**1**) is shown in Figure 3; the corresponding COSY spectrum is shown in Figure 4. Using a heteronuclear version of the probe in conjunction with specialized processing software, Shoolery demonstrated that an INADEQUATE spectrum of a 3.8 mg sample of sucrose could be acquired in 62 h.⁸ Since the initial development of the Nano-probe, a gradient inverse-detection version of the probe has also been developed yielding impressive results.¹¹ Applications of the Nano-probe for the characterization of small samples are discussed below.

The next step in the development of high-sensitivity, small volume NMR probes was the initial report of the μ -coil NMR probe by Sweedler and co-workers in 1995, which essentially overlapped the development of the nano-probe.¹² Unlike conventional NMR probes or the nano-probe described above, the μ -coil probe was instead a flow probe design, with the rf coil wrapped around a polyimide-coated fused-silica capillary. To obtain usable lineshape, it was necessary to immerse the coil in Fluorinert FC-43 when in use. While a linewidth of 0.6 Hz was initially reported, lineshape, based on visual inspection of figures in the initial report, was evidently not well optimized. Nevertheless, the authors reported a detection limit, defined as a $s/n = 3:1$, for a 19 ng sample of sucrose (56 picomoles) using a 1 min acquisition. It is also worth noting that since the μ -coil probe was a flow probe design that a smaller percentage of the actual sample, <20%, was calculated to be contained within the rf coil of the probe.

Figure 2 Comparison HMQC spectra of 1 μmole samples of the simple alkaloid harmaline (**2**). The spectrum shown in the bottom panel was acquired with a sample dissolved in 600 μl of d_6 -DMSO using a 5 mm inverse detection probe. The data were acquired in 23 min. The same quantity of material was dissolved in 160 μl of d_6 -DMSO and the data were acquired using a 3 mm micro inverse probe in 12 min to afford the spectrum shown in the top panel. To achieve comparable signal-to-noise using the 5 mm probe required ~ 70 of data acquisition

Figure 3 Proton NMR spectrum of a 75 ng (32 picomoles) sample of the indoloquinoline alkaloid cryptolepine (**1**, inset structure) acquired overnight using a Varian Nano-probe™. Both the residual water and the protio DMSO signals were suppressed in the experiment. Note the intensity of the ^{13}C satellite lines of the solvent relative to the intensity of the N-methyl group (~ 5.05 ppm) of cryptolepine

In contrast, conventional NMR probe designs can load up to $\sim 80\%$ of the sample within the confines of the rf coils in conventional NMR tubes and $>95\%$ of the sample when Shigemitsu micro cells are employed, or 100% with a nano-cell.

Following the initial report, refinements of the μ -coil NMR probe design have been reported. Designs have included probes for ^{13}C detection, although only labeled samples have thus far been studied.¹³ Multiple solenoidal microcoil probes for possible applications to high-throughput screening have been developed.¹⁴ Susceptibility matching plugs used in conjunction with microcoils have also been described for limited sample applications.¹⁵ Using this approach it was possible to position $\sim 43\%$ of the sample within the coil volume, a substantial improvement over initial flow designs. Perhaps the most interesting report has been a probe design for inverse-detection experiments.¹⁶ In the latter study, the authors reported the acquisition of a ^{13}C decoupled HMQC spectrum of a $13\ \mu\text{g}$ sample of chloroquine diphosphate dissolved in 745 nl of D_2O . These data were acquired by accumulating 32 transients for each of 2048×128 increments of the 2D NMR data matrix. The few applications of the μ -coil probe that have appeared thus far have all been contained in papers reporting the development of these probes and are discussed below.

Following in 1998, the development of 1.7 mm gradient submicro inverse-detection or SMIDG NMR probes was reported.^{17,18} This probe design returned to the 1.7 mm format pioneered in the 1970's by Shoolery.² The SMIDG probe design employs a conventional 1.7 mm NMR tube format that

can be inserted pneumatically as with 5 mm or 3 mm micro NMR probes. Sample volumes range from 22–30 μl depending on the coil dimensions and allow $\sim 78\%$ of the sample to be located within the coil volume when careful sample positioning and shimming are done. In one of the original reports, an 8% cryptolepinone impurity contained in a 0.55 μmole sample of cryptolepine was fully characterized by a combination of GHMQC and GHMBC experiments despite the dynamic range problems inherent to the sample.¹⁸ The SMIDG probe has also been used for a number of low-level, long-range ^1H – ^{15}N 2D NMR studies at natural abundance, dramatically lowering sample requirements for this very insensitive experiment.^{19,20} A number of applications of 1.7 mm SMIDG NMR probe technology for natural product and pharmaceutical impurity characterization have been reported and are discussed below.

In 2001, the development of a 1 mm gradient inverse NMR probe was reported.²¹ Using this probe technology, it was possible to record the HMQC spectrum of a $1\ \mu\text{g}$ sample of ibuprofen (**3**) overnight. To date, there have not been any reported applications of this probe technology to the best of the author's knowledge.

Figure 4 Overnight COSY spectrum obtained using a 200 ng sample of the simple alkaloid cryptolepine (**1**) dissolved in 40 μ l d_6 -DMSO and acquired using a Varian Nano-probeTM

More recently, intensive effort has been directed toward the development of cryogenic NMR probes. Thus far, 5 and 3 mm designs have been reported by various manufacturers. Several studies using prototype cryogenic 3 mm probes have been presented as posters^{22–24} and several reports have appeared in the published literature.^{25,26} Cryogenic NMR probes operate by cooling the rf coils to temperatures in the range of 10–25 K to reduce noise; preamplifiers used in conjunction with these probes are also frequently cooled to temperatures in the range of from 40–60 K. Considerable sensitivity gains are obtained by using this complex and technologically demanding design strategy. Early versions of the 3 mm cryogenic NMR probe tested in the author's laboratory gave *s/n* ratios for the anomeric proton of a 2 mM sucrose sample in the range of $\sim$ 180:1. More recent designs have given *s/n* ratios as high as 242:1. In comparison, a conventional 3 mm probe can be expected to give *s/n* ratios in the range of 62–67:1 for the same sample tube. The extremely high sensitivity of the cryogenic NMR probes translates to very considerable time savings to achieve identical *s/n* ratios when compared to conventional NMR probeheads. In the initial report from the author's laboratory using a prototype Nalorac 3 mm CryoSPECTM (CryoM{H}C500-3) probe²⁵ a 40 μ g sample of strychnine (**4**) was employed as a model compound and HSQC data were acquired. All of the responses were observable in 45 min albeit with noise still present in the spectrum; an essentially noise-free spectrum was recorded in 90 min.

In comparison, to achieve a comparable *s/n* ratio using a conventional 3 mm micro NMR probe, the sample had to be run for 17.5 h, which is a factor of 12.5 in time. These comparative spectra are shown in Figure 5. Although not performed in a small volume probe, still more impressive results have been obtained for long-range ^1H – ^{15}N experiments run on a 2 mg sample of the antibiotic eperezolid (**5**) in 160 μ l of solvent in a 3 mm NMR tube run coaxially in

Figure 5 Comparison of 3 mm gradient inverse triple resonance and 3 mm cryoprobe performance comparison using a 40 μg (120 nanomole) sample of strychnine (**4**). The same sample, prepared by serial dilution, was used for the acquisition of the HSQC spectra (non-gradient) shown in all three panels. The data shown in (a) were acquired by accumulating 32 transients/ t_1 increment as 2048×48 (hypercomplex files $\times 2$) data points, which were linear predicted to 192 points in the second frequency domain and zero-filled to 256 points during Fourier transformation using a Nalorac CryoSPEC 3 mm cryogenic micro inverse NMR probe. The data acquisition time was 90 min. Data shown in (b) were acquired identically except that a conventional Nalorac MIDTG-500-3 gradient inverse 3 mm triple resonance NMR probe was employed. Processing and scaling were identical to the data presented in (a), obviously lower in quality since these data were acquired using a conventional NMR probe. Data shown in (c) were again acquired using the Nalorac MIDTG-500-3 gradient inverse triple resonance probe except that 352 transients were accumulated/ t_1 increment giving an acquisition time of 17.5 h. Processing and scaling were identical to that used to prepare panel (a). S/n ratios in panels (a) (90 min) and (c) (17.5 h) are comparable

Figure 6 Comparison ^1H – ^{15}N CIGAR-HMBC²⁷ 5–10 Hz optimized long-range heteronuclear shift correlation data for the oxazolidinone antibiotic eperezolid (**5**) at natural abundance ^{15}N . The data shown in (a) were acquired using a Varian Cryo-Q 500 MHz HN gradient cryogenic NMR probe in 26 min with a s/n ratio of 101 : 1. To acquire comparable s/n data using a conventional Nalorac MIDTG-500-3 gradient inverse triple resonance probe using the same sample required 17 h 40 min (b)

a 5 mm Varian Cryo-Q 500 MHz HN probe.²⁶ A CIGAR-HMBC²⁷ spectrum in which all of the anticipated long-range ^1H – ^{15}N 2D NMR responses were observed was recorded in 26 min. To achieve comparable s/n ratio in a conventional 3 mm gradient inverse triple resonance probe required 17 h 40 min, corresponding to a factor of 38 in time. These results are shown in Figure 6.

2 HIGH SENSITIVITY, SMALL VOLUME PROBE PERFORMANCE COMPARISONS

One question that immediately comes to the mind of an investigator when faced with the problem of acquiring NMR data for a small sample is what probe should be used? This question has prompted a number of comparisons of various probe formats since the introduction of the 3 mm micro NMR probes in 1992. A complete set of all possible comparisons

is unfortunately not available. Indeed, there are no direct comparisons at all between any of the formats discussed in the contribution vs. any of the μ -coil NMR probes. Nevertheless, those comparisons that have been reported are summarized below.

2.1 3 mm Micro Inverse vs. 5 mm Inverse NMR Probe Performance Comparison

The first comparison of a small volume NMR probe to the standard 5 mm probe was reported in late 1992 following the introduction of the 3 mm micro NMR probes.⁶ Using a 1 μmole sample of the simple alkaloid harmane (**2**) dissolved in appropriate volumes of d_6 -DMSO for 3 and 5 mm NMR probes, comparison HMQC spectra were recorded. When data were acquired for identical times, the pair of spectra shown in Figure 2 were obtained. The advantage of the 3 mm micro probe over the conventional 5 mm probe when dealing with the 167 μg (1 μmole) sample of harmane (**2**) is obvious. When data were acquired in 12 min (4 transients/ t_1 increment, $2048 \times (2 \times 32)$ hypercomplex files) using the 3 mm micro inverse probe, it was necessary to acquire data for 69 min (32 transients/ t_1 increment $2048 \times (2 \times 32)$ hypercomplex files) to achieve comparable performance with a conventional 5 mm inverse-detection probe. These data heralded the beginning of renewed interest in the utilization of high-sensitivity, small volume NMR probes.

2.2 3 mm Micro Dual vs. Heteronuclear Nano-probe Performance Comparison

A rigorous comparison of these probe formats has not been reported. There are, however, several examples in the literature where both probe formats were used to acquire ^{13}C reference spectra. One example is contained in a paper describing the elucidation of the structure of the alkaloid cryptolepicarbolone (**6**) from the Ghanaian plant *Cryptolepus sanguinolenta*.²⁸ The total available sample of the alkaloid was $\sim 100 \mu\text{g}$ ($\sim 0.25 \mu\text{mole}$). The acquisition of a ^{13}C reference spectrum of the alkaloid sample in 40 μl of d_6 -DMSO using a heteronuclear nano-probe was accomplished overnight giving a spectrum with a s/n ratio of 9 : 1. In comparison, the same sample of alkaloid, after transfer to a 3 mm micro NMR probe in the process of which the sample was diluted to 140 μl gave a spectrum with 9 : 1 s/n over a weekend. A similar non-rigorous comparison of the performance of the 3 mm micro dual and heteronuclear nano-probes is found in a report of the characterization of an N-acetyl keto derivative of fumonisins-B₁ (**7**).²⁹ An overnight acquisition of a ^{13}C reference spectrum of an $\sim 200 \mu\text{g}$ sample of the material gave a carbon spectrum with a s/n ratio of 5.5 : 1 when a 3 mm micro dual probe was employed. Curiously, a ketone carbonyl resonance expected on the basis of mass spectrometric fragmentation data was not observed in the spectrum. The acquisition of the ^{13}C reference spectrum was repeated with the same sample after concentration to 40 μl to allow the use of a heteronuclear nano-probe. The overnight nano-probe acquisition gave a spectrum with a s/n ratio of 11 : 1 and the carbonyl resonance at 219.5 ppm was observed in the spectrum. These data are presented in Figure 7. There is no obvious reason why carbonyl resonance wasn't observed in the spectrum recorded using the 3 mm micro dual probe;

Figure 7 Overnight ^{13}C reference spectra of an $\sim 200\ \mu\text{g}$ sample of a secondary fungal metabolite, fumonisins- B_1 (**7**), in D_2O . The data shown in the top panel were acquired using a 3 mm micro dual NMR probe in $145\ \mu\text{l}$ of solvent and gave a signal-to-noise ratio of 5.5:1. A ketone carbonyl resonance expected on the basis of mass spectrometric fragmentation data was not observed in the spectrum. Following the concentration of the sample to $40\ \mu\text{l}$ to allow the use of a heteronuclear Nano-probeTM, the data shown in the bottom panel were acquired. The overnight Nano-probeTM acquisition gave a spectrum with a s/n ratio of 11:1 and the carbonyl resonance at 219.5 ppm was observed in the spectrum

the relaxation delay between transients was identical. From these data, however, it can be concluded that the per transient efficiency of the conventional micro dual probe is somewhat better than that of the nano-probe. This conclusion derives from the nearly four-fold concentration of the sample for acquisition of the nano-probe data. If probe efficiencies were identical, a s/n ratio for the nano-probe approaching 22:1 should have been obtained on the basis of the concentration factors.

2.3 1.7 mm SMIDG vs. 3 mm Micro Inverse Probe Performance Comparison

A rigorous comparison of the 1.7 mm submicro gradient inverse or SMIDG and a 3 mm micro inverse detection NMR probes has been reported for both ^1H – ^{13}C direct and long-range and ^1H – ^{15}N long-range heteronuclear shift correlation experiments.³⁰ In addition, the results obtainable by running a 1.7 mm sample coaxially in a 3 mm micro probe were also reported in this study. Using an $0.5\ \mu\text{mole}$ sample of the non-steroidal anti-inflammatory agent ibuprofen (**3**) in either 30 or $150\ \mu\text{l}$ of d_6 -DMSO, gradient ^1H – ^{13}C HSQC spectra were acquired using both probes. Data accumulation for the three experiments performed was 48 min for each spectrum. Using the 1.7 mm SMIDG probe, a s/n ratio of 148:1 was obtained. All of the expected responses were observed in the spectrum, including that of the relatively weak *sec*-butyl methine resonance. When the 1.7 mm sample was run in the 3 mm micro inverse probe, again all of the responses were observed; the s/n ratio was 75:1. When the GHSQC data were acquired using the 3 mm micro inverse probe, the *sec*-butyl methine resonance was absent from the spectrum; the s/n ratio was 62:1. Similar results were obtained for the same series of ^1H – ^{13}C GHSQC experiments using a $1\ \mu\text{mole}$ sample of strychnine (**4**). These comparison GHSQC spectra are presented and described in Figure 8.

Using a 1 mg sample of strychnine (**4**), long-range ^1H – ^{15}N GHMBC experiments were also performed using both the 1.7 mm SMIDG and the 3 mm micro inverse probes; these data are presented in Figure 9. The 1.7 mm SMIDG data gave all of the expected long-range ^1H – ^{15}N responses;^{30–33} all responses were well above the noise floor of the spectrum. When the 1 mg sample in the 1.7 mm tube was run coaxially in the 3 mm micro inverse probe, again, all of the expected long-range responses to the two strychnine nitrogen resonances were observed although there were some noise spikes contained in the spectrum with comparable intensity to the desired, long-range responses. For the 3 mm sample, all but one of the expected long-range responses was observed. However, there were substantial numbers of spurious peaks with greater intensity than the desired long-range responses. It was concluded that a sample containing $\sim 3\ \mu\text{moles}$ ($\sim 1\ \text{mg}$ in the case of strychnine) was borderline for an overnight long-range ^1H – ^{15}N 2D NMR experiment at natural abundance in a 3 mm probe.

2.4 Conventional vs. Cryogenic NMR Probe Performance Comparison

To date there are two studies in the literature that report comparisons of conventional and cryogenic NMR probe performance. The first is a direct comparison of 3 mm cryogenic inverse and conventional 3 mm inverse-detection probes.²⁵ Using a $40\ \mu\text{g}$ (120 nanomoles) sample of strychnine dissolved in $150\ \mu\text{l}$ d_6 -benzene, identical HSQC spectra were recorded using a Nalorac 3 mm CryoSPEC inverse probe and a conventional Nalorac Z•SPECTM MIDTG-500-3 gradient inverse-detection probe. With the cryogenic probe, all of the aliphatic direct correlation responses were observable within 45 min and a noise-free spectrum was obtained in 90 min. To achieve a comparable s/n ratio using the conventional probe required 17 h of data acquisition. With the initial prototype

Figure 8 Comparison 600 MHz ^1H – ^{13}C GHSQC spectra acquired for a $1\ \mu\text{mol}$ sample of strychnine (**4**) in CDCl_3 in either a 1.7 or 3 mm NMR tube in a volume appropriate to the tube format. All data were acquired by accumulating four transients at each of 64 increments of the evolution time, t_1 , giving identical data acquisition times. All data were processed and scaled identically to prepare the three panels shown. Data shown in (a) were acquired using a 1.7 mm sample in a Nalorac SMIDG-600-1.7 submicro gradient inverse detection NMR probe; using the region from 5.5 to 4.5 ppm as representative noise, the s/n ratio for this spectrum was 112:1. The data shown in (b) were acquired by running the 1.7 mm sample coaxially in a conventional Nalorac MIDTG-600-3 gradient triple resonance micro inverse NMR probe. The s/n ratio for these data was 75:1. Finally, the data shown in (c) were acquired using a $1\ \mu\text{mol}$ sample in a 3 mm tube, the data again acquired using the conventional Nalorac MIDTG-600-3 probe. The s/n ratio for this experiment was 62:1. Projections through the F_2 frequency domain are plotted above each of the contour plots to provide a more effective portrayal of the relative s/n ratio in the three experiments

cryoprobe used for this comparison, a $3.5\times$ improvement in signal-to-noise was afforded by the cryoprobe, which corresponds to a 12.5-fold time advantage to equivalent signal-to-noise. The comparison 90 min HSQC spectra are shown in Figure 5.

More recently, a comparison was drawn for the acquisition of long-range ^1H – ^{15}N 2D experiments at natural abundance.²⁶ Using a 2 mg sample of the oxazolidinone antibiotic eperezolid (**5**) dissolved in $160\ \mu\text{l}$ d_3 -acetonitrile in a 3 mm NMR, ^1H – ^{15}N CIGAR-HMBC 2D NMR spectra optimized for a long-range coupling range of from 5 to 10 Hz^{34–36} were acquired using a Varian 5 mm Cryo-Q HN probe (because of the considerable variability of long-range ^1H – ^{15}N couplings, it is advisable to use an accordion-optimized long-range 2D NMR experiment such as IMPEACH-MBC or CIGAR-HMBC to record long-range ^1H – ^{15}N 2D NMR spectra at natural abundance. See Ref.³⁴). In less than 10 min, most of the anticipated long-range ^1H – ^{15}N responses were observed. A second experiment run in 26 min afforded a spectrum with 101:1 (projecting through the F_1 or ^{15}N frequency domain) s/n in which even the weakest response had $\sim 40:1$ s/n. Acquisition of a 26 min data set using a conventional Nalorac Z•SPEC MIDTG-500-3 gradient inverse probe gave only the N7-9CH₃ response. A longer 4 h experiment gave all of the expected long-range responses albeit with $<50:1$ s/n.

To attain a s/n ratio comparable to that of the 26 min cryoprobe experiment, it was necessary to acquire data with the conventional 3 mm probe for 17 h 40 min (112:1 s/n). A comparison of the 26 min 5 mm cryoprobe data with the 17 h 40 min 3 mm ^1H – ^{15}N CIGAR-HMBC spectra optimized over the range of 5–10 Hz is shown in Figure 6. Thus, for long-range ^1H – ^{15}N experiments, the cryogenic NMR probe afforded a $>38\times$ time advantage relative to a conventional 3 mm micro probe despite potential losses of signal due to filling factor associated with running a 3 mm tube coaxially in the 5 mm probe. Unfortunately, at present, it is not possible to make a direct comparison of 3 mm NMR probes for long-range ^1H – ^{15}N 2D NMR experiments at natural abundance as a 3 mm cryogenic NMR probe with an X-coil tunable to ^{15}N or doubly tuned to ^{13}C and ^{15}N has yet to be developed.

While 5 mm cryogenic NMR probes are not in the category of small volume NMR probes by any means, the extremely high sensitivity which they offer makes them competitive when dealing with small samples, particularly when 3 mm tubes are run coaxially or specialized micro cells are employed to restrict sample volume. To date, there have not been any reports of tubes smaller than 3 mm in diameter being run coaxially in a cryogenic probe; it is likely that filling factor losses would substantially offset the gains in sensitivity offered by the probe if a small tube such as 1.7 mm were run coaxially in a 5 mm cryogenic probe. Thus, it is likely that as cryogenic probes

Figure 9 Comparison ^1H – ^{15}N 8 Hz optimized GHMBC spectra of 3 μmole samples of strychnine (**4**) at natural abundance prepared in either a 1.7 or 3 mm NMR tube in a volume appropriate to the tube format. All spectra were recorded at 600 MHz, accumulating 4096 transients for each of 40 increments of the evolution time, t_1 , giving identical 18 h data acquisitions. The data shown in (a) were acquired using a 1.7 mm sample in a Nalorac SMIDG-600-3 gradient inverse submicro NMR probe. Again using the region of the proton spectrum from 5.5 to 4.5 ppm for representative noise, the SMIDG data gave a s/n ratio of 60 : 1. All anticipated responses were observed either directly in the contour plot or readily in the traces from the N9 amide or N19 aliphatic nitrogen resonances. When the 1.7 mm sample was run coaxially in a Nalorac MIDTG-600-3 gradient inverse triple resonance probe, the data shown in (b) were obtained, giving a s/n ratio of 41 : 1. Some spurious responses are observed in the projection through F_2 as well as in the contour plot. Finally, when a 3 mm sample was used in a 3 mm probe, the result shown in (c) was obtained. In this case, spurious responses in the projection are of greater intensity than some legitimate responses, suggesting that either a longer data acquisition or larger sample would be desirable with this probe technology to obtain reliable data. The s/n ratio of the spectrum shown in (c) was 26 : 1

become more widely available that 5 mm versions of this probe technology will be used to deal with small NMR samples in those labs not equipped with more specialized probeheads.

2.5 Conventional NMR Tubes vs. Specialized Sample Cells

One alternative available to researchers without access to any of the specialized NMR probeheads described in this contribution is to use a specialized sample cell to restrict overall sample volume, thereby keeping a greater percentage of a scarce sample within the confines of the rf coils of the probe being used. Various tactics have been employed to achieve this goal. Approaches have included the development of plastic NMR tube inserts, the properties of which are matched as closely as possible to those of the solvent being employed. Shigemi, using a more novel approach, has employed specialized glass that matches the magnetic susceptibility of several NMR solvents, to make both the NMR tube and a precision bore ‘plunger’. Tubes have been manufactured thus far for use with CDCl_3 , CD_3OD , D_2O and d_6 -DMSO. With a conventional 5 mm NMR tube, sample volumes can be reduced from $\sim 500 \mu\text{l}$ to roughly 225–250 μl . The resulting two-fold increase in sample concentration will correspondingly quarter acquisition time to a given s/n ratio.

To date, two studies have appeared in the literature that compare the results obtainable with normal NMR tubes vs. specialized NMR cells. The earliest report was a study of Caribbean ciguatoxin.³⁷ A substantial improvement in the HMQC data that could be recorded for an $\sim 0.95 \mu\text{mole}$ sample of Caribbean ciguatoxin was noted when the data were acquired in 67 μl d_5 -pyridine when the sample was run in a 3 mm Shigemi D_2O -matched micro NMR cell (despite the mismatch of the solvent to the optimization of the micro cell) vs. data acquired in 120 μl in a conventional 3 mm NMR tube. No quantitative comparison was drawn. A similar improvement was noted by Reynolds, Yu and Enriquez³⁸ for ^{13}C -detected 2D heteronuclear NMR experiments when run in Shigemi micro NMR cells vs. data acquired in normal 3 mm NMR tubes. Although 1.7 mm Shigemi cells have been developed, there have not been any reported applications of this type of tube in the literature.

3 APPLICATIONS OF SMALL VOLUME NMR PROBES IN THE SOLUTION OF CHEMICAL STRUCTURE PROBLEMS

There is a wide range of potential applicability of specialized NMR probe technology in the solution of structural

problems, not all of which have yet been reported. Some research areas where specialized NMR probe heads can be highly advantageous include: characterization of scarce natural product samples; identification of metabolites of pharmaceuticals; characterization of forensic samples; protein characterization; and the identification of chemically unstable species. Given that the first of the new generation of small volume specialized probes to be described were the 3 mm micro inverse and dual probes, applications utilizing these probeheads will be surveyed first, followed by applications utilizing Nano-probe technology. To date, there have not been any applications of μ -coil probes in the solution of structural problems of which the author is aware. The examples that have been reported in conjunction with the development of this probe technology will be summarized next. Examples of potential applications and structural problems solved using 1.7 mm SMIDG probes, and then cryogenic probe applications will complete this section.

3.1 Existing Reviews

Several reviews have been published that deal with either probe-specific or the general topic of small sample NMR spectroscopy.^{39–44} Various aspects of dealing with small samples by NMR have also been discussed in reviews of specific classes of molecules, which include alkaloids,⁴⁵ carbohydrates,⁴⁶ and a recent review of long-range ^1H – ^{15}N 2D NMR applications.⁴⁷

3.2 Applications of 3 mm Micro Probes

Following the initial reports on the development of 3 mm micro NMR probe technology in the authors laboratories, then at Burroughs Wellcome, Co., the first reported 'real world' application of this technology was in the characterization of a 30 μg (0.07 μmoles) metabolite sample through the use of a combination of 3 mm micro and heteronuclear nano-nmr probe technology.⁴⁸ A heteronuclear nano-nmr probe was used to record a ^{13}C reference spectrum and a homonuclear nano-nmr probe was used to record a COSY spectrum. Following transfer of the sample and dilution to 120 μl , heteronuclear shift correlation spectra were recorded using a 3 mm micro inverse NMR probe. In 1995, the structure of an N-acetyl keto derivative of fumonisins-B₁ (**7**) was determined, again using a combination of probeheads. Two-dimensional NMR spectra were recorded using a 3 mm micro probe while a ^{13}C reference spectrum was recorded using both a 3 mm micro dual and heteronuclear nano-nmr probe. Interestingly, the keto resonance at 219 ppm was not observed in the data from the 3 mm micro dual probe while it was readily observed in the data recorded with the nano-nmr probe.²⁸ Later in 1995, the structure of the complex indoloquinoline alkaloid cryptolepicarboline was reported.²⁷ The homo- and heteronuclear 2D NMR data were recorded using a 3 mm micro inverse nmr probe. A comparison of the ^{13}C spectra recorded using a 3 mm micro dual and heteronuclear nano-nmr probe were also contained in the report.²⁷ Later in 1995, in a report by the author and co-workers³⁷ the benefits of using reduced volume Shigemi micro nmr cells was reported in the context of a study of Caribbean ciguatoxin. In a related study, the proton and carbon NMR spectra of the marine toxin brevetoxin-2 were fully assigned on less than 1 μmole of material through the use of 3 mm micro nmr probe technology.⁴⁹

Late in 1995, the structure of the indolobenzazepine alkaloid homocryptolepinone, which serves as a structural component of the complex spiro nonacyclic alkaloid cryptospirolepine, was reported.⁵⁰ Continuing in the indoloquinoline series of alkaloids in 1996, two new members of this series with novel ring fusion between the indole and quinoline portions of the molecule were reported.⁵¹ Cryptosanguinolentine was based on an indolo[3,2-*c*]quinoline ring fusion rather than the more common [3,2-*b*] ring fusion. Cryptotakiine was based on an indolo[2,3-*b*]quinoline ring system which placed both annular nitrogens on the same side of the molecule. Later in 1996 the structure of the novel, dimeric alkaloid cryptomisine was reported.⁵²

In 1997, Reynolds and co-workers,³⁸ as noted above, examined the limits of ^{13}C detected heteronuclear shift correlation experiments through the combined usage of 3 mm micro probes and Shigemi micro nmr cells. Although the sensitivity of ^{13}C -detected heteronuclear 2D nmr methods is inarguably lower than that of newer, proton-detected methods, there are still occasions when high digitization requirements in the ^{13}C frequency domain are better addressed by direct ^{13}C detection, provided that sufficient sample is available.⁵³

3.3 Applications of Nano-nmr Probes

Magic angle spinning (MAS) liquid NMR probes, or nano-nmr probes as they are frequently referred to *in lieu* of Varian's trademarked Nano-probe™ nomenclature, have been applied in the study of a diverse range of chemical structure problems. A very useful subdivision of these applications is suggested in the review by Keifer.³⁹ For discussion, it is convenient to separate applications into heterogeneous and homogeneous sample types. The former encompasses samples as diverse as whole cells, tissue samples and solid phase synthesis (SPS) supports used for combinatorial chemistry and related applications. Homogeneous samples, as the name implies, refers to solutions in the usual NMR sense.

3.3.1 Heterogeneous Samples

Nano-nmr probes, which spin at the magic angle (54.7°) at speeds of up to several KHz, are quite useful for the study of heterogeneous samples. The earliest such application, of which the author is aware, is a 1994 report dealing with SPS beads on which the synthetic chemistry was being carried out. The first report, which employed ^1H NMR, used a Varian homonuclear Nano-probe.⁵⁴ Results that can be obtained with various SPS resins using various types of probes were reported in 1996 by Keifer and co-workers.⁵⁵ The effect of tether length between the resin and the synthetic site has been examined⁵⁶ as has the use of MAS liquids probes to monitor the extent of reaction completion on SPS supports.^{57,58} More recently, Seffler and Gerritz⁵⁹ have used 1D and 2D NMR methods to characterize reaction products bound to Chiron SynPhase crowns used in the elaboration of combinatorial chemical libraries. Finally, although not chemically bound, Mohri and co-workers⁶⁰ have studied the mobility of surface-adsorbed molecules on insoluble pigment particles using ^1H T₁ relaxation measurements in a nano-nmr probe. Reviews on the analysis of materials on solid supports include those of Keifer³⁹ and Gallop and Fitch.⁶¹

Another interesting heterogeneous nano-nmr probe application has been used in an attempt to biochemically classify kidney carcinoma biopsy samples.⁶² While by no means a rapid analytical or screening tool, this study does provide a glimpse of where the probe technology may be applied in the future.

3.3.2 Homogeneous Samples

Numerous reports of applications of nano-nmr probes to homogeneous solution samples have been reported. Broadly, these applications can be further subgrouped into natural products or small molecules and biomacromolecule studies. One of the first reported small molecule applications was a combined 3 mm micro NMR probe/nano-nmr probe study of a metabolite structure.⁴⁸ The 3 mm micro probe was used to record the heteronuclear 2D nmr data on a 30 µg sample of a low molecular weight metabolite while a heteronuclear nano-nmr probe was used to record the ¹³C reference spectrum. Combined 3 mm micro probe/nano-nmr probe applications have also been reported in the elucidation of a complex indoloquinoline alkaloid structure²⁷ and a fumonisins-B₁ fungal metabolite structure.²⁸ In both of these studies, comparative ¹³C NMR spectra acquired in a 3 mm micro dual probe and a heteronuclear nano-nmr probe are presented. Another combined 3 mm micro probe/nano-nmr probe application is found in the structural characterization of laingolide, a novel 15-membered macrolide from a blue green alga.⁶³ In this study, the direct and long-range heteronuclear chemical shift correlation experiments were performed in a 3 mm micro probe while the ¹³C reference spectrum was recorded using a heteronuclear nano-nmr probe.

The sensitivity of heteronuclear nano-nmr probes, combined with the small volume of a nano cell (40 µl) has led to the application of this probe technology for the characterization of a novel steroid skeleton⁶⁴ through the use of the INADEQUATE^{65,66} experiment.

More recently, several additional applications of nano-nmr probe technology have been reported in the characterization of natural product samples. Bierer and co-workers⁶⁷ reported using a nano-nmr probe in the characterization of the indoloquinoline alkaloid cryptolepinone, which was independently characterized by Martin and co-workers⁶⁸ using 3 mm micro probe hardware. A modified tetrapeptide, lyngbyapeptin A, has been characterized, in part, using nano-nmr to acquire a ¹³C reference spectrum.⁶⁹ Lyngbyapeptin A was described as being produced by a cyanobacterium in 'trace' amounts and thus it is likely that the heteronuclear shift correlation data were recorded using a 3 mm micro NMR probe although this was not specified in the report. Most recently, the structure of a new macrocyclic trichothecene produced by a marine-derived fungus has been reported.⁷⁰ In this case, a Varian Nano-probe was used for the acquisition of all of the NMR data reported, including the heteronuclear shift correlation spectra.

The first reported application of nano-nmr probes in the study of biomacromolecules is found in the report of Manzi et al.⁷¹ on the identification of a novel glycosaminoglycan core-like molecule. Delepierre and co-workers⁷² next reported studies of the structure of a potassium channel blocking toxin (peptide) from the scorpion *Pandinua imperator* using a homonuclear nano-nmr probe. That report was followed by another from the same laboratory that examined the kinetics of secondary structure recovery during the refolding of reduced

hen egg white lysozyme.⁷³ Further work on potassium channel blocking peptide toxins was also reported later in 1997 by Delepierre and co-workers.⁷⁴ Delepierre and colleagues⁷⁵ next reported the results of a study of renatured lysozyme using nano-nmr techniques. In 1999, Delepierre, et al.,⁷⁶ reported the analysis of the structure of Pi7, an orphan peptide from the scorpion *Pandinua imperator* using ¹H nano-nmr methods. Van Halbeek and co-workers⁷⁷ initiated studies of glycan classes and their analysis by nano-nmr methods that were first reported in 2000. Finally, the biosynthesis of ganglioside mimics of *Campylobacter jejuni* has been studied at the nanomole level through the use of nano-nmr methods.⁷⁸

Most recently, Kupce et al.⁷⁹ have examined the issue of adiabatic TOCSY MAS in liquids, demonstrating that adiabatic mixing sequences are less susceptible to modulation effects due to both rf and magnetic field homogeneities than are conventional mixing sequences.

3.4 Applications of Small Volume Cryoprobes

To date, only a scant few reports on the use of small volume cryogenic NMR probes have been reported. Withers and co-workers²²⁻²⁴ have presented several posters describing the utilization of a 2.5 or 3 mm cryogenic probes for the acquisition of heteronuclear shift correlation data needed for metabolite characterization. The author and colleagues²⁵ have reported a comparison of conventional and cryogenic 3 mm NMR probes using a 40 µg (120 nanomoles) sample of strychnine (**4**) shown in Figure 5. Finally, although not using a small volume cryogenic probe, the author and co-workers²⁶ have reported a comparison of long-range ¹H-¹⁵N heteronuclear shift correlation data (shown in Figure 6) acquired using a 3 mm sample in both a 5 mm cryogenic and conventional 3 mm NMR probes. Undoubtedly more applications of small volume cryogenic probes will appear given the substantial sensitivity advantage which these probes afford.

3.5 Phase Cycled vs. Gradient NMR Experiments When Dealing with Very Small Samples

Work in the author's laboratories at Pharmacia, directed to the characterization of very small samples of isolated and impurities of potential drug candidates, has shown that at very low concentrations the use of gradient NMR experiments is disadvantageous. Reynolds and Enriquez⁸⁰ after a discussion of this observation have gone on to report a rigorous experimental verification of this observation. They demonstrated that at high concentrations, the t₁ ridges due to incomplete suppression of ¹H-¹³C components of magnetization (or that from protons bound to heteroatoms) constitutes the main source of noise in phase-cycled 2D NMR spectra. Gradient NMR pulse sequences strongly suppress this noise, as would be expected. This observation is consistent with the generally accepted advantage of gradient-based NMR experiments when only a few transients/t₁ increment will be accumulated. However, as also reported by Reynolds and Enriquez, the intensity of the t₁ ridges appears to be directly proportional to the signal strength and consequently, for very dilute samples, t₁ ridges contribute to the total noise in an HMBc experiment to only a minor extent. When sufficient numbers of transients are accumulated

per t_1 increment, the intrinsically higher sensitivity of phase-cycled experiments vs. gradient-based experiments makes the former preferable.

To illustrate this observation rather dramatically, Russell⁸¹ has recorded gradient and phase-cycled HMBC data for a 20 μg sample of retrorsine (**8**). These data are shown in Figure 10 compared to data from a 700 μg sample of the same molecule. The 700 μg data were acquired overnight at 500 MHz using a conventional Nalorac MIDTG-500-3 gradient micro inverse 3 mm NMR probe and provide a references for the responses expected to be observed in the spectrum.

The reference gradient HMBC spectrum acquired overnight using the 700 μg sample of the alkaloid is shown in Figure 10 Panel a and contains all of the responses expected for the molecule. The phase-cycled, non-gradient HMBC spectrum acquired using a 20 μg sample of the alkaloid in 160 h is shown in Panel b. A significant percentage of the possible responses are observed in the spectrum, particularly when traces for the individual carbons are extracted from the data matrix. In contrast, the gradient HMBC spectrum on the same 20 μg sample after an identical data acquisition, shown in Panel c, shows only the most intense responses in the spectrum. This result is consistent with the work of Reynolds and Enriquez⁸⁰ which was done with substantially larger samples.

4 CONCLUSIONS

Small volume, high sensitivity NMR probes have had a significant impact on the conduct of research in many areas of chemistry and biochemistry that depends on NMR methods since the first reports on the contemporary versions of these probes appeared about a decade ago. Probes have been developed in a number of formats for conventional tube configurations including 3, 2.5, 1.7 and 1 mm. New probe technologies such as Varian's Nano-probe and the μ -Coil probes have also been reported. The development of small volume, cryogenic NMR probes is now on-going. With the continuing developments and refinements in this rapidly advancing field of NMR research, sample requirements have concomitantly decreased. COSY spectra on samples as small as 200 ng of cryptolepine (**1**), HMQC spectra on 1 μg of ibuprofen (**3**), and HMBC spectra on 6 μg of cryptolepinone, an oxidative degradation product contained in a sample of cryptolepine (**1**) have been discussed in this report. While it is difficult to foresee how much further sample requirements will diminish in the coming years, it is assured that with the advent of small volume, cryogenic NMR probes that the frequency of studies with very small samples will increase in the near future.

Figure 10 Comparison HMBC spectra of retrorsine (**8**).⁸¹ The 8 Hz optimized gradient HMBC reference spectrum shown in panel (a) was acquired overnight using a 700 μg sample of the alkaloid dissolved in 150 μl of d_4 -methanol. The data shown in panels (b) and (c) were accumulated using a 20 μg sample of the alkaloid dissolved in 150 μl of d_4 -methanol. The data shown in panel (b) were acquired using a conventional phase-cycled, non-gradient HMBC pulse sequence. In comparison, the data shown in panel (c) were obtained using the more contemporary gradient HMBC experiment. The superior performance at these low levels of the phase-cycled non-gradient HMBC experiment is consistent with the recent report of Reynolds and Enriquez⁸⁰

1 INTRODUCTION

From the early days of NMR, the word probe (or probe-head) has been used to refer to the complete piece of equipment intimately associated with the sample (except the sample tube). For the simplest experiments, the probe consists of the mechanical structure required to hold the sample in the 'sweet spot' of the magnet, a coil surrounding the sample, a tuning capacitor, and an rf transmission line. However, most chemical problems of interest require control over the sample environment (temperature, electromagnetic irradiation, pressure, orientation, and re-orientation), and apparatus associated therewith becomes a part of the NMR probe.

The modern NMR probe is a complex piece of apparatus designed to accommodate all of the environmental requirements of the NMR experiment. The radiofrequency (rf) portion often includes (a) an rf 'observe' channel optimized for highest signal-to-noise-ratio (SNR, or S/N, also called sensitivity) at the X nucleus frequency, (b) a less efficient rf channel for heteronuclear decoupling (usually ^1H , except for indirect detection), and (c) another low-efficiency channel for magnetic field lock (usually ^2H). Variable temperature (VT) control is achieved with a resistive heater in a gas stream that flows over the sample. In high-resolution liquids probes, slow sample spinning (10–200 revolutions per second, Hz) about the B_0 axis to average out azimuthal inhomogeneity in B_0 is usually accomplished with a pneumatic system external to the probe, but high-speed sample spinning apparatus (200–26 000 Hz) for solids averaging techniques is an integral part of a solids probe.

One of the most demanding technical aspects of liquids probes is the requirement of extremely high B_0 field homogeneity (as high as several parts per billion), but sometimes it is advantageous to be able deliberately to spoil the field homogeneity over precise time periods by applying field gradients. When very high gradients and fast switching are required, as in diffusion measurements or solids microscopy magnetic resonance imaging (MRI), the gradient coils must be as small as possible and incorporated into the probe. However, for most

MRI work with samples larger than 40 mm, the gradient coils are external to the probe.

Another challenging technical requirement is often that of minimizing NMR background signals from construction materials that contain trace amounts of the nuclide of interest—particularly for highly sensitive proton (^1H) experiments. Other technical complications may stem from provisions for optical or microwave irradiation and operation at extreme temperatures.

Addressing the often conflicting requirements of high sensitivity, high resolution, large spectral bandwidth, low background signals, wide VT range, high-speed sample spinning, intense irradiation, and uniform field gradients requires careful attention to a number of problems in materials science, physics, electrical engineering, and mechanical engineering. The engineering effort often makes the price of a probe comparable to the price of a new sports car.

2 GENERAL CLASSES OF NMR PROBES

2.1 Liquids Probes

Approximately 80% of NMR experiments are performed on high-resolution liquids probes designed for samples in axially aligned glass tubes in superconducting magnets using saddle-shaped rf coils or slotted resonators for signal reception. They are often required to achieve a spectral resolution of several parts per billion on slowly spinning samples. A small fraction of their usage has been for in vivo experiments on small living animals or ex vivo or in vitro experiments on surgically removed tissues kept alive for short periods of time by perfusion with nutrients in saline solutions furnished by a flow system in the probe. Most multinuclear liquids probes have provided proton decoupling with multinuclear observe and deuterium lock, but recently many have been designed for inverse experiments (proton detection with X -nucleus decoupling). At present, high-resolution liquids probes are commercially available for experiments from -180°C to 380°C .

2.2 Gradient Probes

Pulsed field gradient (PFG) and microscopy MRI probes are usually similar to conventional liquids probes with the addition of gradient coils for one or three axes respectively. PFG probes are used for the measurement of diffusion coefficients, solvent suppression, or selection of specific coherences. Their usage has grown very rapidly in the past several years because of the time savings they provide in two-dimensional NMR. Microscopy in vivo probes may include surface coils for improved localized signal reception.

2.3 Solids Probes

The original (and simplest) probe for NMR of solid samples is the wideline probe, which is normally characterized as being able to generate 90° pulse lengths less than $3\mu\text{s}$ (spectral excitation bandwidths greater than 80 kHz) by withstanding

peak rf coil voltages in excess of 3 kV. Often they are double tuned (DT) to permit cross polarization (CP) with high-power decoupling for increased sensitivity and resolution. High-speed magic angle spinning (MAS) of the sample is added in the CP MAS probe for line narrowing of spin- $\frac{1}{2}$ nuclei, and dynamic angle spinning (DAS) and double rotation (DOR) may be provided for quadrupolar nuclei. When sufficiently large single crystals of the sample can be grown, high-resolution spectra and the chemical shift tensor can be obtained using a single crystal probe that includes a suitable goniometer and crystal orientation mechanism.

3 HISTORICAL PERSPECTIVE ON NMR PROBES

Through the late 1960s ‘NMR’ implied ‘proton NMR of liquids’ unless specifically stated otherwise, and multinuclear probes were unheard of. There was a rather widespread misconception that sensitivity increased linearly with coil inductance, even though the early classic treatments^{1,2} were sound. High-inductance solenoids (1–50 μ H, compared with 40–200 nH for modern probes) wound around the sample tube could be used for efficient reception in the transverse field of the electromagnet, but audio field-modulation coils were needed to shift the detection frequency above the $1/\nu$ noise region of the phase-sensitive video detector. The orthogonal Helmholtz transmit coils could be driven with low-power (milliwatt) oscillators for most continuous wave (CW) techniques, and the transmit/receive coils were carefully isolated using Faraday shields and tuning paddles. Since low-impedance preamplifiers with low noise figures were not available, it was best to include the first stage of the preamplifier in the probe and match it (usually 300–2000 Ω) directly to the receive coil.

Although many time domain pulsed NMR experiments were performed in the first two decades of NMR for relaxation studies, the explosion of NMR techniques awaited the application of Fourier transform (FT) by Richard Ernst in 1966 to the time domain data to obtain the complete frequency domain spectra in a single free induction decay (FID). The increase in sensitivity was comparable to the ratio of the total spectral width to the narrowest line in the spectrum—often two or three orders of magnitude.^{3,4} (See also *Fourier Transform Spectroscopy*.)

Field shimming (homogenizing) was extremely crude and tedious prior to Golay’s development of the theory and practice of orthogonal shim coils.⁵ With the advent of FT NMR came more incentive to obtain higher resolution because of its dramatic impact on sensitivity. Ultrahigh purity (99.9995%) copper receive coils with precision magnetic compensation and Varian’s sample spinner mounted on top of the probe quickly became standard. An external lock employing a sealed sample and separate coil (usually tuned to ^{19}F or ^2H) beside the sample coil was used to stabilize the field.⁶

The probe rf circuitry was also quickly impacted by FT NMR. To excite the entire spectral width with large Helmholtz coils at 60 MHz required 10–100 W and generated several kV across the coil, so impedance matching to the transmit circuit became important. The increase in sensitivity from FT NMR opened up the field of multinuclear MR—especially ^{13}C and ^{31}P .⁷ The advantages in resolution and sensitivity provided by proton decoupling required double resonance circuits, which

made it more difficult to use separate transmit/receive coils, and double-tuned single-coil circuits with transmit/receive duplexers began to appear.^{8,9} It is fair to say that modern NMR probe technology was ushered in by David Hoult in 1976 with his transparent analysis of S/N based on the obscure concept of reciprocity.¹⁰ Today, separate transmit/receive coils survive only in single resonance MRI where the high rf homogeneity afforded by a large transmit coil is beneficial and small surface coils are optimum for reception.

Probe technology has matured over the past two decades, and major advances in most probe specifications are not expected. Nonetheless, probe technology will retain its pivotal role in NMR progress because even small improvements can contribute a lot to total system performance.

4 RADIOFREQUENCY ENGINEERING—BASICS

Basic rf engineering has been treated in a number of elementary texts^{11,12} and introductory review articles,^{13,14} but the probe engineer also needs a working understanding of some of the more advanced concepts in electromagnetic field theory.^{15,16} NMR signal reception is different from (and simpler than) antenna theory, in that antennas are designed to receive electromagnetic waves in the far-field limit whereas NMR probes are designed to sense magnetic fields in the near-field limit.¹⁷ While the rf circuits in NMR probes can usually be approximated with simple circuits and analyses, the critical importance of the probe to the total spectrometer performance justifies a level of detailed field and efficiency analysis seldom encountered outside of NMR probes. A number of articles^{10,18–25} and a textbook²⁶ have presented excellent treatments of general NMR probe design problems over the past two decades. A summary of basic NMR probe electronics follows.

4.1 Capacitance

Capacitance (farads) is defined as electric charge per volt (Q/V), and capacitive energy storage is equal to $CV^2/2$. Stray capacitance can often be estimated to sufficient accuracy from the expression for the parallel plate capacitor C_p of area A (m^2), separation distance d (m), and dielectric constant k_d ,

$$C_p = \frac{k_d \epsilon_0 A}{d} \quad (1)$$

or from the expression for the low-frequency capacitance of a coaxial capacitor²¹ of length h , dielectric o.d. d_o , and dielectric i.d. d_i ,

$$C_c = \frac{2\pi k_d \epsilon_0 (h + d_o)}{\ln(d_o/d_i)} \quad (2)$$

where ϵ_0 is the permittivity of free space, 8.84 pF m^{-1} . Parallel capacitors add algebraically, ($C_T = C_1 + C_2 + \dots$), while series capacitors add reciprocally ($C_T^{-1} = C_1^{-1} + C_2^{-1} + \dots$).

4.2 Inductance

The simplest definition of inductance L (henrys) comes from Faraday’s law of induction—the induced voltage divided

by the rate of change in current di/dt . For inductance calculations, the most practical ‘definition’ follows from the energy equation

$$U = i_T^2 L / 2 \quad (3)$$

where U is the total energy in the magnetic field (the integral of $B^2/2\mu\mu_0$ over all space) and i_T is the current at the pair of terminals generating the magnetic field $\mathbf{B}$. [We follow popular usage of denoting the magnetic flux density or induction field $\mathbf{B}$ (T) as the ‘magnetic field’ and $\mathbf{H} = \mathbf{B}/\mu\mu_0$ as the field intensity (A m^{-1}) where μ is the relative permeability of the material.] For all NMR probes, μ is always unity. The permeability of free space μ_0 equals $4\pi \times 10^{-7} \text{ H m}^{-1}$.

The inductance of the finite, multturn, single layer rf solenoid of Figure 1 with a constant pitch, an integral number of turns, and a high surface coverage is given in nH, for dimensions in mm, by the following expression:

$$L_S = \frac{4n^2 r^2 (1 - 0.2/n)}{h + 1.2r^{0.9}} \quad [\text{mixed}] \quad (4)$$

where n is the number of turns (Figure 1 has five turns), h is the overall axial length, and r is the effective inside

Figure 1 A five-turn solenoid

radius, which for round wire is approximately equal to the inside coil radius plus 20% of the wire radius. The last term in the numerator corrects for the fact that the helix makes the effective coil length a little less than the overall length. The above expression is correct to within several per cent for $h/r > 0.2$. For the loop-gap resonator^{27,28} (a single-turn solenoid, also called a split ring), the helix correction term is dropped, and the coefficient changes to 3.9 to correct for current concentrating at the ends of the ring. Higher order corrections for multturn coils with low surface coverage can be added.

Lead (parasitic) inductance is usually best estimated by calculating the inductance of a loop-gap resonator having a length equal to the diameter of the lead wire and $r^2 = A_C/\pi$, where A_C is the area enclosed by the loop formed by the leads. Sometimes lead inductance is better estimated from the expression for the inductance L_C of a coaxial transmission line:

$$L_C = \frac{\mu_0 h}{2\pi} \ln \left(\frac{d_o}{d_i} \right) \quad (5)$$

Clearly from equation (5), series inductors add like resistors ($L_T = L_1 + L_2 + \dots$); likewise, parallel inductors add reciprocally ($L_T^{-1} = L_1^{-1} + L_2^{-1} + \dots$).

4.3 Single Resonance Circuits

4.3.1 Power

Figures 2 and 3 illustrate the basic RLC series and parallel circuits, respectively. The losses in the series RLC circuit of Figure 2 are best represented by the total effective series resistance R_s (from the coil, capacitor, leads, etc.). For the parallel circuit of Figure 3, the losses may be represented more conveniently by a total effective parallel resistor R_p . In both cases, the basic equations from ac circuits apply for rms power P and peak power P_p . (Power is assumed to be rms unless denoted otherwise.)

$$P = \frac{P_p}{2} = \frac{i_p^2 R_s}{2} = \frac{V_p^2}{2R_p} \quad (6)$$

Power ratios are often expressed in dB, $10 \log(P_2/P_1)$, and power is often expressed in dBm—defined as dB relative to a milliwatt:

$$\text{dBm} \equiv 10 \log(1000P) \quad (7)$$

In practice, peak-to-peak voltages ($2V_p$) are usually measured on an oscilloscope, and the measurements are significantly influenced by harmonic distortion, VSWR (Voltage

Figure 2 Series RLC circuit

Figure 3 Parallel RLC circuit

Standing Wave Ratio), loading, and oscilloscope bandwidth. Most conventional liquids probes are excited with 100 W pulses of 10–80 μ s at the observe frequency (usually the low frequency, LF) at duty cycles below 0.1% while they are driven with 10 W at the decouple frequency (usually ^1H , the high frequency, HF) at duty cycles below 50%. Solids probes typically see LF pulses of 200–400 W with duty cycles up to 1% while irradiating with HF power of 50–200 W at duty cycles below 30%. Whole body MRI probes are usually driven with 1–10 kW at duty cycles below 0.5%.

4.3.2 Resonance

Since charge (q) equals CV and $i = dq/dt$, a capacitor reaches a steady-state (monochromatic) reactance X_C (analogous to resistance, V/i) of $1/i\omega C$ after several RC time-constants, where i is the imaginary unit, $\sqrt{-1}$. Likewise, since $V = -L di/dt$, an inductor has reactance $X_L = i\omega L$ and time constant L/R . For the normal high- Q condition ($Q = \omega_0/\Delta\omega_{1/2}$), resonance occurs when the inductive reactance X_L plus the capacitive reactance X_C equals zero. (Often the phase is omitted for convenience, but it must be remembered that the voltage phase in the inductor leads by 90° while in the capacitor it lags by 90° relative to that in the resistor.) Hence,

$$\omega_0 = \frac{1}{\sqrt{LC}} \quad (8)$$

At resonance, the series impedance of the series RLC circuit is R_s (since $X_L + X_C = 0$) and the parallel impedance of the parallel RLC circuit is R_p [since $(X_L X_C)/(X_L + X_C) = \infty$]. The 3 dB width $\Delta\omega_{1/2}$ of the resonance defines the quality factor of the unloaded (and unmatched) RLC circuit, and the following relationships are readily derived:

$$R_p = QX_L \quad (9)$$

$$R_s = X_L/Q = R_p/Q^2 \quad (10)$$

4.3.3 Matching

Since X_L is typically 20–200 Ω , R_s is usually less than 1 Ω and R_p is greater than 2000 Ω . For efficient coupling to the transmitter and preamplifier, the resonant circuit, transmission lines, preamplifier, and transmitter must all be matched to approximately the same impedance, although mismatches of up to a factor of two are often unimportant. The international standard is 50 Ω (except in the television industry, where it is 75 Ω). Figures 4 and 5 illustrate the two basic methods of impedance matching: shunt inductor and series capacitor.

The inductive matching technique has the advantage of not requiring a second high-voltage capacitor, but the matching

Figure 4 Shunt inductive matching circuit

Figure 5 Series capacitive matching circuit

range is limited by the difficulty of adjusting very small inductors. The required shunt inductor (for $R_p \gg Z_0$) is

$$L_M = L_T \sqrt{Z_0/R_p} \quad (11)$$

where L_T is the total series inductance ($L_s + L_M + \text{leads}$) and Z_0 is the transmission line characteristic impedance—normally 50 Ω . The resonant frequency is calculated from L_T and C .

The capacitive matching circuit simplifies multinuclear (broadband) tuning requirements as high-voltage (HV) variable capacitors are readily available. The required match capacitance (again, for $R_p \gg Z_0$) has reactance X_{CM} given by

$$X_{CM} = \sqrt{R_p Z_0} \quad (12)$$

and rms current equal to that in the transmission line, $\sqrt{P/Z_0}$. In practice, some combination of capacitive and inductive matching is often used, and capacitive voltage division is often employed to reduce the demands on the matching variable capacitor.²⁹ Properly ‘pruned’ transmission lines can also be used to transform impedance (see *Probes for Special Purposes*).

5 SIGNAL-TO-NOISE RATIO AND B_1

5.1 Magnetization and the NMR Signal

The NMR voltage signal S from a sample with susceptibility χ , with nuclear spins precessing at angle ϕ in magnetic field B_0 at angular frequency ω , detected by a coil that generates a circularly polarized (rotating) transverse field $B_1(r)$, over the sample volume V_S for current i , may be shown from the principle of reciprocity^{10,26} to be

$$S = \frac{\chi B_0 \omega}{\mu_0 i} \int_S \sin \phi B_1(r) dV \quad (13)$$

Simply put, the receiver coil need only be analyzed as a B_1 transmitter. For a uniform B_1 generated by a current i ,

immediately following a 90° pulse,

$$S = \frac{\chi B_0 \omega B_1 V_S}{\mu_0 i} \quad (14)$$

The equilibrium magnetization M_0 is given by^{1,6}

$$M_0 = \frac{\chi B_0}{\mu_0} = \frac{n_s \gamma^2 \hbar^2 I_x (I_x + 1) B_0}{3 k_B T_S} \quad (15)$$

where n_s is the number of spins at resonance per unit volume, γ is the magnetogyric ratio, I_x is the spin quantum number, k_B is Boltzmann's constant, T_S is the sample temperature, and $\hbar = h/2\pi$, where h is Planck's constant.

5.2 Thermal Noise

The Johnson (thermal) rms noise N from a resistor R_E for filter bandwidth $\Delta\nu$ (not ν/Q) is^{1,2}

$$N = (4 R_E k_B T_R \Delta\nu)^{1/2} \quad (16)$$

where T_R is the temperature of the resistor. (For $R_E = 50 \Omega$, $N = -168 \text{ dBm Hz}^{-1/2}$.) The effective series resistance (X_L/Q) of the loaded circuit is best determined by measuring Q . Other noise sources (interference, triboelectric, spurious, shot, microphonic, preamplifier) can usually be made negligibly small with careful engineering.²³

5.3 B_1 in the Rotating Frame

A linearly polarized oscillating magnetic field $2B_1$ (as in a solenoid) may be decomposed into the sum of two oppositely rotating circularly polarized fields, each of magnitude B_1 . One of these components can be used to drive NMR precession within a bandwidth approximately equal to its magnitude (in Hz) if it is transverse to B_0 ; the other has no effect on NMR precession, as its frequency in the rotating frame is -2ω . From the Biot-Savart law,¹⁵ B_1 at the center of a solenoid is given by

$$B_1 = \frac{\mu_0 n i}{2h \sqrt{1 + 4(r/h)^2}} \quad (17)$$

Using equations (3), (6), and (10), it may be shown that $U = PQ/\omega$, and B_1 may be expressed as follows for the infinite solenoid:

$$B_1 = \left[\frac{\mu_0 P Q}{2\omega V_C} \right]^{1/2} \quad (18)$$

where V_C is the coil volume. [Adding the term $1 + 4(r/h)^2$ in the denominator inside the brackets of equation (18) improves the accuracy for typical solenoids.]

The unloaded Q_0 of the typical multiturn solenoid (well below self-resonance and with high surface coverage) is, in mixed units, approximately

$$Q_0 \approx 6\sqrt{hrf} \quad [\text{MHz}^{1/2} \text{ mm}^{-1}] \quad (19)$$

Saddle coils (commonly, but incorrectly, called Helmholtz coils;¹⁵ more properly they could be called Ginsberg³⁰ or Golay⁵ coils) and slotted resonators^{19,25} are better suited for liquids NMR in superconducting magnets, as they generate a transverse B_1 while allowing axial access. Moreover, their axial symmetry makes it easier to obtain high B_0 homogeneity. The coefficient in equation (19) is reduced to a value of 2 for saddle coils with medium surface coverage, as is necessary for orthogonal double resonance operation.

The loaded circuit quality factor Q_L will be lower than that of the coil because of losses in capacitors, shields, and sample. A convenient method of measuring Q_L is with a reflectance bridge, where the appropriate Δf value is measured at -7 dB return loss, which may be calibrated with a 21Ω or 119Ω load on a 50Ω line.²³ (Q_L is not lowered much by 'matching' to the preamplifier if its noise figure is less than $\sim 1 \text{ dB}$.)

For any coil, average B_1 in gauss over the usable volume may be expressed in mixed units by the following:

$$\langle B_1 \rangle = \beta \left[\frac{\eta_E P Q_L}{f V_C} \right]^{1/2} \quad [\text{mixed}] \quad (20)$$

where β is a dimensionless function of coil geometry, f is in MHz, V_C is in mL, and η_E is the rf efficiency—the fraction of the power delivered to the rf coil and sample.²¹ The rf efficiency η_E is usually greater than 0.9 for single resonance circuits at low fields, but it may be less than 0.2 for double resonance at high fields. In practice, it is always necessary to measure rather than calculate Q_L , which then includes the capacitor losses. The above equation is still valid if η_E is then defined as $1 - \eta_L$, where η_L is the fraction of the power dissipated in inductors not generating B_1 (leads and coils added for multiple resonances).

For special high-resolution applications of solenoidal rf coils, the optimum h/r value is 2, and $\beta \approx 2.4$. For very lossy samples, the optimum h/r is the largest permitted by space constraints, and $\beta = \sqrt{10}$ for the infinite solenoid. For MAS, the optimum h/r is 3, and $\beta = 2.1$ when the coil is at the magic angle. For saddle coils and slotted resonators, β ranges from 0.8 to 1.4, depending on surface coverage, subtended angle, and the ratio of height to diameter.

A magnetic filling factor η_f may be defined by

$$\eta_f = \frac{\int B_1^2 dV}{\mu_0 U} \quad (21)$$

where the integration is over the sample volume V_S . From equations (3), (10), (20), and (21) comes a very practical (and exact) definition of the filling factor:

$$\eta_f = \frac{\beta^2 V_S}{20 V_C} \quad (22)$$

5.4 S/N

From the above, the S/N from a single 90° pulse with an optimum filter [$1/(\pi \Delta\nu) = T_2$, the spin-spin relaxation time, and $\Delta\nu < \omega/2\pi Q_L$] can be written as follows:

$$\begin{aligned}
S/N &= \frac{S}{2N} \\
&= \left[\frac{\hbar^2 \sqrt{\pi \mu_0}}{12 k_B^{3/2}} \right] \left[\frac{n_s \gamma I_x (I_x + 1) \sqrt{T_2}}{T_S \sqrt{T_R}} \right] (\eta_E \eta_f Q_L V_S)^{1/2} \omega^{3/2}
\end{aligned} \quad (23)$$

The extra factor of 2 in the denominator arises because S is the initial peak signal voltage that decays with time-constant T_2 and N is the rms noise voltage. The product of the two bracketed terms is $1.65 \times 10^{-5} \text{ s}^{3/2} \text{ m}^{-3/2}$ for protons in water with $T_2 = 0.1 \text{ s}$ and $T_S = T_R = 300 \text{ K}$.

A useful simplification of equation (23) is the following for given NMR conditions (sample, γ , B_0 , T_S , T_2 , technique):

$$S/N \propto \frac{V_S}{\tau_{90} \sqrt{P}} \quad (24)$$

where τ_{90} is the mean 90° pulse width obtained over sample volume V_S with power P .

5.5 Minimizing Losses

For small samples, the Q_L is usually dominated by coil resistance. However, above 400 MHz it may be dominated by capacitor losses unless extreme care is taken in their selection, and it may be necessary to parallel a number of low-value capacitors for sufficiently low capacitor losses. For large, lossy samples, Q_L and T_R are dominated by sample losses. Dielectric losses from electric fields in the sample may be reduced by decreasing the coil inductance and increasing the capacitance.^{20,31} Usually, the only ways to reduce power P_S deposited by the inductive mechanism in a sample of uniform resistivity by a rotating B_1 are to maximize the B_1 homogeneity and to maximize the rms flux path length ξ for a given volume, but sometimes it is possible to use insulating films to suppress currents in the sample.³² The presence of skin, fat, and bones in MRI can make the estimate of P_S as much as an order of magnitude too large when using a worst-case tissue resistivity ρ_S of $1.2 \Omega \text{ m}$.

$$P_S \approx \frac{B_1^2 \omega^2 V_S^2}{16 \pi \rho_S \xi} \quad (25)$$

Equation (25) is equivalent to the low-frequency limit given by Carlson²⁴ for a sphere, but the inclusion of ξ improves loss predictions for nonspherical samples. The loaded Q_L may be estimated from the unloaded Q_0 and the sample Q_S :

$$Q_L = \frac{Q_0 Q_S}{(Q_0 + Q_S)} \quad (26)$$

For reasonably uniform, linear B_1 , Q_S is approximately

$$Q_S \approx \frac{32 \pi \rho_S \xi V_C}{\mu_0 \eta_E \beta^2 \omega V_S^2} \quad (27)$$

The numerical coefficient in equation (27) is increased to 64 for circular polarization.

The ratio Q_0/Q_L has frequently been used as a figure-of-merit for coils in MRI, but this does not properly consider the

dielectric losses nor the major effects of B_1 inhomogeneity in surface coils.³³ equation (24) provides a better figure-of-merit, but it still does not adequately evaluate homogeneity.

The ‘birdcage’ resonator of Edelstein et al. made quadrature coils practical for generating a single rotating B_1 .^{22,34} Liquids and solids NMR find few applications for quadrature rf coils, as coil losses usually dominate. However, in MRI, when inductive sample losses dominate, quadrature coils offer up to a 40% improvement in S/N. For an advanced treatment of the birdcage resonator, the reader is referred to the article by Tropp.³⁵ (See also *Birdcage Resonators: Highly Homogeneous Radiofrequency Coils for Magnetic Resonance*.)

A proper calculation of L , B_1 , and Q_0 requires a knowledge of the surface current distribution in the conductors—especially in single-turn resonators.²⁵ The so-called ‘proximity effect’ is ambiguous. A better method of determining current distribution in large conductors is to iterate on Biot–Savart integration, letting the currents move around in the conductors to a minimum inductance ($2U/i_T^2$) configuration. The current usually prefers to take the shorter paths (inside surface) and tends to concentrate near regions of high flux curvature (end edges) and high flux density (nearby shields). The normal component of the rf magnetic field always vanishes near the surface of conductors, and the current penetrates only to a depth given by the classical skin depth:

$$\delta = \left(\frac{2}{\omega \mu_0 \sigma} \right)^{1/2} \quad (28)$$

where σ is the electrical conductivity. For copper at 300 K, $\delta = 6.4 \mu\text{m}$ at 100 MHz. Nonuniform surface current density is responsible for Q_0 being lower by a factor of 3–8 than would occur for uniform surface current density. In some cases, Q_0 may be improved by the use of Litz wire (woven wire, using individually enameled strands as fine as 0.03 mm).

6 DOUBLE RESONANCE

Two saddle coils, rotated 90° about the B_0 axis provide a convenient method of doing double resonance NMR with good isolation. However, only the innermost coil can have the optimum filling factor, and sometimes it is beneficial to have the same spatial distribution of the two rf fields, B_1 and B_2 . Also, triple- or quadruple-resonance NMR experiments are often useful. Thus, it is often desirable to double-tune or triple-tune a single sample coil, although Anderson described in 1973 a clever method of using three orthogonal, single-tuned coils.³⁶

The number of modes in a resonant circuit will generally be equal to the number of unique inductors or capacitors, whichever is fewer. (Resonant transmission lines may count as either.) It is sometimes necessary to add additional inductors or capacitors (producing extraneous modes) to improve isolation or to achieve balance at the frequencies of interest, although this can complicate tuning.^{37,38} The most common double-tuned circuit, shown in Figure 6, has been analyzed by several authors.^{21,23,39} It has an HF parallel mode and an LF series mode. The efficiency at the HF is increased by decreasing L_S/L_H , where L_S is the sample coil inductance and L_H is the HF tuning coil inductance. On the other hand, efficiency

Figure 6 Double resonance circuit

at the LF is increased by increasing L_S/L_H . In principle, if the losses in L_H and the tuning capacitors can be made vanishingly small compared with sample losses, the efficiency can approach 100% at both frequencies.⁴⁰ Rise time, however, will be degraded (because the total Q_L must increase), but this is seldom significant for in vivo experiments. For 8-mm sample coils, efficiencies at HF and LF are typically 40% and 75% respectively (when Q_L includes capacitor losses, as in the referenced analyses). From equations (20) and (23), B_1 and S/N are degraded only as the square root of the efficiency.

7 CONSTRUCTION MATERIALS AND TECHNIQUES

Although B_0 homogeneity specifications sound frighteningly stringent, the capability of orthogonal shim systems is such that only in the immediate vicinity of the sample is magnetic susceptibility critical. Austenetic stainless steels (with SI volume susceptibility $\chi_v = \mu - 1 \approx 0.02$) can often be used for thin-walled Dewars surrounding the sample region and for Dewared transfer lines, although glass is preferred if space permits. It is, of course, desirable to minimize the amount of shimming effort required when the probe is changed, so low-susceptibility construction materials and thin sections are preferred. The magnetic susceptibilities of the components immediately above and below the sample region (in the B_z direction) are more significant, and axial and azimuthal symmetry are both important.^{41,42}

The common aluminum alloys⁴³ 6063-T6 (0.7% Mg, 0.4% Si, up to 0.3% Fe) and 6061-T6 (1% Mg, 0.6% Si, 0.3% Cu, 0.3% Cr, up to 0.7% Fe) are usually acceptable for thin shield cylinders and support structure since the iron is usually in a nonmagnetic phase (FeAl_3 or Fe_2Al_7),⁴⁴ but they often present acoustic ringing problems below 15 MHz.⁴⁵ Jewelry bronze [copper alloy C22600, 87.5% Cu, 12.5% Zn, 0.005% (max.) Fe] is usually a better choice for shields and support structure because of its lower magnetism, much higher acoustic absorption, good electrical conductivity, high strength, and excellent finishing and joining properties. Iron content is also rather carefully controlled in the more readily available phosphor-tin bronzes, such as C51000 [94.8% Cu, 5% Sn, 0.2% P, 0.1% Fe (max.)]. Aluminum, silicon, and zinc bronzes (or brasses) have to be checked carefully if they are to be used within $r_b/3$ of the sample, where r_b is the bore radius, as iron contents can exceed 0.5%. Copper-rich iron compounds are not stable, and the solubility of iron in copper at 200 °C is only 13 ppm,⁴⁴ thus copper alloys are likely to be ferromagnetic unless the iron is bound up in iron-poor compounds (such as FeAl_3 or FeSi_2), in which case it is still strongly paramagnetic ($\chi_v \sim 2$ for Fe_2O_3). For B_0 above 2.16 T, the ferromagnetic components saturate with a high-field χ_v of 2.16 T/ B_0 .

The critical importance of high-integrity ground connections throughout multiple resonance probes cannot be overemphasized, especially as the wavelength becomes comparable to or shorter than four times the maximum dimension of the electronics region. Welding, press-fits, and solder joints are preferred over silver-filled epoxy and silver paint.²³ The external shield cylinders are often anodized for an aesthetically pleasing finish that also helps eliminate variability in grounds. Figure 7 illustrates three typical NMR probes: a high-resolution liquids narrow bore probe, a CP MAS wide bore probe, and a single crystal probe with a goniometer.

Quartz is usually selected for coil forms in high-field magnets because of its lower dielectric loss, even though its magnetic, mechanical, and acoustic properties are inferior to those of Pyrex. Acoustic ringing in quartz, Macor, and ceramic capacitors may cause problems at frequencies up to 50 MHz. Zirconia has often been used in MAS probes for solids because of its superior mechanical properties.

One of the best engineering thermoplastics is polyether ketone (PEK) because of its low dielectric loss and excellent chemical, thermal, and dimensional stability at modest cost, but other insulating materials (Kel-f, Teflon, Macor, Vespel, zirconia) are often chosen for specific background or thermal considerations. Fiberglass reinforced composites are also widely used, but they must be cleaned well after machining to

Figure 7 Three typical NMR probes

remove traces of steel from the tools, and the glass fibers may produce aluminum and silicon background signals. Excellent epoxies are available for securing components and mounting coils—such as Epo-Tek 354, 360, and 377 from Epoxy Technology, Inc., Billerica, MA, USA. Several brands of Kelf and heat-shrink Teflon have sufficiently low hydrogenous content for critical proton applications, but experimentation and careful control are necessary.

8 THERMAL ENGINEERING

Linewidth and lineshape are often critically dependent on temperature control and stability.⁴⁶ Most commercial probes are intended to operate from -100°C to $+120^{\circ}\text{C}$, but special liquids probes are commercially available for operation from -170°C to $+380^{\circ}\text{C}$, and solids probes are available to cover the range 35–900 K. Temperatures are usually regulated by using a dc resistive heater (designed for minimal magnetic interaction) to heat a stream that is directed past the sample.

First-order heat-transfer calculations and simple power balance analysis are generally sufficient in the probe design. The heater power P_H required to increase the temperature of the gas by δT with specific heat C_p ($1000\text{ J kg}^{-1}\text{ K}^{-1}$ for N_2) and flow rate G (typically $1\text{--}2\text{ g s}^{-1}$ for MAS probes) is

$$P_H = GC_p\delta T \quad (29)$$

The gas temperature is usually measured with a copper–constantan thermocouple shortly before it reaches the sample, but optical sensors have also been used.⁴⁷ Platinum resistors (RTDs) are best in the range from 20–75 K and above 700 K, but in the intermediate range they are not as accurate as a thermocouple unless small magnetic-field-dependent corrections are made. They are often used to sense the heater temperature for protection in the event of inadvertent loss of gas flow. The control problems are more difficult than usually encountered elsewhere because of the requirement for precision temperature control of a stream of low specific heat that may encounter large fluctuations in flow rate. Standard PID (proportional-integral-derivative) control algorithms have been incorporated within the past several years by all manufacturers with vast improvements over the simple PI algorithms used previously. Dynamic control stability can be further improved by adding a power estimate that is a function of temperature and flow rate, and fuzzy logic may have advantages. Lead shot has occasionally been used for a thermal ballast because of its high volumetric specific heat and low Debye temperature (105 K).

Heat-transfer calculations are often limited to simple conduction calculations through thin sheets:

$$P_T = k_T A \delta T / d \quad (30)$$

where P_T is the thermal conduction power (W), k_T the thermal conductivity (W m^{-1}) of the material, A the area perpendicular to the direction of heat transfer, δT the temperature difference between the two surfaces, and d the thickness in the direction of heat transfer. The other common conduction problem is through a thick-walled tube with i.d. d_i , o.d. d_o , and length h :

$$P_T = \frac{2\pi k_T h \delta T}{\ln(d_o/d_i)} \quad (31)$$

The high Reynolds numbers (often greater than 10^5) that are seen in Dewared transfer lines result in a very high heat transfer through the bare glass or metal joints unless they are lined internally with plastic tubing, in which case the above equation can be used to estimate the losses.

The extreme temperatures that are often desired^{48–50} can make differential thermal expansion responsible for stresses that exceed the rupture limit of one of the components in the probe if not properly designed. However, most of the materials used in NMR probes have high strength. The exceptions, Macor and glasses, tolerate high compressive stresses. Hence, even these materials can often be used with plastics in properly designed situations even though their thermal expansions differ widely. Macor is the only commonly used material that is likely to rupture from internal steady-state thermal stresses, as its maximum thermal stress temperature ($T_T = S/b_T E$, where S is tensile strength, b_T thermal expansion coefficient, and E the Young's modulus of elasticity) and thermal conductivity are both very low.

9 GRADIENT NMR PROBES

By applying magnetic field gradients in three orthogonal directions ($\delta B_z/\delta x$, $\delta B_z/\delta y$, $\delta B_z/\delta z$), it is possible to use NMR to image macroscopic structures, and indeed this has made clinical magnetic resonance imaging (MRI) an important medical diagnostic technique.^{51,52} Obtaining spatial resolution below 1 mm on liquid-like samples requires gradients above the 10 m T m^{-1} available in most clinical MR machines. Higher gradients are easily obtained by reducing the size of the gradient coils or improving their efficiency. MR microscopy generally involves incorporating the gradient coils into wide-bore or narrow-bore probes along with small rf coils so that spatial resolution down to $10\text{ }\mu\text{m}$ can be obtained on liquid-like samples. Limited imaging experiments are also then possible on solid samples.⁵³

Single axis gradients ($\delta B_z/\delta z$) based on Maxwell pairs (sometimes called anti-Helmholtz coils) are much easier to implement in small spaces and are very useful for diffusion experiments using pulsed field gradients (PFG).⁵⁴ Similar probes (with lower gradient coefficients, to keep digital-to-analog convertor and amplifier drift requirements more manageable) have recently become very popular for gradient enhanced spectroscopy (GES), as the run time is often dramatically reduced for 2D NMR.

Rapid switching of large gradient coils requires high-power audio amplifiers (up to 500 kW). Hence, the switching efficiency η_s is very important:

$$\eta_s = \frac{\alpha^2 d_s^4 h_s}{\mu_0 L} \quad (32)$$

where α is the gradient coefficient ($\text{T A}^{-1}\text{ m}^{-1}$), d_s the sample diameter, h_s the sample length, and L the gradient coil inductance. (The gradient coefficient is sometimes called the 'efficiency', but the above dimensionless definition is more consistent with other efficiency definitions.) The 'fingerprint'

design of Schenck et al.⁵⁵ achieves much higher η_s values than earlier Golay coils, but new proprietary designs achieve even higher efficiency.

Image linearity has often been described in terms of field linearity—the relative difference between the gradient field and a linear field at the edge of the sample. A better definition of image linearity is rms local deviation of the gradient from its mean value throughout the sample volume. This has also been called differential linearity. It is sometimes desirable to use highly nonlinear local gradients (more than 40% local deviation) and image distortion correction software so that higher gradients can be achieved,⁵⁶ but local deviation below 10% is usually preferred.

When the gradients are switched, eddy currents are induced in the cold radiation shield of the magnet that have long decay times because of the ultralow resistivity of copper below 40 K. Active shielding of the gradients greatly reduces the external fields generated by the gradients and permits rapid pulse techniques without excessive cryogen boiling or high-order compensation techniques.^{57,58} Acoustic resonances in the gradient coils are then likely to limit gradient decay time, particularly at very high fields, but novel coil geometries are becoming available that greatly reduce this electromechanical or acoustic efficiency.

1 INTRODUCTION

The NMR probe provides the coupling between the nuclear spins of the sample and the spectrometer electronics. As such, it must provide a rotating radiofrequency (rf) field perpendicular to the polarizing magnetic field to excite the spins and, similarly, detect the rotating magnetization of the spins. While these considerations apply to any NMR probe, a particularly important requirement for high-resolution NMR probes is to minimize the perturbation of the polarizing magnetic field so as to maintain the inherent resolution of the signals. This has become more important as the proton resonance frequency of high-resolution spectrometers has increased from the earliest values of 30 MHz to 750 MHz or more.

For a given magnetic field strength, the probe is a primary determinant in the *sensitivity* of a *spectrometer*. Sensitivity can be improved by using a larger sample, thereby including more spins, provided that the field homogeneity can be maintained over the sample volume. Larger volumes are typically used to observe the resonances of low- γ nuclei for which the inherent sensitivity is lower, and the resolution requirements are less severe, than for proton NMR.

The excitation and detection of a single nuclear species can be accomplished with a fairly simple probe structure. However, as the techniques of high-resolution spectroscopy have developed, it has become increasingly common to excite and perhaps detect the response from more than one nuclear species simultaneously.

The probe structure must also provide the required environment for the sample. This usually means the provision of an accurate and stable temperature control. For more sophisticated experiments, it may also be necessary to provide pulsed magnetic *field gradients*, optical excitation, or high sample pressure.

2 HISTORICAL REVIEW

The earliest high-resolution spectrometers operated in the continuous wave (CW) mode and were designed to excite and observe a single nuclear species, usually protons. Two different types of probe systems were used for the detection of the weak NMR response in the presence of the strong rf

excitation. In the single coil system, derived from the work of Purcell,^{1,2} one coil was used for excitation and detection, while isolation of the transmitter and receiver was achieved by including the probe in one arm of a bridge circuit. The bridge was adjusted close to a complete balance in the absence of an NMR absorption. A nuclear resonance changed the balance to produce a detectable signal. In the crossed-coil system, first used by Bloch and his co-workers,^{3,4} two separate coils were used for transmission and reception. By arranging the coils to be geometrically orthogonal to minimize the magnetic coupling, and by including an electrostatic screen between the two coils to minimize capacitive coupling, the direct interaction could be kept to a low value. An NMR response induced a signal in the receiver coil. With both coil systems, it was possible to detect either an absorption or a dispersion signal by detecting the NMR response as a change of a deliberately introduced 'leakage' signal. The bridge circuit included two adjustments to control the in-phase and quadrature phase imbalance. The crossed-coil probe included two 'paddles'^{5,6} to control in-phase and quadrature phase leakage between the transmitter and receiver coils.

The magnetic field was typically generated between the poles of an electromagnet or permanent magnet with the sample arranged perpendicular to the axis of the magnet poles. A solenoidal coil around the sample provided the appropriate orientation of the rf field for the detection of the nuclear magnetization. In a crossed-coil probe, a second coil system, arranged in the form of a large Helmholtz pair, with its axis perpendicular to the polarizing field, was used as the transmitter. The use of a separate transmitter coil provided a very uniform rf excitation although it did require a larger transmitter power. For CW experiments, this additional transmitter power was not a serious problem.

Sample spinning^{7,8} was introduced to average transverse gradients and thereby improve resolution. Consequently, from an early date, a high-resolution NMR probe included a mechanism to provide for spinning the sample at a few tens of revolutions per second. An air bearing and drive was the preferred method, since this was the only way to provide a sufficiently smooth rotation.

The influence of the probe design on the spectrometer resolution was recognized early on. Symmetry of materials around the active sample volume was vital, as was the choice of probe material itself. It was particularly important to use materials which were uniform in composition and free from ferromagnetic impurities. The receiver coil, which was, of necessity, very close to the sample, was a particular concern. Low susceptibility materials were selected or specially manufactured⁹ to minimize the magnetic perturbations introduced by the coil.

The use of modulation^{10,11} and the phase-sensitive detection of modulation sideband signals helped to improve the isolation of the transmitter and received signals. Magnetic field modulation, at frequencies typically in the range of a few kHz, was provided by coils built into the probe. Field modulation allowed the generation of multiple effective rf fields by the addition of different modulation frequencies. Thus, the use of homonuclear decoupling^{12,13} or of a homonuclear field/frequency lock¹⁴ did not change the rf configuration of the probe.

The introduction of pulsed *Fourier transform* (FT) methods^{15,16} required much higher rf excitation fields and, to keep transmitter powers to reasonable levels, the use of separate

transmitter and receiver coils for a single nucleus quickly died out. Since the transmitter and receiver functions occupied separate time intervals, a single coil could be switched between transmission and reception using techniques which were well established in pulsed NMR methods.^{17,18}

Superconducting magnets for high-resolution NMR were introduced at about the same time as FT methods.¹⁹ The configuration of the superconducting magnet was different from that of existing electromagnets and permanent magnets; it was in the form of a solenoid with the magnetic field generated along the axis of the solenoid. This required a significantly different probe geometry.

3 MODERN PROBE TECHNOLOGY

3.1 Introduction

Since the majority of modern high-resolution probes are designed for use in superconducting magnets with pulsed FT spectrometers, the most common configuration is one in which the sample is parallel to the axis of the magnet and one or more saddle-shaped rf coils are arranged around the sample. Solenoidal coils are somewhat more efficient than saddle coils^{20,21} but their use would require the sample to be placed perpendicular or at an angle to the magnet axis. The added inconvenience in sample handling and the implications for resolution are only warranted for special applications.

The transmit and receive functions for the nuclear species being observed are handled on a single coil. However, most high-resolution experiments require the probe to support more than one nuclear resonance frequency. In the simplest configuration, this may be only a single observe nucleus (for example, protons) and a field/frequency lock nucleus (for example, deuterium). In this case, the most common practice is to 'double tune' a single coil²² to support both frequencies.

In addition, many experiments demand the irradiation of other nuclear species, either to provide coupling information by *multidimensional methods*^{16,23,24} or to remove couplings during acquisition, for example by broadband *decoupling*.^{25,26} While it is possible to multiply tune a single coil, by an extension of the double tuning scheme, it is more common to provide a second coil, arranged geometrically orthogonal to the first, to support the additional frequency or frequencies. Coupling between the two coils can be reduced to about -20 dB or -30 dB from geometry alone. Greater isolation is required to prevent overloading of the receiver electronics and is provided by frequency-selective filters (either internal to the probe, or external).

3.2 Probe Tuning

The probe coil is tuned and matched, usually to $50\ \Omega$, to provide efficient coupling to the rest of the circuit. A common circuit for a single tuned coil is shown in Figure 1(a) and for a double tuned circuit in Figure 1(b). The resonant frequency of the singly tuned circuit is given by

$$\omega = \frac{1}{\sqrt{L(C_1 + C_2)}} \quad (1)$$

Figure 1 (a) A two capacitor network to tune and match a sample coil, L , to a resistive impedance. (b) A double tuned circuit providing separate inputs for the high- and low-frequency signals. The trap circuit formed by L_T and C_T is tuned to approximately the same frequency as the high-frequency circuit. Capacitors C_3 and C_4 provide tuning and matching for the low-frequency signal

and the input resistance at resonance by

$$R_{in} = \frac{1}{\omega^3 L Q C_2^2} \quad (2)$$

For a high- Q circuit, $C_1 \gg C_2$, and C_1 primarily affects the tuning and C_2 the impedance match. By providing a wide range of variability in the values of these capacitors, a probe may be made to tune over a wide frequency range to allow excitation and/or detection of many nuclear species. It is normally not feasible to provide a very wide tuning range with a variable capacitor alone. Instead, a range of fixed capacitors is switched in parallel with a variable capacitor of more limited range. In this way the physical size of the circuits and the associated inductance can be kept small.

3.3 Sensitivity

For a given operating magnetic field strength, the NMR probe is the primary factor governing the sensitivity of a spectrometer. Both the signal voltage and the major noise source originate in the probe.

The factors affecting the sensitivity of a signal excited by a single pulse can be understood by considering the equivalent circuit of a receiver coil shown in Figure 2. The voltage source e_s represents the signal voltage induced in the coil by the precessing magnetization, while e_n represents the rms thermal noise voltage generated in the resistance r of the circuit. The resistance may be due to losses in the coil and capacitors of the probe, or to conductive losses in the sample itself.

The signal voltage is best calculated by invoking the principle of reciprocity as described by Hoult and Richards.²⁰ If a coil carrying a unit current produces a transverse magnetic

Figure 2 The equivalent circuit of a receiver coil

field B_t at a given point in space, then a magnetic dipole m at that point will induce an emf in the coil given by

$$e_s = -(\mathrm{d}/\mathrm{d}t)(B_t \cdot m) \quad (3)$$

For an extended sample, this expression must be integrated over the sample volume, V_s . In terms of the probe parameters and its operating frequency, ω , the signal voltage may be written as

$$e_s \propto N\lambda\omega^2 B_t V_s \quad (4)$$

where N is the concentration of spins and λ has been introduced as an ‘inhomogeneity factor’ to reflect the variation of B_t over the sample volume. This may be calculated analytically for some geometries and numerically in more complex cases. The induced voltage is expressed in terms of the coil inductance by introducing a ‘filling factor’ defined by

$$\xi = \frac{\int_{\text{sample}} B_t^2 \mathrm{d}V}{\int_{\text{all space}} B^2 \mathrm{d}V} \quad (5)$$

and representing the fact that only a portion of the total magnetic energy of the coil is effective in exciting magnetic resonance. The inductance of the coil is given by

$$L = \frac{1}{\mu_0} \int_{\text{all space}} B^2 \mathrm{d}V \quad (6)$$

since B has been defined for a unit current in the coil. We may then write

$$\xi' = \frac{B_t^2 V_s}{\mu_0 L} \quad (7)$$

where ξ' represents a modification of the filling factor to account for the inhomogeneity of the rf field over the sample volume. The induced signal is thus

$$e_s \propto N\lambda\omega^2 (\xi' L V_s)^{1/2} \quad (8)$$

The signal is coupled to the spectrometer by a tuning and matching network, for example that shown in Figure 1(a).

The rms thermal noise voltage generated in the resistance r of the coil is

$$e_n = (4kTr\Delta f)^{1/2} \quad (9)$$

where k is Boltzmann’s constant, T is the temperature of the resistance (normally equal to the sample temperature), and Δf

is the bandwidth of the measurement. The noise voltage is transformed by the matching network exactly as the signal voltage, but additional noise power, characterized by the noise factor F , is introduced by the spectrometer electronics. The receiver bandwidth appears in the expression for the noise voltage in the time domain but drops out of the corresponding expression for noise voltage in the frequency domain when the correct antialiasing filter is utilized before digitization and Fourier transformation. In terms of probe and spectrometer parameters, the sensitivity, as given by the signal-to-noise ratio in the frequency domain, is then

$$\frac{e_s}{e_n} \propto N\lambda\omega^{3/2} \left[\frac{\xi' V_s Q}{F} \right]^{1/2} \quad (10)$$

where Q , the quality factor of the resonant circuit, is defined by

$$Q = \frac{\omega L}{r} \quad (11)$$

The expression for sensitivity highlights a number of important considerations for probe design. There is a strong dependence on operating frequency, hence the continued emphasis on spectrometers with higher field magnets. Since coil Q values generally increase as $\omega^{1/2}$, the frequency dependence is slightly greater than the explicit function included in equation (10). The selection of the sample volume is governed to a large extent by the sample and the application. For a fixed *concentration* of spins, the sensitivity increases with increasing sample volume. However, for a fixed *number* of spins, the sensitivity can be increased by concentrating them into a smaller volume and adjusting the coil dimensions to maximize the filling factor. The volume, V_s , is that volume from which signal is detected while for homogeneity reasons, discussed below, the total sample volume must be somewhat greater. Typical total sample volumes are approximately 400 μL to 500 μL in 5 mm diameter sample tubes and 2.5 mL in 10 mm diameter sample tubes.

The filling factor and the coil Q value are parameters which the probe designer can control by careful choice of probe layout and materials. The filling factor is increased by coupling the coil as tightly as possible to the sample (by reducing the coil diameter relative to that of the sample) and by minimizing the fraction of inductive energy stored outside the sample volume, for example in that part of the circuit associated with the tuning elements. This suggests the use of a coil with as large an inductance as possible. However, this limits the upper frequency of the coil and requires the use of higher voltages to generate a given rf field strength. This, in turn, results in higher electric fields within the sample. The use of a low inductance coil to minimize these problems requires keeping the tuning elements as close as possible to the coil.

The coil Q value is influenced both by the conductor of the coil itself and also by the insulating materials which are used to support the coil. Naturally the coil should be constructed from the best possible conductor, e.g. copper or silver, and also be constructed in such a way as to minimize the concentration of currents in small volumes of the conductor. For this reason, sharp corners and edges should be avoided. Insulating materials close to conductors should be very low loss. Most plastic materials do not satisfy this requirement.

Epoxies are particularly poor and should be avoided if at all possible. Losses in the capacitors of the tuned circuit also contribute to a reduction in the overall circuit Q value. While such losses are generally small, they are not negligible and the best quality capacitors are required for high-sensitivity probe circuits.

In many cases, particularly for biological applications, the sample can be a significant contributor to the losses in an NMR probe. Both inductive losses, from currents induced in a conductive sample by the rf magnetic field, and dielectric losses, associated with the rf electric field from the distributed capacitance of the coil, contribute to the overall loss.^{27,28} The electric fields can be reduced by balancing the coil with respect to ground²⁹ and by including electrostatic shields within the probe structure. Typical circuit configurations for balanced coils are shown in Figure 3.

If the coil resistance is the primary source of noise, the noise voltage may be reduced by cooling the coil. To provide thermal isolation from the sample, the filling factor is sacrificed but, by cooling a standard coil to approximately 20 K, significant sensitivity advantages have been achieved.^{30,31} The use of high-temperature superconducting materials for probe coils may also prove advantageous for sensitivity improvement.

3.4 Resolution

A probe and a sample can cause significant distortions of the polarizing magnetic field due to differences in the magnetic susceptibility of materials.³² A major aspect of high-resolution probe design is the control and correction of those distortions. Materials commonly used in probe construction have diamagnetic volume susceptibilities of several ppm. Therefore, abrupt changes in susceptibility near the sensitive volume of the probe can cause serious degradation of the field uniformity. Probe designs use two important methods to minimize such perturbations: (a) the geometry and symmetry; and (b) a careful choice of materials.

The use of cylindrically symmetric components and material boundaries well removed from the sample region ensures that perturbations within the sample volume are minimized or are at least correctable by adjustment of the magnet shim coils. The most critical element is the sample coil, since it is closest to the active volume of the sample and inevitably includes some susceptibility discontinuities in its geometry. Sometimes

Figure 3 Two configurations for balancing a coil with respect to ground. For optimum performance $C_{1a} \approx C_{1b}$ and $C_{2a} \approx C_{2b}$. In (a) the tuning capacitor, C_1 , must support the full voltage across the coil, while the voltage across the matching capacitors is approximately one-half the coil voltage. In (b) the voltage across all capacitors is approximately one-half the coil voltage, but tuning over a wide frequency range is more difficult since C_{1a} and C_{1b} are twice the value of C_1 in configuration (a)

the geometry can be modified to minimize the effect of these discontinuities, but the main strategy employed to minimize perturbations is to construct the coil from a material which is specially designed to have a very low magnetic susceptibility. This is accomplished by making the coil from a composite material with diamagnetic and paramagnetic components, either by electroplating or by some other method of making a sandwich structure, while maintaining a high conductivity. Diamagnetic materials which can be used are copper, silver, and gold. Suitable paramagnetic materials are aluminum, rhodium, and platinum. For a good quality coil, it is necessary to reduce the effective volume susceptibility to less than one-tenth that of copper.

The ends of the sample itself are a major source of perturbation and must be kept at some distance from the active sample region if their effects are to be corrected by shim coils. Some reduction in the sample volume can be realized if the sample is restricted by a container with a volume susceptibility which closely matches that of the sample.³³

As operating field strengths have increased, the requirements for absolute resolution have remained fixed or even tightened. Thus the demands on the probe performance with respect to resolution have increased. In addition, many experiments are performed with static rather than spinning samples because of undesirable artifacts caused by sample spinning.

3.5 Radiofrequency Excitation

Both the intensity and the uniformity of the rf excitation are important parameters. The rf field strength must be sufficient to excite all the spins of interest. This has become more of a technical challenge as spectrometer frequencies have increased.

The relationship between the various factors contributing to the rf field strength may be understood by considering the fundamental definition of the quality factor, Q , of a resonant circuit:

$$Q = \frac{\omega U}{P} \quad (12)$$

where U is the energy stored and P is the power dissipated in the circuit. Now,

$$U \propto B_1^2 V_c \quad (13)$$

where V_c is the volume of the coil. For a given coil, operating in the range where $Q \propto \omega^{1/2}$, the strength of the rf field, expressed in frequency units is

$$\omega_1 \propto \gamma P^{1/2} \omega^{-1/4} V_c^{-1/2} \quad (14)$$

Thus, for a given nuclear species and a fixed coil volume, the power required to generate a given rf field strength increases as $\omega^{1/2}$. However, to provide an equivalent frequency range of excitation, the rf field should increase in proportion to the resonance frequency. Therefore, to maintain the same effective spectral excitation, the power increases as $\omega^{5/2}$. This strong dependence represents a significant challenge in the design of probes for high-field spectrometers. The power dissipation becomes an important factor in the generation of

long pulses or continuous rf excitation as in spin locking pulses or decoupling. For the generation of short excitation pulses, the major design consideration is the voltage handling capability of the tuning capacitors of the circuit.

Because of the increased size of the outer coil of a multicoil probe, correspondingly higher powers are required to generate the required rf fields. In a high-frequency probe of this type, designed to observe protons on an inner coil and to irradiate ^{13}C and/or ^{15}N with an outer coil, several hundreds watts of power are needed for the ^{13}C and ^{15}N channels. This requires the use of capacitors which can handle many thousands of volts. These are values which are more traditionally associated with probes for solids applications.

Uniformity of the excitation is important in a number of different types of measurements. In a simple pulsed FT experiment with a spinning sample, nonuniformity in the rf field distribution can cause spinning sidebands. These arise from phase and amplitude modulation of the detected signal and, unlike sidebands arising from inhomogeneity of the polarizing magnetic field, have an amplitude which is independent of the spinning frequency. Positive and negative sidebands may be of different intensity and may not always be in phase with the parent peak.

In many multidimensional experiments, rf pulses are used to transfer magnetization from one spin system to another. The efficiency of the transfer depends on the effective rotation induced by the pulse. Many such transfers may occur^{34,35} before a spin response is detected. Variation of rf intensity over the sample volume results in a variation of the magnetization transfer and a loss of sensitivity.

The uniformity of the excitation can be improved by careful attention to the design of the coil shapes and the arrangement of multiple coil systems. Electromagnetic modeling programs are useful in this regard for the calculation of field distributions.

3.6 Probe Artifacts

Precautions must be taken to eliminate a number of possible signal artifacts which can originate in the probe.

3.6.1 Spurious rf Signals

An NMR probe is a very sensitive antenna and must be shielded from external sources of rf such as other electronic equipment or radio stations. Special attention must be paid to the grounding of all electrical connections into the probe. It is difficult to provide complete shielding since access must be provided for the sample. In exceptional cases, it may be necessary to adjust the spectrometer frequency to avoid external interference.

3.6.2 NMR Background Signals

NMR background signals from probe materials can be troublesome. Very small amounts of proton-bearing material may give rise to a detectable signal. Some relief is achieved from the fact that most of the signals are from solid probe construction materials and hence are very broad. Probe surfaces should be clean to avoid picking up signals from

fingerprints. Moisture in gases in the probe will also give strong signals.

3.6.3 Acoustic Ringing

Acoustic ringing³⁶ can be a very serious problem, particularly for probes designed to detect low- γ nuclei. The probe coil and other metal parts of the probe may be excited into mechanical oscillation at the rf frequency by Lorentz forces during the rf excitation pulse. These oscillations often have a very high mechanical Q value and persist long after the pulse. The oscillating metal in the magnetic field induces an rf field which can be picked up by the probe coil. The signal may persist for several hundred microseconds and be transformed into serious baseline distortion of spectra. Acoustic resonance signals can be distinguished from NMR signals by the use of special pulse sequences,³⁷ but are best eliminated by changing the materials of the probe.

3.7 Other Requirements

3.7.1 Variable Temperature

Sample temperature is normally controlled by passing a temperature controlled gas stream past the sample. The probe structure is designed to minimize thermal losses and to provide a uniform temperature distribution over the sample itself. A temperature sensor (thermocouple or resistance thermometer) is located as close as possible to the sample and used to regulate the gas temperature via a heater in the gas stream.

3.7.2 Pulsed Field Gradients

An increasingly useful technique is the application of pulsed field gradients,³⁸⁻⁴⁰ either to suppress strong solvent signals or to provide selective detection of coherence transfers. To provide rapid switching and to minimize the generation of eddy currents, these gradients are best provided by a set of shielded coils⁴¹ built into the probe itself. The gradient coils have sufficient symmetry and are far enough removed from the sample that they cause little problem with resolution, but may be close enough to some of the rf coils to degrade their electrical performance.

3.7.3 Optical Excitation

High-resolution experiments are combined with optical excitation in the method of chemically induced dynamic polarization (CIDNP).^{42,43} Here, pulses from a laser are typically coupled via a light pipe from the base of the probe and a mirror or prism to the active sample volume. This usually results in an asymmetric structure close to the sample and may cause some loss in resolution.

4 CONCLUSIONS

The range of applications for high-resolution probes continues to develop. It seems likely that the field strengths

used for NMR will continue to increase, placing additional demands on the performance of the probes.

Sensitivity remains the major disadvantage of NMR spectroscopy. As a result, efforts will continue to improve the performance. In addition to the possible use of high-temperature superconductors for probe coils, the use of these new superconducting materials also offers the possibility of building magnets to generate still higher magnetic fields. Already high-resolution magnets at greater than 20 T are being developed. If history is any guide, the requirements for absolute resolution will remain constant, or even increase, and the demands on the probe will be even more stringent.

As improvements are made, it is likely that new applications for high-resolution NMR will be opened up, perhaps necessitating the development of different probe configurations.

1 INTRODUCTION

With the development of CP MAS solid state NMR experiments in the 1970s using dipolar decoupling and with the recent development of REDOR and TEDOR type experiments, the need for multiple tuned probes has evolved. This article describes the use of transmission lines in designing these types of probes. There have been several probes for doing two frequency, i.e. ^1H and ^{13}C CP MAS, described in the literature.¹⁻⁴ (See also *Probe Design and Construction* and *Solid State Probe Design*). Some of these use transmission lines in their design, but all have some tuning elements at the sample coil. The probes described in this article will not, in general, have any tuning elements at the sample coil but may have a fixed capacitance in series with the sample coil in the magnet. All other tuning elements are remote from the magnet. The advantages of this type of design are (1) good frequency discrimination, (2) the use of more rugged tuning elements, and (3) the sample can be in a hostile environment.

2 TRANSMISSION LINE THEORY

The theory of rf transmission lines, and coaxial lines in particular, are covered in many texts, and the reader is referred to them for additional help. Smith charts will not be used, but understanding them can make visualizing these designs easier.

Two fundamental equations regarding transmission lines are

$$Z_{\text{in}} = Z_0[Z_r \cosh(\gamma l) + Z_0 \sinh(\gamma l)]/[Z_0 \cosh(\gamma l) + Z_r \sinh(\gamma l)] \quad (1)$$

$$V_x = V_s[\cosh(\gamma x) - Z_0/Z_s \sinh(\gamma x)] \quad (2)$$

where Z_{in} is the impedance looking into a section of transmission line of length l terminated with an impedance Z_r , Z_0 is the characteristic impedance of the transmission line, Z_s is the Z_{in} for a particular line looking into the line from the sending end, x is the distance measured from the input to the point of calculation, V_s is the applied voltage, and γ is the propagation constant and is equal to $\alpha + i\beta$ where α is the attenuation constant in nepers/meter and β is the phase

Figure 1 Magnitude of voltage and impedance along a mismatched transmission line

constant equal to $2\pi/\lambda$, where λ is the wavelength of the frequency of measurement. All units are SI.

The voltage and impedance along a section of transmission line terminated with an impedance of a typical sample coil have a similar dependence, i.e. they both have a minimum at a common point. A magnitude plot for both is shown in Figure 1. This point will be referred to as the null point. The impedance to the left of the null point is inductive and to the right capacitive for lengths less than a quarter wavelength. This can be verified from equation (1) by noting the phase angle of Z_{in} . Therefore, a single-frequency probe can be made by using standard tuning and matching capacitors at the left or sending end of the line since it looks inductive. This should be the highest frequency channel in a multifrequency probe. At this frequency the impedance at the null point is very low and is insensitive to other circuit elements being connected there. Therefore it is a good point to connect the tuning elements of lower frequency channel(s). Using the null point in this manner achieves a high degree of isolation between the high-frequency channel, usually proton, used for CP and dipolar decoupling, and the lower frequency channel(s) used for observation, dephasing, or coherence transfer. The length of the transmission line used to the left of the null point is just sufficient so that reasonable values of capacitance can be used. (1) can be used to calculate the inductive reactance and hence the value of capacitance to use.

The isolation is very good, but there is a price to pay, and it is efficiency. When transmission lines are terminated in an impedance other than their Z_0 , the efficiency is reduced. The impedance of a typical sample coil will be considerably different from Z_0 mainly by the fact that it will have a large imaginary part and a small real part where Z_0 is purely real. The efficiency of a transmission line (Eff) with a high SWR (Standing Wave Ratio) is given by⁵

$$Eff = 1/(1 + SWR \cdot \alpha \cdot l) \quad (3)$$

where SWR is the ratio of the maximum voltage to the minimum voltage in Figure 1 and l is the length of line. The quantities SWR and α can be minimized with respect to Z_0 and α can also be reduced by increasing the diameter of the coaxial conductors. The quantity SWR is optimized when the magnitude of reactance of the load (sample coil) is equal to Z_0 ⁶ and α is minimized when the ratio of the outer to inner radii of the transmission line is 3.59.⁷ The optimization

Figure 2 Efficiency parameter of transmission line as a function of its characteristic impedance

for SWR should be done for the highest frequency since α decreases with decreasing frequency. Figure 2 shows a plot of the product $SWR \cdot \alpha \cdot l$ for a typical transmission line and sample coil with the $|Z_r|$ ca. 50% higher than Z_0 . It shows that there is a broad minimum from about 65 Ω to 125 Ω that gives low loss.

3 TWO- AND THREE-FREQUENCY PROBES

Figure 3 shows a general schematic diagram for a two- or three-frequency probe. TL1 is the main transmission line connecting the sample coil L3 to the tuning elements remote from the magnet. Point A is the null point on the transmission line as discussed above and is the tie-in point for the lower frequency channel(s).

Depending on the proton frequency $F1$, point A may or may not be outside the bore of the magnet. If $F1$ is below 175 MHz, point A will most likely be outside the bore, and the low-frequency tuning elements can be placed in a separate box connected to TL1 at point A. If the value of $F1$ is above 175 MHz, point A will be in the bore of the magnet and a second transmission line TL2 can be used to connect the low-frequency tuning elements into TL1. Since the overall length

Figure 3 Two- or three-frequency transmission line probe

of TL1 will not be too long, it is very convenient to put the tuning elements for all channels in one box and terminate both TL1 and TL2 in that box. In this case the sizes of TL1 and TL2 must be selected so that both, plus a shield, can fit inside the bore of the magnet. This requires a wide bore (89 mm) magnet for a good low loss design. If point A is just inside the bore, three things can be done to gain a little extra length. The inductance of the sample coil can be reduced by removing turns, the Z_0 of TL1 can be increased by increasing the ratio of outer to inner radii of the conductors, and a capacitor C3 can be used in series with the sample coil. Using C3 can cause problems with the low-frequency channels and will be discussed later. As shown above, there is broad latitude in choosing Z_0 for minimum loss. Also, lowering the inductance will generally help meet the criteria for $|XL3|$ to equal Z_0 . Hoult and Richards⁸ have shown that the sensitivity of the NMR experiment is not critically dependent on the Q of the sample coil if proper winding parameters are used. Therefore reducing the number of turns, which will lower the value of Q , will not degrade the sensitivity.

Making the outer diameter of TL1 as large as possible is important since it is used for the highest frequency. If this criterion is to be met, a wide bore magnet is necessary. In this laboratory using 89 mm bore magnets, transmission lines using 3.81 cm (1.5 in) outer diameter and both 0.953 cm (0.375 in) and 0.635 cm (0.25 in) inner diameters have been used. TL2 has an outer diameter of 1.0 cm (0.4 in) and an inner diameter of 0.441 cm (0.173 in). Standard rigid copper plumbing pipe has been used to make the TL1 transmission lines and TL2 is a commercial 50 Ω rigid coaxial cable with these dimensions. They are essentially air dielectric since the center conductor is supported at a few points with Teflon® discs.

To locate point A, a narrow slot can be cut in the outer conductor of TL1 in its approximate location. This point can be calculated from equation (1) by knowing Z_r for the sample coil and letting $\alpha = 0$. The hyperbolic functions reduce to trigonometric functions, and by solving for several values of x , the crossover point between inductive and capacitive can be located. By driving point D (C1 and C2 not in place) with a sweep generator and using an oscilloscope probe to detect the voltage along TL1 in the region of the slot, a point of minimum voltage will be found. This is the null point. Care should be taken in making this measurement, since the isolation between the proton and the low-frequency channels depends on the location of this point. Good rf practices and test equipment designed for the frequencies needed must be used. Once this point is located, a connection must be made and brought out through the outer conductor to make a connection to TL2, or in the case of lower frequency systems tuning elements in a box. This must be a well-insulated connection capable of carrying large values of rf current and withstanding high rf voltage, since this is part of a resonant circuit. A conductor size of 0.318 cm (0.125 in) insulated with Teflon® can be used.

After TL1 and TL2 are in place, C1 and C2 (a conventional tuning network) can be used to tune and match the circuit at $F1$. It is important that this is done before the low-frequency channels are constructed because their tuning will depend on C1 and C2.

A two-channel probe will be described first. The highest frequency for the low channel that has been designed in this laboratory is for ^{31}P , except for some special probes where ^{19}F was the next lowest frequency. These require special

considerations, and space does not allow their discussion here. For a two-channel probe, L1 is replaced by a short circuit, and C4, C5, and L2 are not used.

After TL1 and TL2 are in place and C1 and C2 are tuned and matched to $F1$, the impedance at point C is measured at the frequency $F3$. In most cases it will be inductive, and C6 and C7 are used to tune and match to $50\ \Omega$ at $F3$. If the impedance at point C is capacitive, then a capacitor C3 must be added in series with the sample coil L3. The reactance of C3 at $F3$ should be sufficient such that the impedance at point C is inductive and its real part less than $50\ \Omega$, preferably $20\ \Omega$ or less. For networks such as C1 and C2 and C6 and C7, the real part of the inductive circuit that is being tuned must be less than $50\ \Omega$.

For a three-channel probe, $F3$ should be no more than 65% of $F2$ or some of the power at $F3$ will be absorbed in the $F2$ circuit. All elements in Figure 3 are used in a three-channel probe.

The first requirement for this probe is that the impedance at point B looking into TL2 must be capacitive so C3 will not be needed. If it is still inductive, a capacitor can be added from point A and/or point B to ground or TL2 can be lengthened. Once point B is capacitive, it has a negative imaginary part ($-iX$), and a value of L1 is selected such that its imaginary part is $(+iX)$ making the impedance at point C a small real part (losses in L1, and TL1 and TL2). This is essentially a series resonant circuit and has created an impedance null at point C for $F2$, similar to point A for $F1$. A value for L2 is now chosen such that reasonable values of C5 and C4 can be used to tune and match point E at frequency $F2$ to $50\ \Omega$. L1 and L2 should be made with as high a Q value as possible (i.e. low loss) to keep the efficiency up. A convenient material to use is 0.3175 cm (1/8 in) copper tubing.

Now that the $F2$ circuit is completed, the impedance at point C is measured at frequency $F3$; if $F3$ is 65% of $F2$ or lower, it should be inductive, and C6 and C7 can be chosen to tune and match point G to $50\ \Omega$. Inductor L1 must be shielded from L2 or there will be inductive coupling between them. Since they would not be independent, the circuit will not work properly. A compartmentalized tuning box that gives good rf shielding should separate the tuning elements for all three channels and is recommended.

4 TRAPS

Figure 4 shows two types of traps that are used with the probes described in this article. Type 1 makes a particular channel less dependent on what is connected to the other input ports. Type 2 traps are used to attenuate proton ($F1$) frequencies at the low-frequency input ports to help prevent pre-amplifier overload in the observe channel.

Type 1 traps work as follows. The transmission line TL is a shorted $1/4\lambda$ line at the frequency of the port where it is used. This will always be a port at a higher frequency than the frequency it is used to trap, i.e. a ^{13}C trap used on the proton port. This constraint means that the impedance at point A, looking into the TL, will be inductive, and the circuit can be made series resonant with C at the frequency of the trap. This will cause the input impedance to be very low and create a virtual ground at the frequency of the trap. If too large a value of C is required, an inductor L1 can be added in series

Figure 4 Traps for multifrequency probes

to reduce the value of C required. Since the impedance of TL is infinite at the frequency of the port where it is connected, and it is in series with C and L1, the whole trap will have a very high impedance and will not load the port at its own frequency. There will be two traps of type 1 at the proton input port, one for $F2$ and one for $F3$. The inputs of these traps are connected from the proton ($F1$) input port (point F in Figure 3) to ground. There will be one type 1 trap at the $F2$ input port tuned for $F3$ and connected from point E in Figure 3 to ground. These traps make the tuning of the $F2$ and $F3$ circuits insensitive to what is connected to the other ports. An $F2$ frequency trap is not needed at the $F3$ port since the $F2$ frequency is already highly attenuated at point C in Figure 3 due to the null point there.

Type 2 traps create a low impedance at their input and hence short to ground any $F1$ frequency signal that gets to input ports of the observe channels. This is very important when observing resonances while decoupling protons at $F1$.

An open circuited $1/4\lambda$ line is a short circuit, but cutting a piece of the coaxial exactly is difficult. If the TL is made shorter than $1/4\lambda$, then a variable capacitor can be used to trim the circuit to the exact value necessary to create a short at its input at $F1$. There needs to be one of these traps at the input of the $F2$ and $F3$ ports.

The coaxial cable used for these traps is RG-58A/U, and the capacitors are rated for 400 V.

5 SUMMARY

Probes using the design in this article have been built in this laboratory at proton frequencies of 60, 90, 127, 150, 200, and 300 MHz, some for two frequencies, some for three frequencies and some for four frequencies using the same ideas described here. All of these probes are made for high power (300–1000 W) and are capable of proton decoupling in the 100 kHz range. High-voltage vacuum or Teflon® variable capacitors are used in the high-voltage areas, but since all tuning elements are remote from the magnet, large and, if necessary, magnetic ones can be used. Since the sample coil is the only component in the magnet, the circuit is insensitive to first order to the environment of the sample.

1 INTRODUCTION

During the late 1960s and early 1970s, fairly extensive searches were carried out to find new methods for obtaining the highest sensitivity in NMR experiments. These searches were primarily applied to optimization of high-resolution NMR spectra. It was recognized at a very early stage in the development of modern NMR that the original continuous wave (CW) method was usually inefficient in terms of both the time required to obtain a single NMR scan and the magnitude of the signal produced per scan. In CW experiments, the magnetization vector is tipped only slightly from its equilibrium value, thus producing a relatively weak signal. The necessity of maintaining a small tip or effective flip angle arises because nuclear spin systems become nonlinear in their response at high applied rf field. To record CW spectra properly, it was necessary to approximate slow passage conditions to produce spectral lines that were undistorted by such effects as frequency oscillations in the tails of the spectral lines (ringing), relaxation, and the inability of the detector to respond to the 'ringing'. Because of the necessity of obeying these slow passage conditions, attempts to tip the magnetization vector by a significant amount resulted in a reduction of the total intensity or 'saturation' of the resonance lines. These limitations provided the driving force behind attempts to develop alternative techniques to maximize the sensitivity of the NMR experiment.

Several alternative methods were proposed and developed that allowed rapid acquisition of an entire spectrum as well as the use of a large nutation angle, thus reducing the time required to obtain a single scan while also producing an enhanced signal per scan. The most popular of these methods is the pulse Fourier transform technique, on which almost all modern NMR spectrometers are based. A second method involves stochastic excitation, for which there have been several recent developments that appear quite promising. These two methods rely on simultaneous excitation of the

different resonance transitions of a nuclear spin system. A third method is the rapid scan correlation technique, in which the entire spectrum is traversed under fast passage conditions where typical circumstances involve tipping the magnetization vector into the (x,y) plane. Here each transition is excited successively in a fast sequence. If the field or the frequency is swept rapidly enough, constructive and destructive oscillations characteristic of the spectrum occur. The origin of these frequency oscillations was understood 30 years ago. It was recognized then that all of the available spectral information is in the frequency oscillations found in the tails of resonance lines obtained by rapidly scanning the spectrum. However, the proper analysis procedure for extracting the corresponding undistorted spectra remained elusive for many years. Several papers were published about 20 years ago describing the mathematical procedures for obtaining the undistorted spectrum, and pointing out that this rapid scan technique is capable of producing spectra with sensitivity comparable to the pulse Fourier transform technique. The technique was initially referred to both as rapid scan Fourier transform NMR spectroscopy and correlation NMR spectroscopy, because of the nature of the experiment and because the procedure for obtaining the undistorted spectrum may involve cross correlation. Ultimately, it was named rapid scan correlation spectroscopy. The purpose here is to examine the historical development of the method, review some applications of the technique, and speculate on future developments. Interestingly, the original discovery of NMR by Bloch was a rapid scan experiment where the signal was observed when the field was rapidly changing as the magnet was turned off, after a frustrating failed slow passage search for an NMR signal.

Dadok originally pointed out at the 1972 Experimental NMR Conference in Asilomar, CA that the true undistorted high-resolution NMR spectrum can be obtained from a rapidly scanned response by cross correlation with the response obtained under identical sweep conditions from a single 'reference' line.^{1a} The quality of the spectra was quite good, but suffered from several inherent disadvantages. First of all, the correlated spectra showed broadened lines with widths that were the sums of the inherent linewidths and the width of the single reference line used in the cross-correlation operation. Secondly, any additional spectral lines (e.g., from impurities) present in the reference sample produced additional spectral lines in the correlated spectra. Subsequently, the theoretical basis of this method was examined, and it was shown that the undistorted spectra could be obtained with no added linewidth by Fourier transforming the fast passage response and multiplying it with an analytical function of the form $\exp(-\frac{1}{2}ibT^2)$, where b is the sweep rate and T is the running variable in the time domain.^{1b,2} It was also shown that the data are easily obtained using a spectrometer-computer interface, just as all modern FT spectra are acquired and processed. It was shown that rapid scan correlation FT NMR offers an alternative to pulse methods for rapid acquisition of NMR spectral information. The sensitivity of the rapid scan method was shown to be comparable to that of the pulse Fourier transform method. However, two potential advantages of rapid scan FT over the pulse technique were recognized:

1. the ease with which a portion of the spectrum can be scanned without recording large peaks such as H_2O or

HDO, which cause dynamic range problems and severely limit the sensitivity of pulse FT NMR;

2. the ability to study selectively in a multiline spectrum the spectral properties of some spins without perturbing others, thus avoiding complications due to cross relaxation or chemical exchange.

At that time, another distinct advantage appeared to be that no new spectrometer hardware was required and no high-power pulse equipment was needed. Furthermore, for heteronuclei with large chemical shift dispersion, or for protons in paramagnetic systems, the rapid scan technique offered a simple straightforward procedure to obtain spectra of a chemical shift region of particular interest. The typical problems associated with foldover that are often encountered in pulse FT were avoided.

2 DESCRIPTION OF THE TECHNIQUE

2.1 Slow Passage Spectrum from the Rapid Scan

Response

In the rapid scan technique,^{1,2} the entire spectrum is traversed under fast passage conditions such that the magnetization corresponding to each line produces pronounced ringing (wiggles), which persists a time of the order of $3T_2^*$, and results in badly distorted spectral lines. The true spectrum is then obtained from such a fast scan response by cross correlating the response with that obtained from a reference consisting of only a single sharp NMR line scanned under identical conditions, or alternatively by applying to the Fourier-transformed response an analytical function $\exp(\frac{1}{2}ibT^2)$. Unlike pulse FT NMR, where the different resonance conditions of a complex spin system are satisfied simultaneously, in rapid scan correlation NMR, as in CW NMR, the resonance conditions are met sequentially.

Cross correlation of two complex functions G and H defined mathematically as

$$\int_{-\infty}^{\infty} H^*(\tau)G(t + \tau) d\tau \quad (1)$$

where H^* is the complex conjugate of H , has the physical meaning of one function searching for itself in another function, and is useful in picking out hidden periodicities. The property that cross correlation in one domain is equivalent to complex conjugate multiplication in the Fourier domain is used to simplify data handling considerably.

The detailed theory of rapid scan correlation NMR treats the spins as a linear time-independent system. The frequency response function $Y(\omega)$ of such a system and the corresponding impulse response $h(T)$ form a Fourier transform pair. In rapid passage experiments, the frequency ω is scanned rapidly ($\omega_t = bt$) and the response $Y(\omega_t)$ is observed as a function of time (frequency), giving rise to the well-known transient effects as wiggles or ringing following passage through a resonance. The linear response $R(t)$ of the spins to a swept rf field $E(t) = \exp(\frac{1}{2}ibt^2)$ is given by the convolution integral

$$R(t) = \int_{-\infty}^{\infty} h(\tau)E(t - \tau) d\tau \quad (2)$$

so that the detected NMR signal $Y(\omega_t)$, which is the component of the response in phase with the rf field, is given by

$$Y(\omega_t) = R(t) \exp(-\frac{1}{2}ibt^2) = \int_{-\infty}^{\infty} h(\tau) \exp[\frac{1}{2}ib(\tau^2 - 2t\tau)] d\tau \quad (3)$$

It is straightforward to show that the inverse Fourier transform $F(T)$ of this response is given by

$$F(T) = h(T) \exp(\frac{1}{2}ibT^2) \quad (4)$$

where T is the running variable of the time domain. This result for the Fourier transform of the rapid scan signal can also be obtained from the usual Bloch equations,² as well as the Bloch equations modified to include chemical exchange,³ provided that spin saturation is avoided. However, nonlinearities due to spin-spin couplings can modify the observed response.⁴

It is clear from the expression for the inverse Fourier transform $F(T)$ of the rapid scan response that multiplication of $F(T)$ by $\exp(-\frac{1}{2}ibT^2)$ gives the impulse response of the system $h(T)$, from which the slow passage spectrum is readily obtained by another (forward) Fourier transformation (Figure 1). Because of the extensive use of Fourier transformations for rapid data processing, we suggested that the technique be named rapid scan FT NMR, despite the fact that the resulting slow passage spectrum and the initial rapid scan response are in the same Fourier domain.

Use of an experimental reference involves cross correlation of an unknown rapid scan response with the rapid scan response of a single narrow reference resonance. Cross correlation is carried out most efficiently by Fourier transforming both the reference and the unknown responses and then multiplying the Fourier transform of the unknown response, $h(T)\exp(\frac{1}{2}ibT^2)$, with the complex conjugate of the Fourier

Figure 1 Signals at various stages of analysis in rapid scan correlation NMR. (c) The real part of the function $\exp(-\frac{1}{2}ibT^2)$ for $b/2\pi = 200 \text{ Hz s}^{-1}$. (d) The result of multiplying (b) and (c), followed by zeroing of half of the data points. (e) The Fourier transform of (d), with phase correction applied if necessary.

Figure 2 Rapid scan (a) and correlated spectrum (b) obtained at 60 MHz on a Hitachi Instruments, Inc. Model R-1200 rapid scan NMR spectrometer

transform of the reference response, $h_{\text{ref}}^*(T)\exp(-\frac{1}{2}ibT^2)$, to obtain $h_{\text{ref}}^*(T)h(T)$. The Fourier transform of this product is then taken as an approximation to the slow passage spectrum (Figure 2). The linewidths of the resulting spectrum in this case will be the sums of the true linewidths and the width of the reference line. When using the reference line approach, the final slow passage spectrum is properly phased, provided that the same phase setting is used for both the reference and the unknown. Also, the frequency axis of the final spectrum is shifted so as to set the reference line to zero frequency. In using the theoretical function approach, an adjustment of the spectral phase may be needed to produce a pure absorption signal, if the initial rapid scan response was not properly phased. However, when the theoretical function is used, the resonance positions remain unchanged with respect to their original positions in the rapid scan response. Cross correlation using the experimental reference results in slightly broader resonances, but this broadening could be minimized by choosing a very narrow reference line such that the broadening effect will be

negligible for lines whose widths are greater than 1–2 Hz. With a strong reference signal, the additional noise introduced by cross correlation is normally very small, and the decay constant inherent in h_{ref} leads in effect to exponential filtering, which improves the signal-to-noise ratio. It was noted that TMS is not the most suitable reference since its NMR response shows observable ^{29}Si satellites. It was suggested that a sample of degassed benzene or cyclohexane would be better.²

It is interesting to note that just before the final Fourier transformation, the data in the rapid scan technique are analogous to a simple free induction decay (see Figure 1). Thus, digital filtering techniques (e.g., resolution and sensitivity enhancement) to manipulate the quality of the final spectrum can be used just as in pulse FT NMR. The maximum intensity of the absorption signal in the rapid scan mode has been shown to be equal to the equilibrium magnetization, and it has been shown that the sensitivity of the rapid scan technique is comparable to that of the pulse FT technique. However, a necessary condition to be satisfied for the spin

system to be driven into the rapid passage region is that the sweep rate be greater than $1/2\pi T_2^{*2}$.

2.2 Nonlinear Effects in Rapid Scan Correlation Spectroscopy of Coupled Spin Systems

The existence of spectral distortions due to nonlinear effects in rapid scan correlation NMR of coupled spin systems has been described in the literature.⁴ These distortions depend strongly on the applied sweep rate and the rf power level where the effective flip angle may be close to 90° . The resultant spectra can show serious variations in resonance lineshapes (both phase and intensity), which depend upon the sweep rate, power level, and the initial state of the spin system, although the resonance frequencies remain essentially unaltered. These effects occur when the spin system does not completely recover in the time between passage through adjacent resonance lines owing to incomplete transverse and/or longitudinal relaxation. Under rapid passage conditions, the transverse magnetization components of the first scanned lines will be mixed by later passage through any connected resonance transitions, causing distortion of the resonances traversed first, while the later lines show normal behavior (e.g., for certain sweep rates in Figure 3, the first two lines are badly distorted). Maximum distortion of the spectrum of a weakly coupled two-spin system was found to occur for values of the sweep rate (in radians per second squared) $b = 2J(\omega_1 - \omega_2)$ where J is the coupling constant (in hertz), and $(\omega_1 - \omega_2)$ is the chemical shift difference (in radians per second). Effects of incomplete longitudinal relaxation manifest themselves as flip angle dependent anomalies in the intensities of the spectral lines that are observed when the spin system is initially in a nonequilibrium state. The above nonlinear effects should be kept in mind in interpreting the results of rapid scan correlation experiments with coupled spin systems.

Figure 3 Rapid scan correlation spectra of 2,3,4-trichloronitrobenzene at different scan rates.

2.3 Spin-Lattice Relaxation Measurements

An analog of the progressive saturation experiment well known in CW and pulsed FT works well in rapid scan spectroscopy.² The entire spectrum or a part of it is repetitively scanned and a steady state is established where there is a dynamic balance between the passages through the resonances. It is important to make optimum adjustments such that the spin magnetization following passage through a resonance ends up in the (x, y) plane. This requires careful adjustment of rf power and sweep rate. Further, this technique is limited to relatively long T_1 values.

A different approach, somewhat analogous to the saturation recovery pulse method, is applicable for measurement of both long and short T_1 s using rapid scan FT NMR.⁵ Here, the initial state of the spin system is established by applying a saturating rf field to the spectral lines to be studied. Such an rf field causes essentially complete demagnetization of the spins in a time of the order of a few times $T_{1\rho}$. The saturating rf is then turned off, and, after a variable delay time, the partially relaxed spins are rapidly scanned under fast passage conditions with another rf field of appropriate strength. The fast passage response thus obtained is cross correlated or treated with an analytical function to yield a partially relaxed slow passage spectrum. Repetition of saturation and observation sequence permits the determination of T_1 for each saturated line from its exponential recovery. In a multiline spectrum, T_1 values in the range 0.7–10 s were easily measured by this technique.⁵

3 SELECTED APPLICATIONS

3.1 Observation of Hyperfine Shifted Resonances in Hemoproteins

Ho and co-workers⁶ used rapid scan correlation spectroscopy at 250 MHz to obtain proton nuclear magnetic resonance spectra of human deoxyhemoglobin in D_2O in the region from 6 to 20 ppm downfield from the proton resonance of residual water, showing a number of hyperfine shifted resonances due to groups on or near the α - and β -hemes. They showed, by the use of correlation spectroscopy, that at least two resonances, one at about 18 ppm downfield from HDO due to the β chain and the other at about 12 ppm downfield due to the α chain, can be used to study the binding of oxygen to the α and β chains of hemoglobin. They also used rapid scan correlation proton NMR in H_2O to investigate the conformations of proximal histidyl residues in human deoxyhemoglobin and its mutants.⁷ Two resonances sensitive to the quaternary state of hemoglobin that occur between 58 and 76 ppm, far downfield from the water proton signal, could be readily observed and assigned to the hyperfine-shifted proximal histidyl NH-exchangeable protons of the α and β chains of deoxyhemoglobin. The biochemical information derived from these hyperfine-shifted proximal histidyl NH-exchangeable proton resonances complemented that obtained from the other hyperfine-shifted exchangeable and nonexchangeable proton resonances of deoxyhemoglobin in the spectral region from 5 to 20 ppm downfield from H_2O .

These studies made use of the ability of the rapid scan correlation technique to observe selected spectral regions, in the

presence of a large chemical shift dispersion, without perturbing other regions of the proton spectrum. No presaturation of the water resonance was necessary.

3.2 Transfer of Saturation from Water and 'Underwater' Decoupling

In several studies of biologically important peptides,⁸⁻¹² the rapid scan correlation technique provided well-resolved proton NMR spectra with signal-to-noise ratios significantly better than those obtainable using the CW but comparable to those obtained with the pulse FT technique. Furthermore, when protonated solvents were used, rapid scan correlation spectroscopy provided distinct advantages over the short pulse method because of its ability to avoid interference from the overwhelmingly large solvent signal. Peptide NH resonances of individual amino acids could be assigned by the correlation method using 'underwater decoupling' (i.e., decoupling from the corresponding C- α proton resonances, which are buried beneath the intense water peak). These experiments could be done maintaining good signal-to-noise ratio and resolution. Solvent exposure of specific hydrogens and exchangeability of NH protons could be studied by comparing peptide proton spectra in H₂O, with and without rf saturation of the large water resonance. Such experiments would have been difficult to perform using the pulse FT technique, since the latter requires saturation of water as a precondition for spectral data acquisition. Underwater decoupling experiments are useful for assignment of peptide NH resonances, while transfer of saturation from water measures solvent exposure of specific nuclei in the biomolecule.

As an example of the above, peptide NH resonances in the 250 MHz NMR spectrum of oxytocin in H₂O were assigned to specific amino acid residues by the 'underwater decoupling' technique.¹² Exposure to solvent of specific hydrogens of oxytocin in H₂O could be studied by monitoring intensity changes of peptide resonances when the solvent peak was saturated. Positive nuclear Overhauser effects (NOEs) of sizeable magnitude were observed for the Tyr *ortho*-CH and *meta*-CH resonances, indicating intimate contact between water and the aromatic CH hydrogens of the Tyr side chain. Transfer of saturation from water to NH protons reflected acid-base catalysis of the proton exchange reaction. There was no indication that any NH protons were substantially shielded from the solvent, which pointed to the need for avoiding solvent saturation to observe true resonance intensities.

3.3 Nonexchangeable Protons in Proteins

The rapid scan correlation technique has also been used for routine observation of one-dimensional protein proton NMR spectra as an alternative to pulse techniques with comparable signal-to-noise ratio and resolution.¹³⁻¹⁵ For example, Markley and co-workers¹⁴ used the technique at 250 MHz to measure titration curves of the three histidine residues of staphylococcal protease, while Arata and co-workers¹³ applied it to lysozyme. Bothner-By and co-workers¹⁵ used rapid scan correlation at 600 MHz to study glucocerbrosidase activator protein from Gaucher spleen. The upfield ring current shifted aliphatic region and the downfield aromatic region were examined using NOE methods in the correlation mode.

3.4 Applications in Food Chemistry

Since the rapid scan correlation NMR technique combines the sensitivity advantage of pulse FT NMR with the dynamic range advantage of the CW method, it has found recent applications in the analysis of food products.¹⁶ Results of qualitative as well as quantitative studies from a variety of foods and food-related systems have been reported. The rapidity and noninvasiveness of the technique are important considerations in such applications. A quantitative analysis of the ethanol content of various wines has also been carried out with this technique.¹⁷

4 FUTURE PROSPECTS

Even though rapid scan correlation spectroscopy showed significant promise in 1970s, it was soon overtaken by the rapid developments in the pulse FT method. With the advent of the new generation of pulse Fourier transform spectrometers, the advantage of not requiring new instrumental hardware for the rapid scan method disappeared. Eventually, most NMR manufacturers discontinued producing spectrometers capable of performing swept field or frequency experiments. Also, it is quite difficult to envision numerous heteronuclear and homonuclear multidimensional applications, now known for pulse FT NMR. Nevertheless, Hitachi Instruments, Inc. manufactures a spectrometer operating at 60 MHz that functions exclusively in the rapid scan correlation mode. Recent applications of the technique seem to have been in the area of quality control in food chemistry and in the study of biomolecules in H₂O solution. The ability to avoid overdriving the dynamic range of the spectrometer, which is still problematical on modern NMR spectrometers, implies that the rapid scan correlation technique is still a useful complement to pulse FT NMR. Also, one can envision applications in magnetic resonance imaging that might be advantageous in terms of rf power requirements. One purpose of this review is to remind the NMR community of the existence of this potentially powerful alternative to pulse techniques.

While we do not envision any widespread resurgence in the use of the rapid scan method, the technique is likely to continue to be useful for routine one-dimensional NMR analyses and for specific applications in the study of biomolecule-water interactions. Possible applications of the rapid scan technique in imaging and in vivo proton spectroscopy may still result in the future.

Biographical Sketches

Raj K. Gupta. *b* 1943. Ph.D., 1969, Indian Institute of Technology, Kanpur. Introduced to NMR by A. G. Redfield. Professor of Physiology & Biophysics, and of Biochemistry, Albert Einstein College of Medicine, NYC, 1982–present. Approx. 200 publications. Research interests include applications of NMR in physiology and biochemistry, especially in the measurement of intracellular ions.

James. A. Ferretti. *b* 1939. Ph.D., 1965, University of California at Berkeley. NIH, 1966–present, currently Chief of the Structural Biophysics Section, Laboratory of Biophysical Chemistry, National Heart, Lung & Blood Institute, Bethesda, MD. Approx. 100 publications. Research interests include 3D solution structures of peptides and proteins.

Edwin D. Becker. *b* 1930. B.S., 1952, University of Rochester, Ph.D., 1955, chemistry, University of California, Berkeley, USA. National Institutes of Health, 1955–present; Laboratory Chief (1972–80, 1988–present); Associate Director for Research Services (1980–88). Concurrent position on Faculty, Georgetown University, 1959–present. Books on NMR. Research interests and publications: hydrogen bonding, molecular structure elucidation, technique development in NMR and other areas of molecular spectroscopy.

Sensitivity of the NMR Experiment

David I. Hoult

1 INTRODUCTION

With any spectroscopic technique, there is a lower limit to the amount of material that yields a detectable signal, and NMR is no exception in this regard. Indeed, in comparison with other methods such as mass spectroscopy or electron spin resonance, NMR is a very insensitive tool. As such, it is therefore a tribute to its versatility that it occupies such an important position in the analytical armory, be it in chemistry, biochemistry, or medicine. However, it is almost an axiom that the desired detection sensitivity is always a little greater than that available, and in repeated efforts to prise more from the technique, the limits thereof have been explored in great detail. This article therefore seeks to explain those limits, and to give an account of the origins of the NMR signal and the unwanted voltages that tend to mask it.

The NMR phenomenon is detected overwhelmingly nowadays by its transient response to a 'pulse'—a brief burst of oscillating magnetic field of suitable duration, orientation, and frequency. In the simplest of experiments that pulse leaves in its wake an ensemble of nuclei that, for our purposes, can be considered to constitute a small magnet that rotates at the Larmor frequency about a direction parallel to the main applied magnetic field. However, as Michael Faraday was well aware as long ago as 1830, a rotating magnet creates an electromotive force (EMF) in a nearby conductor—the phenomenon of electromagnetic induction. Thus, at its simplest, detection of the NMR phenomenon is accomplished by placing a coil of wire (the 'receiving coil') round the sample, be it a human being or in a test tube, and, after the pulse, recording the voltage induced in the coil by the rotating nuclear magnetism. The principle is the same as that employed to generate current with a bicycle dynamo or car alternator. However, the induced signal voltage is usually at least seven orders of magnitude less than in these well-known generators, and therefore rather difficult to measure. Thus, the receiving coil is part of a special circuit (the probe) that aids in passing the signal without degradation to the electronics of the NMR receiver. Regrettably, in many elementary descriptions of NMR, particularly in the medical literature, it is wrongly stated that radio waves are emitted from the NMR system and then received by an antenna rather than a probe. It cannot be stressed too strongly that this is a wrong (and needlessly complex) description.^{1,2} Only at field strengths considerably higher than those normally in use, when the sample dimensions approach the wavelength of any radio waves, does the emission of such waves begin to contribute appreciably (constructively or destructively) to the received signal.³

Unfortunately, in addition to the NMR signal, there are many potential sources of unwanted voltage that may obscure the desired signal—so-called noise. Some of them are, at the time of writing, unavoidable, but others can enter through bad design of the NMR instrument, or through some usage that the manufacturer did not envisage. Unavoidable noise, which we shall consider in detail, is associated with Brownian motion: firstly, of the electrons in the receiving coil (the coil's resistance is a measure thereof) and, secondly, of electrolytes in the sample. Noise in the electronics of the receiving system can also not be completely eliminated. Avoidable noise sources tend to be of human origin away from the immediate vicinity of the NMR magnet. (An exception is dielectric loss in the sample.) Chief offenders are television and radio stations, cellular telephones and radio paging systems, fluorescent lights, computers (including the NMR computer and pulse programmer), electric motors, etc. When badly constructed or modified, an NMR spectrometer or imager can function only too well as a radio receiver. Thus, we shall also examine briefly how these sources can interfere with the NMR signal and degrade the signal-to-noise ratio, and how such interference can be avoided. In accord with the earlier statement concerning radio waves, the design goal is to minimize this far-field receptive ability while maximizing the ability to detect near-field induced voltages. We begin, then, with a description of signal reception.

2 SIGNAL RECEPTION

2.1 The Principle of Reciprocity

Once a sample has been in the main magnetic field B_0 for a time greater than a few longitudinal relaxation times T_1 , the ensemble of nuclear spins has become magnetized: there is a net alignment (typically tens of ppm) of nuclear magnets with the field, which, following convention, we assume to be in the z direction. The magnitude of the magnetic moment per unit volume (or magnetization M_0) so created is given by

$$M_0 = \mathcal{N} \gamma^2 \hbar^2 I(I+1) / 3k_B T \quad (1)$$

where $\mathcal{N}$ is the number of nuclei of interest per unit volume, γ is their gyromagnetic ratio, and I is their spin. T is the absolute temperature of the sample, $\hbar$ is Planck's constant h divided by 2π , and k_B is Boltzmann's constant. Table 1 shows the magnetization of a 1 M solution for several common nuclei at 20 °C in a field of 1 T.

Thus, in an elementary volume dV , there is a magnetic moment $d\mathbf{m}$ given by

$$d\mathbf{m} = M_0 dV \mathbf{z} \quad (2)$$

where $\mathbf{z}$ is the unit vector in the z direction. Application of a pulse realigns the magnetic moment, placing it in a new direction with declination θ relative to $\mathbf{z}$ (the pulse is said to have a 'flip angle' of θ), so that there is a component

$$dm_{xy} = dm \sin \theta \quad (3)$$

parallel to the (x,y) plane. The component then precesses (rotates) about the z direction with frequency ν_0 (the 'Larmor frequency') and suffers transverse relaxation.

A full calculation of the voltage induced in a neighboring conductor is not difficult,² but valuable insight may be gained as follows: consider the form of the magnetic field that *would* be created by the conductor if 1 A of current at the Larmor frequency were to be passed through it. This is shown in Figure 1(a). Now it is intuitively obvious that if the rotating nuclear magnetic moment is close to the coil at, say, point P, a much larger voltage will be induced than if the moment is far away at, say, point Q. Equally, it may be seen that the magnetic field created by a hypothetical current is much stronger close to the coil than far away. This behavioral correspondence suggests that the induced voltage is proportional to the field, a hypothesis supported by calculation and measurement,² and the variation of both quantities with distance along the x axis is shown in Figure 1(a). Mathematically, this example of the near-field principle of reciprocity is expressed by⁴

$$d\xi = -\frac{d(\tilde{\mathbf{B}}_1 \cdot d\mathbf{m})}{dt} \quad (4)$$

where $d\xi$ is the induced electromotive force or voltage. The tilde above the magnetic field $\tilde{\mathbf{B}}_1$ indicates that the field is hypothetical—it is the field that would be created by unit current. As the magnetic moment rotates at the Larmor frequency, the scalar product in equation (4) is constantly changing, and the more rapid the rotation, the greater the time derivative and the induced voltage. However, note that if the field $\tilde{\mathbf{B}}_1$ were in the z direction, the scalar product would always be zero. This is illustrated in Figure 1(b), where there is no change of magnetic flux through the receiving coil as the magnet rotates. It follows that the primary design criterion for any receiving coil

Figure 1 The principle of reciprocity. Following a pulse, the nuclear magnetic moment of a sample can be considered to be a small magnet rotating about the z axis. (a) Close to the loop of conductor at point P, the rotating magnet induces therein a much larger voltage than if it were at point Q. Similarly, if a current of 1 A at the Larmor frequency were passed through the loop, the magnetic field $\tilde{\mathbf{B}}_1$ produced (a graph of the field along the x axis is shown) at point P would be much larger than that at point Q. Thus, there would appear to be a correspondence between field strength and induced voltage, and this is borne out by a full calculation. (The graph therefore represents both signal ξ and field $\tilde{\mathbf{B}}_1$.) However, if the hypothetical $\tilde{\mathbf{B}}_1$ field produced by the loop is in the z direction at the sample, as shown in (b), there is no change in flux linkage through the loop as the nuclear magnet rotates, and therefore no induced voltage. We therefore conclude that, to receive an NMR signal, a receiving coil must generate a $\tilde{\mathbf{B}}_1$ field with a component in the (x,y) plane

Table 1 Nuclear Magnetization of a 1 M Solution at 20 °C

Nucleus and atomic weight	Natural % abundance	Spin I	Frequency (MHz T ⁻¹)	Magnetization ($\mu\text{A m}^{-1} \text{T}^{-1}$)
¹ H	99.98	$\frac{1}{2}$	42.5749	29.62

⁶⁵ Cu	30.91	$\frac{3}{2}$	12.0887	11.19

is that its field $\tilde{\mathbf{B}}_1$ must have a substantive component in the (x,y) plane. Hence, allowing for the transverse relaxation that takes place once magnetization is unaligned with the z direction, we have, from equations (2)–(4)

$$d\xi = 2\pi\nu_0(\tilde{B}_{1,xy}M_0 \sin \theta dV) \exp(-t/T_2) \cos(2\pi\nu_0 t + \phi) \quad (5)$$

where ν_0 is the Larmor frequency (in Hz), $\tilde{B}_{1,xy}$ is the component of $\tilde{\mathbf{B}}_1$ at the sample parallel to the (x,y) plane, T_2 is the sample's transverse relaxation time, and ϕ is a phase constant determined by the relative orientations of the $\tilde{\mathbf{B}}_1$ field and the magnetic moment $d\mathbf{m}$ at time $t = 0$. Equation (5) is the master equation for the signal from an NMR experiment in which the emission of radio waves is negligible, and is directly applicable to, say, a small volume element in an imaging experiment.

Equations (1) and (5) contain one of the main reasons for the drive in NMR to ever higher magnetic field strengths. (The other main reason is improved spectral resolution.) From equation (1), the magnetization M_0 may be seen to be proportional to B_0 , while in equation (5), the frequency is also proportional to B_0 via the Larmor relation $2\pi\nu_0 = -\gamma B_0$. Thus, the induced EMF $d\xi$ is proportional to the square of B_0 . As the time taken for many NMR experiments diminishes as the square of the signal strength, equation (5) holds the promise (albeit not fully realized, see later) that even a modest increase in field will be richly rewarded in time saved. However, there are other factors in equations (1) and (5) that merit attention with a view to increasing the signal strength as much as possible. Apart from the obvious strategy, where feasible, of increasing the effective concentration of the sample, we note that both a reduction of temperature and an increase in $\tilde{B}_{1,xy}$ increase the induced EMF. Assuming that the temperature is minimized whenever necessary and possible, let us therefore turn our attention to the hypothetical field created by unit current at the Larmor frequency in the receiving coil.

2.2 Receiving Coil Geometry

Viewing the receiving coil of Figure 1(a), it would appear that it should tightly surround the sample to receive the largest induced EMF, for it may be shown that the field at the center of a current loop varies inversely with its size (any good text on electromagnetic theory deals with the fields created by simple conductors—see, e.g., that by Bleaney and Bleaney⁵). (We ignore for the moment the question of whether the homogeneity of the $\tilde{\mathbf{B}}_1$ field is of import.) It would also appear that if we place more turns of wire on the coil, the field for unit current, and hence the signal strength, can be increased at will. We must remember, however, that the hypothetical field $\tilde{\mathbf{B}}_1$ is for unit current at the Larmor frequency. Thus, consider a coil, short in comparison to its diameter, that has many turns but whose conductor length is effectively one wavelength λ (a 'helical resonator'). As current at different points on the coil therefore has different phases (thanks to the finite speed of light and the presence of distributed capacitance between turns), the alternating field produced at the coil center (but not elsewhere) is almost zero. It follows that an NMR sample placed at the middle of the coil will give negligible signal—a phenomenon not predictable from measurements of bulk parameters such as coil inductance or quality factor. The corollary of this observation is that the length of conductor may not be

increased ad infinitum to boost signal strength. Indeed, there is an optimal length for receiving coil use, and experience shows that this length is usually less than about $\frac{1}{20}\lambda$.² Put another way, the optimal number of turns on a coil diminishes as its operating frequency increases, and it is interesting to note that a single turn can exceed $\frac{1}{20}\lambda$ at 600 MHz with 10 mm sample tubes, and can approach λ in whole body applications at 170 MHz. It follows that designing good coils for these applications is both nontrivial and very difficult.

A further practical problem is that the loop geometry of Figure 1(a) may be unsuitable for use with most superconducting magnets, since the sample is usually inserted therein down the z axis. While such loops are sometimes employed to give a strong signal from a limited region on the side of an extensive sample (so-called 'surface coils', see *Surface and Other Local Coils for In Vivo Studies*),² if signal from a complete section of a long, cylindrical sample is desired, the latter must be encompassed by a receiving coil having a geometry of the form shown in Figure 2. (Surface coils have been used throughout the history of NMR. The first use specifically to obtain better signal-to-noise ratio is probably that by Abe et al.⁶ See also Ackerman et al.⁷)

Once a coil has been designed to take account of the above factors, we may calculate with confidence, with the aid of equation (5), the induced EMF from an elementary volume of sample. The total signal can then be found by integration (usually numerical) over the complete sample volume. This calculation is simplest when the receiver coil is also used for transmission with a genuine current I at the Larmor frequency. The phase is then invariant with spatial position, while the flip angle for a rectangular pulse of duration τ , is given by

Figure 2 Two geometries for producing $\tilde{\mathbf{B}}_1$ fields predominantly in the (x,y) plane, while allowing sample insertion down the z axis—the preferred direction when employing a superconducting magnet. In (a), a traditional 'saddle coil' is shown. Alternating current entering at P and leaving at Q generates at the coil center a $\tilde{\mathbf{B}}_1$ field in the x direction. In (b), circuits are completed with the aid of capacitors (not shown for clarity) across the eight gaps. Current flowing round the various circuits can create fields in any direction, but, in particular, two $\tilde{\mathbf{B}}_1$ fields (in the x and y directions) with a 90° phase difference between them can be made. In some circumstances, the second field can increase the available sensitivity by 40%.² With both designs, the 'active volume' (see the text) is roughly that of the enclosed cylinder

$$\theta = \frac{1}{2}\gamma\tilde{B}_{1xy}\tau \quad (6)$$

(the factor of 2 in this equation arises because it is the magnetic field in the rotating frame, rather than the laboratory frame, that determines the flip angle). The signal is then

$$\xi = 2\pi\nu_0 \left\{ \int_{\text{all space}} \tilde{B}_{1xy}(\mathbf{r})M_0(\mathbf{r}) \sin\left[\frac{1}{2}\gamma\tilde{B}_{1xy}(\mathbf{r})\tau\right] dV \right\} \times \exp\left(-\frac{t}{T_2}\right) \cos(2\pi\nu_0 t + \phi_0) \quad (7)$$

The dependence of the variables on spatial position $\mathbf{r}$ has been included for clarity, though the main field $\mathbf{B}_0$ has been assumed to be homogeneous so that the Larmor frequency ν_0 is spatially invariant. Of course, for most liquid samples in a test tube, $M_0(\mathbf{r})$ is a constant within and zero without. Equation (7) is then often dispensed with, and, using equation (5) again, an approximate value of ξ is found by taking the values of $\tilde{B}_{1xy}$ and θ to be those pertaining to the center of the receiving coil. An effective volume ΔV [the ‘active volume’, the volume encompassed by the receiving coil of Figure 2(a)], is then substituted for dV .

2.3 Orders of Magnitude

We shall briefly discuss coil geometry further when we consider noise sources, but, at this juncture, it is instructive to put numbers in equation (5) for two common samples that experi-

ence shows are easily detectable. We consider proton signals from first, 0.1% ethylbenzene at 500 MHz (14 T) and 20 °C in a 5 mm tube with a receiving coil having the geometry of Figure 2, and second, from 1 μ l of water at 64 MHz (1.5 T) and 37 °C in a biological sample using a surface coil. Ethylbenzene is routinely used as a standard for checking the sensitivity of high-resolution NMR spectrometers, and it is the signal-to-noise ratio of a central peak in the spectral quartet from the CH₂ group that is usually measured (Figure 3). Thus, signal effectively comes from 0.75 atoms of hydrogen per molecule. We first calculate the magnetic moment of the sample. Taking a specific gravity of 0.867 for ethylbenzene (molecular weight 106.2) and the active volume of sample to be about 150 μ l (Figure 2), the latter contains 130 μ g, or 1.22 μ M, of ethylbenzene. Thus, the magnetic moment of the hydrogen contributing to the measured line is, from equation (1) or Table 1, 3.2×10^{-13} A m². Now the magnetic field created by unit current in a saddle coil of diameter 7 mm and length 15 mm [Figure 2(a)], is approximately 210 μ T,⁴ and so, following a 90° pulse, from equation (5), the tiny voltage induced in the coil is about 210 nV.

Following a similar path, since the molecular weight of H₂O is 18 and its specific gravity to good accuracy is 1, one liter contains approximately 111 mol of hydrogen. Thus, from Table 1, and allowing for the temperature, the proton magnetization is 4.67×10^{-3} A m⁻¹, and the magnetic moment in 1 μ l is 4.67×10^{-12} A m². Consider the signal received at 64 MHz by a single turn surface coil of radius $a = 5$ cm from the sample an axial distance $x = 5$ cm away. If the permeability of free space is μ_0 , the magnetic field created by unit current at this point is⁵

$$B_{1xy} = \frac{0.5\mu_0 a^2}{(a^2 + x^2)^{3/2}} = 4.44 \mu\text{T} \quad (8)$$

Thus, following a 90° pulse, the induced EMF at 64 MHz has an initial amplitude of 8.3 nV. From these examples, we see that the signals received by an NMR spectrometer are truly small. However, let us now see how they compare with the unavoidable noise.

3 UNAVOIDABLE NOISE

3.1 Receiving Coil Resistance

The primary unavoidable source of noise when the sample is an electrical insulator is Brownian motion of the electrons in the receiving coil. The atoms in the coil conductor (usually copper or silver) have vibrational thermal energy, and interact with conduction electrons in the valence band. Thus, when current is passed and the electrons are given kinetic energy, the interaction transfers that energy to the atoms, and the conductor becomes hot. The usual measure of this interaction is the resistivity ρ of the conductor: a superconductor with zero resistivity generates no heat when current is passed. It was Einstein, in his famous paper on Brownian motion, who pointed out that where there is dissipation of energy by such interactions, there must also be energy fluctuations, and when this ‘fluctuation-dissipation’ theorem is applied to an electrical conductor,⁸ the ‘Nyquist formula’

Figure 3 A typical NMR spectrum. To be strictly accurate, the spectral sensitivity (or signal-to-noise ratio, S/N) of such a spectrum should be assessed by measurement, in each of a large set of spectra, of the height of the peak of interest. The mean and standard deviation of the peak height may then be found, and the ratio of these two quantities is the S/N. However, provided the instrument is in all respects stable, the same result may often be obtained in far less time by comparing, as shown, the peak height and the root mean square deviation of the spectral baseline (‘baseline noise’) in some flat region adjacent to the peak. It is stressed that this short cut is only valid with linear data processing techniques such as Fourier transformation, and when there is no phase noise in the NMR signal caused, for example, by sample spinning or an unstable magnetic field. Measurement of baseline noise can also be used in the test of receiver performance discussed later in the article

Figure 4 Proximity effect. When radiofrequency alternating current flows in adjacent conductors, their combined alternating magnetic fields induce EMFs in the conductors that constrain the current flow in such a way as to minimize the stored energy. Thus, in (a), which shows a greatly enlarged section of a circular loop (Figure 1), current flows preferentially on the inner radius, owing to the influence of the fields from the rest of the loop. In (b), similar constraints influence the distribution of current on the surface of a rectangular conductor. This ‘proximity effect’ renders difficult any calculation of conductor resistance

$$N_R = (4k_B T R \Delta\nu)^{1/2} \quad (9)$$

is obtained. Equation (9) states that the voltage measured between the ends of a conductor of resistance R fluctuates with a standard deviation (root mean square value) of N_R . (The distribution of the noise is Gaussian.) Note that the effective bandwidth $\Delta\nu$ of the measuring apparatus affects the measurement. The fluctuations are sometimes called ‘Johnson noise’, and it is clear that a major goal of receiving coil design is to minimize them, by reducing the coil’s resistance.

It might be thought that theoretical prediction of the noise is a simple task. However, this is not the case, because we are concerned with measurements (and therefore fluctuations) in the radiofrequency range. If we consider once again the simple loop of Figure 1(a), a hypothetical current of 1 A at the Larmor frequency generates an alternating magnetic field. While it is well known that this field creates a voltage across the ends of the loop—the phenomenon of self-induction—it is less well known that the electromotive forces it induces also cause the distribution of current in the conductor to become inhomogeneous and asymmetric, as shown in Figure 4. With a (fictitious) infinitely long wire of circular section of radius r_0 , the current flows uniformly in a ‘skin’ over the surface, and its density J decreases exponentially with penetration into the wire as

$$J = J_0 \exp\left(\frac{r - r_0}{\delta}\right), \quad \delta = \left(\frac{\rho}{\pi \nu_0 \mu \mu_0}\right)^{1/2}, \quad r_0 \gg \delta \quad (10)$$

where r is the radius within the wire, μ is the permeability of the wire, and δ is known as the ‘skin depth’. For copper at 100 MHz, $\delta = 6.6 \mu\text{m}$. However, when one conductor is in close proximity to another, the field created by the one alters (via the mechanism of induced EMFs) the distribution of current in the other, and vice versa, in such a manner as to minimize the energy stored in the magnetic field. Thus, in Figure

4(a), we see the effects of the current in the rest of the ring on the current distribution in one short segment. There is more current on the inside bend than elsewhere. This ‘proximity effect’ can effectively increase the resistance of the conductor by a factor ζ of up to an order of magnitude, since the current cannot fully utilize the available surface. It bedevils any calculation of resistance. Figure 4 also shows the effect when the conductor is rectangular. Current flows mainly in the corners of the conductor, illustrating the axiom that where the alternating field is strongest, there the current is.

It follows that, without a very tedious finite element computation, we may only estimate the resistance of a receiving coil, and hence its noise. Once the thickness of a conductor is very much larger than the skin depth (and this is usually so at the frequencies employed in NMR), we may write the resistance R_c as

$$R_c = \frac{\zeta \rho l}{s \delta} = \frac{\zeta l}{s} (\pi \nu \mu \mu_0 \rho)^{1/2} \quad (11)$$

where l is the length of the conductor and s is its circumference. However, increasing s to reduce R_c can also reduce the B_1 field created by the coil, and much of the art of receiving coil manufacture lies in optimization of the ratio $\tilde{B}_1/R_c^{1/2}$. Thus, a well-designed saddle coil of the previous section might have a resistance of roughly 1Ω at 500 MHz, while the surface coil might have a resistance of about 0.1Ω at 64 MHz.

3.2 Sample Losses and Effective Resistance

When the sample is an electrical conductor, as is often the case in biological NMR experiments, our hypothetical alternating magnetic field $\tilde{B}_1$ induces eddy currents which hypothetically heat the sample. (The transmitter B_1 field really does heat the sample, and is potentially dangerous. See *Sensitivity of Whole Body MRI Experiments*.) This dissipation of energy must be interpreted electrically as an extra resistance R_m in series with the coil, for in electrical theory, only resistance can produce heat from current. Conversely, by the fluctuation–dissipation theorem, there must be noise associated with the resistance, as per equation (9), where T is now the temperature of the sample.^{2,9} In general, calculation of R_m is difficult, and if a measure of it is needed, it is best sought experimentally.² However, in one or two simple cases, it may be deduced—and one of these is where a circular coil sits on the surface of a semi-infinite sample. If the skin depth and wavelength in the conductor are very much greater than the radius of the coil, the resistance R_m is

$$R_m = \frac{4}{3} \sigma \pi^2 \mu_0^2 \nu_0^2 a^3 \quad (12)$$

where a is the coil radius and σ is the conductivity of the sample.² Thus, for $a = 5 \text{ cm}$ and a conductivity of 0.3 S m^{-1} (a typical average value for animal tissue), the effective resistance at 64 MHz is 3.2Ω . In practice, measured values tend to be smaller than this, since surface coils are usually lifted a little from the surface.² However, it is clear that inductive losses in the sample can be a major source of noise for most biological NMR experiments, since R_m is often very much greater than R_c . (See also *Sensitivity of Whole Body MRI Experiments*.) The origin of the noise in such experiments is the Brownian

motion of the electrolytes. The random motions of the charges induce random electromotive forces in the receiving coil, and employing the concept of an effective resistance is simply a convenient way of quantifying such random voltages.

3.3 Receiver Noise

No NMR receiver is noiseless, and there are always small contributions to the noise from various parts of the circuitry, notably from the mixers and the audiofrequency amplifiers.^{2,10} However, with a well-designed system, the receiver noise should come overwhelmingly from the first stage of preamplification and be small in comparison to the two sources of noise already discussed. Unfortunately, this desirable situation can easily be abrogated by the user, the most common mistake being the insertion of an attenuator between the preamplifier and the rest of the receiver. This error can easily result in the noise from the receiving coil being so attenuated that the noise from, for example, the first mixer in the receiver, can predominate. The result is inevitably a reduction of sensitivity. An attenuator should only be used as a last resort in the presence of huge signal strength, when the maintenance of an optimal signal-to-noise ratio is of no concern. Another common mistake concerns the matching (see later) of the probe. The preamplifier manufacturer designs the first stage of the device so that it gives its best performance from a signal source of a specific impedance—usually $50\ \Omega$ resistance for NMR purposes. However, this does *not* mean that the input impedance Z_{in} of the preamplifier is $50\ \Omega$, and so matching the probe to the input impedance, for example by maximizing the receiver output, can destroy the conditions for optimal noise performance. It should not be attempted—the signal may be increased, but the noise will increase more rapidly!

The additional noise added by the NMR receiver can be found from the ‘noise figure’ F of the device—a number usually quoted by the manufacturer in decibels. In general, if noise βN_a is added by an amplifier of gain β , to the noise βN_s from a $50\ \Omega$ source, the total noise delivered by the device is $(\beta(N_a^2 + N_s^2))^{1/2}$ (random numbers add quadratically). However, if the device were perfect, N_a would be zero and the output would be βN_s . The ratio of the imperfect to perfect outputs is the ‘noise factor’ F' , and, converted to decibels, this is the noise figure

$$F = 20 \log_{10} F' = 10 \log_{10} \left(1 + \frac{N_a^2}{N_s^2} \right) \quad (13)$$

A good NMR receiver has a noise figure of less than 2 dB; in other words, the noise it adds degrades the inherent sensitivity of the receiving coil by less than 25%.

A devastating test of receiver performance can easily be made with the aid of hot and cold noise sources that temporarily replace the probe on the preamplifier input. The sources are two identical, well-shielded resistances, one $50\ \Omega$ at room temperature and the other $50\ \Omega$ in liquid nitrogen at 77 K both resistances being on the ends of identical short lengths of $50\ \Omega$ cable and both being specified at the Larmor frequency. From equation (9), the noise from the source in liquid nitrogen is about half that from the source at room temperature T , and so we should expect the noise from the spectrometer to change significantly when the two sources are interchanged. If the

measured ratio of the ‘cold’ to ‘hot’ receiver outputs is α , the noise figure is, to fair accuracy²

$$F = 10 \log_{10} \left(1 - \frac{77}{T} \right) - 10 \log_{10} (1 - \alpha^2) \quad (14)$$

For example, if $T = 293\ \text{K}$ and $\alpha = 0.64$, $F = 1\ \text{dB}$, and the system has good noise performance. As many NMR computing systems have software available to measure RMS noise (see, e.g., Figure 3), it is a relatively simple matter to compute the noise figure. The only trap of which to beware is that a shielded resistance that is accurately $50\ \Omega$ at room temperature will almost certainly not be $50\ \Omega$ when plunged into liquid nitrogen! This simple procedure has further value when one remembers that an NMR probe should give the same noise output as the room temperature $50\ \Omega$ resistance. If it does not, the probe is either unmatched or is receiving interference.

4 SIGNAL-TO-NOISE RATIO

4.1 Filtered Fourier Transformation

We have seen that quite a good estimate of the signal induced in a receiving coil can be obtained, while the resistance R_c or effective resistance $R = R_c + R_m$ of the coil can sometimes also be estimated tolerably well. Thus, a reasonable knowledge of signal and noise is available, and both are passed to the preamplifier and thence to the NMR receiver. However, it is not normally the initial amplitude of a free induction decay and its accompanying noise that is observed in an NMR experiment, but rather some function of these voltages obtained by computational manipulation—for example, by a filtered Fourier transform. The purpose of such a transform is to find how much signal is present at a number of discrete frequencies covering a limited spectral width about the Larmor frequency. For simplicity, assume that the spectrometer frequency is such that one of the central peaks of the ethylbenzene quartet of Figure 3 mentioned earlier is exactly on resonance. As the on-resonance FID issues from the NMR receiver, let it be integrated (this mathematical device is equivalent to picking the peak out of the many frequencies present in a Fourier transform). Employing equation (5) with a 90° pulse, and, for simplicity, setting the gain of the receiver to 1, the signal is then

$$\begin{aligned} \xi &= \int_{t'=0}^t 2\pi\nu_0 \tilde{B}_{1xy} M_0 dV \exp\left(-\frac{t'}{T_2}\right) dt' \\ &= 2\pi\nu_0 \tilde{B}_{1xy} M_0 T_2 dV \left[1 - \exp\left(-\frac{t}{T_2}\right) \right] \end{aligned} \quad (15)$$

and in the limit as $t \rightarrow \infty$, $\xi \rightarrow 2\pi\nu_0 \tilde{B}_{1xy} M_0 T_2 dV$. This value represents the height of the spectral peak, and is dependent upon the relaxation time T_2 . (We assume the main magnetic field is homogeneous.)

Next, examine the effects of the integration on the noise. It may be shown that integration is equivalent to applying a filter of width $\Delta\nu = 1/t$ (in Hz) and gain t . Thus the RMS noise on the spectral baseline is

$$N_R = F'(4k_B TRt)^{1/2} \quad (16)$$

and as t increases, so does the noise. Thus, the signal-to-noise ratio (S/N) $\Psi = \xi/N_R$ passes through a maximum when data are gathered for a time $t = 1.255T_2$, and is

$$\Psi_{\text{truncated}} = \frac{0.638}{F'} 2\pi\nu_0 \tilde{B}_{1xy} M_0 dV \left(\frac{T_2}{4k_B TR} \right)^{1/2} \quad (17)$$

In low-field imaging experiments, the signal and noise from the receiver may well only be collected for this length of time, but in spectroscopic experiments, the resulting lineshape is unsatisfactory, and, further, a slightly better S/N can be obtained. Thus, it is common practice *not* to truncate the signal and noise, but to multiply both by an exponential filter $G = \exp(-t'/T_2)$ until the signal has decayed to a negligible value. Following Fourier transformation, a broader Lorentzian line, of width $2\pi T_2$ (in Hz) and of height 22% *less* than previously, is obtained. However, the effect on the noise of such filtering followed by integration is to limit it to

$$N_G = F'(2k_B TRT_2)^{1/2} \quad (18)$$

and when we calculate the S/N under these conditions, it becomes [cf. equation (17)]

$$\Psi_{\text{filtered}} = \frac{0.707}{F'} 2\pi\nu_0 \tilde{B}_{1xy} M_0 dV \left(\frac{T_2}{4k_B TR} \right)^{1/2} \quad (19)$$

In Section 2.3, we calculated the amplitude of the FID for the largest line in the quartet of ethylbenzene to be about 210 nV, while in Section 3.1, an estimate of the probe resistance was $R = R_c = 1 \Omega$. Setting T_2 to a typical value of 300 ms and $F' = 1.26$ ($F = 2$ dB), we obtain a value of 510:1 for the S/N in equation (19). Considering the uncertainties in our estimation of probe resistance, this is in good agreement with the typical experimental value of 594:1 at 500 MHz shown in Figure 3. It may be noticed in equation (11) that the probe resistance is proportional to the frequency to the quarter power. From equation (19) we may then conclude that the S/N increases not as the square of field strength as mentioned earlier, but roughly as the Larmor frequency to the power of $\frac{7}{4}$, provided T_2 does not change with frequency. There is a strong dependence of equation (19) on temperature (roughly as $T^{-7/4}$), since, in addition to M_0 , the resistance of the receiving coil is strongly temperature-dependent, and attempts have been made to fabricate probes where the receiving coil is at very low temperature.¹¹ The challenge is not to freeze the sample while keeping the receiving coil tightly wrapped about it.

When we consider the S/N of an experiment involving a conducting sample, the dependences are very different. If the effective resistance R_m is very much bigger than the intrinsic resistance R_c , we may substitute equations (8) and (12) into equation (19) to obtain the maximum S/N available from an elementary volume dV a distance x below a surface coil of radius a . We then have

$$\Psi_{\text{filtered}} = \frac{M_0 dV}{F'} \left[\frac{3aT_2}{32k_B T \sigma (a^2 + x^2)^3} \right]^{1/2} \quad (20)$$

Provided the conductivity σ (the reciprocal of the sample's resistivity) and the transverse relaxation time T_2 of the sample do not vary with frequency, the S/N only increases linearly with field strength via the magnetization M_0 . This is because the noise, being an induced voltage, also has a linear dependence on frequency. Further, note the very strong dependence of Ψ upon the size of the surface coil. (See *Sensitivity of Whole Body MRI Experiments*.) Thus, we may expect a S/N of about 11 from the example given earlier of 1 μ l of water, at 64 MHz, 5 cm below a surface coil of radius 5 cm (T_2 was set to 300 ms and $F' = 1.26$). While we have chosen an illustrative example of a surface coil, the demonstrated dependences hold for most experiments where the noise from the sample is dominant, regardless of the shape of the coil.

4.2 Data Accumulation

Of course, many experiments will be performed repetitively, and the results summed to increase the S/N. This strategy is possible because the signal, being deterministic, adds linearly, whereas the noise, being random, adds as the square root of the number of repetitions. Thus, the S/N also increases as the square root of the number of repetitions—and of time. Conversely, the time taken for an experiment to acquire a desired S/N will depend on field strength between $B_0^{-7/2}$ and B_0^{-2} , depending on the sample's conductivity and size. However, to repeat the NMR experiment, we must wait for magnetization to relax longitudinally before attempting a repetition. Suppose that during a cumulative experiment and just prior to a pulse of flip angle θ , no vestige of transverse magnetization remains from the effects of the previous pulse that was applied a time T_R earlier. In other words, $T_R \gg T_2$. If the longitudinal magnetization at this time is M_1 , immediately after the pulse, the longitudinal magnetization has become $M_1 \cos \theta$, while the transverse magnetization is $M_1 \sin \theta$. The latter determines the voltage induced in the receiving coil, but a repetition period T_R later, the longitudinal magnetization M_z has recovered somewhat to become once again M_1 :

$$M_z = M_0 - (M_0 - M_1 \cos \theta) \exp(-T_R/T_1) = M_1 \quad (21)$$

Thus,

$$M_1 = M_0 \frac{1 - \exp(-T_R/T_1)}{1 - \cos \theta \exp(-T_R/T_1)} \quad (22)$$

Now, in a time T_n , there can be $n = T_n/T_R$ repetitions, which, notwithstanding the type of experiment (spectroscopic, imaging, etc.), increases the S/N Ψ by a factor of $n^{1/2}$. Thus, at the end of data accumulation, at time T_n ,

$$\Psi \propto n^{1/2} M_1 \sin \theta = M_0 \left(\frac{T_n}{T_R} \right)^{1/2} \sin \theta \times \frac{1 - \exp(-T_R/T_1)}{1 - \cos \theta \exp(-T_R/T_1)} \quad (23)$$

A normalized contour plot of this function is shown in Figure 5, but, by simple differentiation, it is easy to show that for constant T_R , it passes through a maximum when $\theta = \arccos[\exp(-T_R/T_1)]$, the so-called 'Ernst angle'. Substituting this value into equation (23), we find that

Figure 5 The signal-to-noise ratio in a spectrum accumulated for a given fixed time as a function of the pulse flip angle, and the ratio T_R/T_1 of the repetition period T_R and longitudinal relaxation time T_1 . The plot is normalized to unity, since it takes no account of vagaries such as spectral filtering and transverse relaxation time. Note that the y axis is logarithmic. (For a plot of the dependence of signal strength on variations in T_1 , see *Sensitivity of Whole Body MRI Experiments*, Figure 1)

$$\Psi_{\max} \propto M_0 \left[\frac{T_n}{T_R} \frac{1 - \exp(-T_R/T_1)}{1 + \exp(-T_R/T_1)} \right]^{1/2} \quad (24)$$

and a global maximum is obtained when T_R is as small as possible, say $2.5T_2$. Thus, in a spectroscopic experiment, from equations (19) and (24), when $2.5T_2 = T_R \ll T_1$, $\Psi_{\max} \propto M_0(T_n T_2/T_1)^{1/2}$, and, not surprisingly, we see that it is the ratio of the relaxation times that governs the accumulated S/N. However, we can see from Figure 5 that the sensitivity is excessively dependent upon the flip angle under such conditions, and so it is often better to sacrifice a little sensitivity and use, say, a 50° pulse with a repetition time T_R of about $0.4 T_1$.

5 ELECTRIC FIELDS AND EXTRANEIOUS NOISE

Almost nothing has been said so far concerning matching of the probe. The calculations above assume that this task has been performed correctly and that the additional components required have negligible effect upon the sensitivity of the instrument. However, we now turn to it as a possible conduit for noise. It has been mentioned that the preamplifier is designed to give its best noise performance from a source of impedance 50Ω resistive, this value being chosen by the manufacturer to be compatible with a common value of coaxial

cable characteristic impedance. It follows that the predominantly reactive impedance of the receiving coil, $Z_L = R_c + R_m + i2\pi\nu_0 L$ (typically, $0.5 + i70, \pm 50\%$), where L is the coil inductance and $i = \sqrt{-1}$, must be transformed to 50Ω resistive. This statement implies the use of capacitors (capacitance C), with their negative reactance $Z_C = -i/2\pi\nu_0 C$. The capacitors should have a resistance that is much less than $R_c + R_m$ so that they introduce negligible extra noise—they should have a high quality factor. The theory of impedance transformation in LCR circuits is outside the scope of this article.² (Any good electronics text deals with the subject of impedance transformation—a ‘classic’ is that by Terman.¹²) However, we note that as soon as capacitance is deemed to be an important circuit component, we must take cognizance not only of magnetic fields but also of electric fields. This aspect of probe design, often neglected, is of crucial importance whenever the size of the probe is not very much less than wavelength $\lambda = c/\nu_0$ where c is the speed of light in free space or the sample. The ideal probe has no electric fields running through the sample, no fields escaping from its confines into the outside world, and an average potential that is equal to that of its surroundings. The corollary of these statements is that (i) dielectric properties of the sample or its holder neither generate noise nor modulate the impedance transformation, and (ii) no interference is received from the outside world. Thus, for example, a dielectrically lossy sample such as a human does not produce noise by

Figure 6 Electric fields. In (a) are shown the fields (conservative and nonconservative) of the Hertzian loop of Figure 1. Because there is only a single gap in the loop (across which is placed the sole tuning capacitor), a considerable dipolar field is created. The direct consequence is that the tuning and Q factor are dependent upon the dielectric properties of the sample. Concomitantly, the loop acts as an excellent antenna for reception of electromagnetic interference (EMI) propagated by electric fields. In (b), the four gaps and tuning capacitors (not shown) create an octapolar conservative field that reduces substantially both the sample dependence of the loop's characteristics and the sensitivity to interference. However, the principle of distributed capacitance is not a sinecure, and each probe design should be individually assessed with regard to its electric field properties and suitable placement of capacitors

the Brownian motion of electric charges capacitively coupling to the probe, nor does a spinning sample modulate the probe tuning, producing so-called ' t_1 noise'. Neither does a sample of high dielectric constant such as water appreciably change the probe tuning when inserted. Equally, grasping the leads entering a probe (a useful test) makes no difference to the probe matching to 50Ω , and does not change the noise emanating from the receiver.

It is sometimes claimed that the ideal situation outlined above is completely unattainable, since Maxwell's equations dictate that whenever there is an alternating magnetic field, such as the hypothetical $\vec{B}_1$ field, there must also be an alternating electric field—the fields are linked. This is correct, but the operative word is 'whenever' not 'wherever'. A standing wave on a transmission line is a simple example of the linking of magnetic and electric fields: however, where the former is greatest, the latter is least. The deleterious effects of conservative electric fields in probes have been known for many years—mainly as a heating mechanism when samples are dielectrically lossy.¹³ The key to rendering such effects negligible is to ensure that the fields' order is as high as possible, and each probe design has to be assessed individually in this regard. However, a simple example is afforded by the Hertzian loop, as shown in Figure 6(a). Commonly used as a surface coil in biomedical experiments, Hertz demonstrated the existence of radio waves with it—it is an excellent antenna and a poor probe. The figure shows that there is a strong dipolar electric field across the gap, which can produce localized heating in a sample beneath, and excessive dependence of resonant frequency on sample position and composition. However, in Figure 6(b), distributing the tuning capacitance symmetrically about the loop creates an octapolar field that reduces dramatically resonant frequency variation, heating and concomitant noise.¹³ It also ensures that any external electric fields (with up

to eighth-order variation with distance) cannot couple to the probe. Such fields can be created by a variety of sources, as mentioned in Section 1—for example, when radio waves impinge on the magnet, or on surrounding objects and cables. Thus, using distributed capacitance also helps reject interference in this instance. It should be stressed that discretely distributed capacitance does not automatically kill dipolar fields—each situation must be analyzed individually. For example, despite a surfeit of capacitors, the well-known bird-cage design (see also *Birdcage Resonators: Highly Homogeneous Radiofrequency Coils for Magnetic Resonance*) has a dipolar field across its mouth if a guard ring is not employed.

The manner in which a tuned and matched probe is connected to the preamplifier can also generate conservative dipolar electric fields—not this time in the confines of the probe, but rather between the cabling and surrounding conductor (e.g., the magnet). In other words, current can spill out of the probe and flow over the outer surface of the coaxial cable linking the probe and the preamplifier. Thus, a large antenna is created that may radiate quite efficiently during transmission and may also receive interference. This situation is far more difficult to analyze, but one approach is shown in Figure 7. Consider the matched probe of Figure 7(a) connected to a preamplifier of input impedance Z_{in} . There is also present a source of electromagnetic interference (EMI) that has capacitance to the probe. For simplicity, only two capacitances are shown, but it is obvious that interference current flows through the coaxial cable and into impedance Z_{in} : the preamplifier receives interference. Now consider the so-called 'balanced' circuit of Figure 7(b). By virtue of the halfwave cable and symmetry, points P and Q must be at the same potential as the braiding of the coaxial cable at point R. Thus, no current can flow into the preamplifier, and there is no interference. Concomitantly, during transmission, no dipolar fields are created between the cabling and the magnet. In practice, there is rarely perfect symmetry, and a balance can never be totally attained, but a reduction in interference of a factor of 50 or 100 can often be garnered with this technique.

Finally, where possible, the probe should be shielded. This is normally not a difficult matter in a high-resolution spectrometer, where the length of the magnet bore is much greater than its diameter. A metal tube of diameter D attenuates radiation as $\exp(-3.68z/D)$. Thus, if the probe is in the middle of a tube whose length is greater than eight diameters, negligible interference can be received, while physical access is still possible. Of course, the efficacy of such a tube shield is easily ruined by having a conductor running through it. A large coaxial cable is then created, which acts as a conduit to transport interference. Thus 50Ω cable running to the probe should always go up the inside tube wall (or even through it) and have its outer conductor electrically attached at numerous places. Any other cabling (for sensors, stimulators, etc.) should be fitted with stringent low-pass filters at the tube entrance; it should also run up the wall and always be 'decoupled' with capacitors to the tube at several positions. When the bore of the magnet is not long in comparison with the diameter, shielding is much more difficult, and it is sometimes necessary, in noisy environments (e.g., close to a radio transmitter), to shield the magnet room and spectrometer or imager. This is an expensive and difficult task, since every electrical conductor entering the

Figure 7 The reduction of electromagnetic interference (EMI) by good total probe design. In both figures, a model circuit for EMI reception is shown. The interference is represented as a voltage source V_{emi} that has distributed capacitance to the probe. For simplicity, this is shown by two small capacitors C_{eff} (say of order 1 fF). The current return path, which typically involves capacitive coupling to the braid of the coaxial cable running to the preamplifier, and to the exterior of the latter, is shown as comprising an arbitrary effective impedance Z_{eff} . In (a), it may be seen that, despite the use of two matching capacitors (which need to be adjusted in tandem), a current I_1 flows into the preamplifier where it generates an interfering voltage across Z_{in} . The current may be reduced by ensuring that Z_{eff} is large, and one way of doing this is to mount a 'quarter-wave balun' at the end of the coaxial cable, as shown in the inset. The sleeve on the cable, being $\frac{1}{4}\lambda$ long, creates an impedance of a few k Ω between the inside and the outside of the coaxial braiding and thereby hinders the flow of current I_1 somewhat, depending on the impedance of C_{eff} . However, in (b), the half-wave cable ensures that any potential common to both points P and Q is shorted to point R. To the extent that the model for interference has electrical symmetry, it therefore follows that no voltage is present across the end of the coaxial cable and no interference is received by the preamplifier. This design of 'half-wave balun' may also be applied to the probe of (a), but the circuit of (b) has the advantage of needing only a single variable matching capacitor C_m while maintaining electrical symmetry

room must then pass through an excellent low-pass filter. Nor must it be forgotten that rectification of rf interference can take place in circuitry, thus rendering audiofrequency devices noisy too. For example, the currents in shims or gradients may alter in the presence of interference, and it is not unknown for a local radio station to be clearly audible near a magnet as the gradient coils act as a loudspeaker. The S/N is then degraded by changes of the Larmor frequency and/or main field homogeneity during data accumulation—'phase noise' appears on the spectrum.

6 CONCLUSION

This article has attempted to provide an introduction to questions of sensitivity in the NMR experiment. However, since there are so many variants of the basic 'pulse and collect' experiment, the reader should be aware that no work of this

type can be comprehensive. Thus, for example, there has been negligible discussion of phase noise and receiver gain, and the effects of field drift, temperature variation, distortion, etc. have not been considered. In addition, when the Larmor frequency is sufficiently high that the wavelength $\lambda = c/\nu_0$ in the sample approaches the sample dimensions, the theory given above needs modification; notwithstanding excellent probe design, the $\vec{B}_1$ field in the sample can become highly inhomogeneous in amplitude and phase. In an imaging experiment, the root mean square S/N will be approximately that predicted by the theory above, but in an experiment that collects signal from the entire sample, there may well be destructive interference between signals from different spatial positions. However, such ramifications affect only the highest sensitivity field imaging experiments and are of little concern to the vast majority of NMR practitioners. Finally, a major extension of the ideas presented concerns the sensitivity of the human NMR imaging experiment. This topic is sufficiently important and complex that it is treated separately under the heading of *Sensitivity of Whole Body MRI Experiments*.

1 INTRODUCTION

In its basic form, nuclear magnetic resonance (NMR) spectroscopy requires a very uniform magnetic field over the region of the sample under observation. Magnets used for NMR do not provide sufficient magnetic field homogeneity for use in high-resolution NMR experiments. The magnet's intrinsic inhomogeneities are further degraded by the magnetic susceptibilities of the NMR instrument's transducer (probe), the NMR sample's container (tube), and the NMR sample itself. The process of correcting the magnetic field to be as uniform as possible is called shimming.

The process of shimming has been one of the least understood aspects of operating an NMR instrument. The process is sometimes very frustrating and shrouded in mysticism. Many different 'procedures' for shimming have developed over time and more continue to evolve. However, most NMR operators do not need a theoretical understanding of shimming, but they all need an empirical approach to the process with some practical tools to use in the process. This article is an attempt to provide an empirical approach to shimming with some tools to use to make the process less magical and more logical.

2 HISTORY OF SHIMMING

Magnetic field homogeneity has always been critical in high-resolution NMR, and is becoming more so as NMR technology advances. In the history of NMR, there have been many different ways to do the adjustment of the magnetic field homogeneity. The methods and techniques for shimming continue to develop and improve today.

Among the first magnets used for NMR were large electromagnets whose field homogeneity was adjusted by purely

mechanical means. The magnet's pole faces were precision ground to be very smooth and flat. As long as the magnet's pole faces were very flat, the more parallel the pole faces, the more homogeneous the magnetic field. The first step in adjusting magnetic homogeneity was to adjust the tilt of the pole faces by turning three large bolts to make the magnet's pole faces as parallel as possible. When the bolts ran out of range, coarse adjustment was done by placing thin pieces of brass between the magnet yoke and the back of the pole pieces. These thin pieces of brass were also placed in other strategic locations to make the pole faces parallel in a manner not addressed by the three adjustment bolts. The metal pieces were called shim stock and the seemingly endless process of placing and removing pieces of shim stock acquired the name 'shimming'. Because the NMR signal is more sensitive to the magnetic homogeneity than any other means of testing either the value of the magnetic field at different positions in the NMR sample area or the precision of the mechanical alignment of the pole faces, the signal from the NMR sample became the only means to adjust the magnetic field homogeneity. Because tons of pressure from the magnetic field existed on the pole faces of an energized magnet, the magnet had to be turned off to add or move pieces of shim stock. The final step in adjusting magnetic homogeneity with these systems was to adjust a bolt with a large ratchet. This pulled together or pushed apart the tops of the magnet pole pieces to give a fine adjustment of the Y gradient.

While these mechanical adjustments seem crude, these instruments were typically capable of giving better than 0.2 Hz resolution. This is rather impressive considering that 0.2 Hz out of 60 MHz represents 3 parts per billion field homogeneity over the volume of the sample. To improve the level of performance and reduce the difficulty of adjusting the magnetic homogeneity, an electrical 'shimming' process, consisting of a set of small electromagnets placed around the sample, was developed to supplement the mechanical process.¹ The magnetic field homogeneity could be adjusted by varying the current in each of these small electromagnets. This process retained the name shimming and the small electromagnetic coils assumed the name 'shims'. With the advent of superconducting NMR magnets, the electrical shims became the only adjustment available to the NMR operator. Each small electromagnet can be used to 'shape' the field to compensate for existing magnetic gradients.

At first only a few low-order (X , Y , and Z) electrical shims were used. As the fields became higher and magnet production became more difficult, more and higher-order electrical shims were added to maintain the same level of performance. The process becomes more difficult as the number of these electrical shims increases, not only because there are more adjustments to make, but because each shim does not generate 100% pure gradients. There are interactions with shims of a similar nature (e.g. ZX creates some Z gradient and X gradient in addition to the intended ZX gradient). Because of these interactions, the number of adjustments necessary to shim the magnet increases geometrically with the number of shims, not just linearly. In addition, the raw field encountered in superconducting magnets is usually worse than in electromagnets, so larger corrections are required. These two facts make the process of shimming superconducting magnets more difficult and the shimming process correspondingly more important to obtain useful NMR spectra.

2 SHIMMING OF SUPERCONDUCTING MAGNETS

Obtaining 0.2 Hz resolution requires 10 times greater magnetic field homogeneity at 600 MHz than at 60 MHz, so shimming becomes more important to achieve the same results as the magnetic fields increase. Other aspects of instrument performance are also dependent on shimming, such as solvent suppression, which requires good lineshape very far down at the base of the peak.

3 THE PROBLEM

An organized and logical approach to shimming is the key if the process is to be both fast and effective. Each shim or shim type generates symptoms in the NMR instrument's performance indicative of its misadjustment. An understanding of the relationship of each shim and the corresponding instrumental performance is essential to achieve good results in a reasonable amount of time.

Shimming has some generalized procedures to be used when certain clues are observed. In addition to these procedures, there are tools available for use in the shimming process. Each tool is called upon as the conditions warrant, and each works in some cases, but not all.

The most common method of adjusting the homogeneity of an NMR magnet is the observation of an NMR signal. Since the natural linewidth of an NMR signal may be less than 0.1 Hz, then even for a 100 MHz NMR instrument a field homogeneity of one part per billion would be required to measure this linewidth. Very few test instruments have this precision. This means that the NMR instrument becomes the test instrument used to adjust itself.

An additional problem with the shimming process is that the observed NMR signal arises from the integrated signal from the total volume of the observed sample, which may have many different resonant frequencies with different degrees of excitation arising from different positions in the sample. Visualize the NMR sample as a collection of isolated minisamples, each of which is infinitesimally small. Each minisample then generates a signal whose linewidth is determined by the T_2 relaxation time of the sample and whose frequency results from the field value at that point. The intensity of the signal generated by each minisample would reflect the amount of excitation at that point. The observed signal is the total integrated signal over the entire sample volume times each area's degree of excitation. It is the integration of the NMR signal response which leads to a major difficulty in the shimming process. Any knowledge as to which part of the NMR sample is experiencing which magnetic inhomogeneity is lost in this integration process.

The NMR operator adjusts the field homogeneity for the NMR instrument with a set of electrical shims, each of which has its effects over a complex geometry. If positional information for each of the mini-samples were not lost in the integration process discussed above, the NMR operator would have much better clues as to which shim to adjust. This is why many NMR magnets are initially set up using a special field plotting probe. This is a tedious process of moving a small NMR sample to different and known positions in the magnet's field, and so retains the positional relationship for each frequency measurement. Automated field mapping equipment has been developed which maps the field, calculates the optimum currents for all shims, applies them and then

Table 1 Room Temperature Shims

Common shim name	Function	Interaction order
Z0	1	0
Z1	z	0
Z2	$2z^2 - (x^2 + y^2)$	1
Z3	$z[2z^2 - 3(x^2 + y^2)]$	2
Z4	$8z^2[z^2 - 3(x^2 + y^2)] + 3(x^2 + y^2)^2$	2
Z5	$48z^3[z^2 - 5(x^2 + y^2)] + 90z(x^2 + y^2)^2$	2
X	x	0
Y	y	0
ZX	zx	2
ZY	zy	2
XY	xy	1
X2 - Y2	$x^2 - y^2$	1
Z2X	$x[4z^2 - (x^2 + y^2)]$	2
Z2Y	$y[4z^2 - (x^2 + y^2)]$	2
ZXY	zxy	2
Z(X2 - Y2)	$z(x^2 - y^2)$	2
X3	$x(x^2 - 3y^2)$	1
Y3	$y(3x^2 - y^2)$	1

iterates,² clearly a more efficient and effective approach. After magnet installation and in general use there are, however, clues from the NMR signal which allow the NMR operator to narrow the selection of shims which probably need adjustment. These clues will be discussed below in Section 8.

The shim gradients used to adjust the magnetic field homogeneity in superconducting magnets have common names which reflect their geometry. However, these shims have more complicated expanded equations describing their actions as indicated in Table 1.³ Although every different type of shim set has a slightly different set of expanded equations, the expanded equations for the shim gradients shown in Table 1 are reasonable examples of the full gradient created by each shim coil. The equations are shown for interest and are not used in the shimming process to be described.

4 SAMPLE SPINNING

In the early days of NMR, Bloch suggested that the effective homogeneity of the magnetic field could be improved in a simple way by creating motion of the molecules within the sample.⁴ The rate of molecular motion necessary to accomplish this task is on the order of 4 Hz, a speed easily obtainable by mechanical spinning of the sample tube. Anderson and Arnold⁵ demonstrated the improvement by spinning a water sample about an axis coincident with the axis of the receiver coil. At rotational speeds in excess of 10 Hz, they reduced the halfwidth of the NMR signal by a factor of 17 and increased the amplitude by a factor of seven. The size of the improvement is proportional to the size of the field inhomogeneity in the plane averaged by the spinning process. As the magnetic field homogeneity increases, the improvement obtained by sample spinning decreases. Spinning the sample also has some undesirable effects, some of which are discussed in Section 4.1 below.

If the magnetic field had no field inhomogeneities which could be averaged by spinning, spinning would not produce better apparent resolution and would not be necessary.

Throughout the development of NMR, more and higher order shims have been added to produce better field homogeneity. This process continues with some advanced shim sets having as many as 38 different shim gradients.⁶ The ability of these expanded shim sets to correct magnet gradients is calculated to be improved by a factor of two to five. Careful adjustment of all these shims while not spinning the sample leads to a field homogeneity approaching that of the spinning sample without the negative effects of spinning. As the trend in the direction of better nonspin homogeneity continues, spinning the NMR sample may not be a common practice in future NMR instruments.

The practice of spinning the sample separates the set of shims into two categories: on-axis shims, which are not averaged by spinning, and off-axis shims, which are averaged by spinning. The process of adjusting the on-axis shims while spinning and the off-axis shims while not spinning ‘decouples’ the two sets of shims to a first approximation and the overall process is divided into two processes of smaller scope. Usually this decoupling process is less than perfect, but with some iteration between spinning and nonspinning shimming processes, spinning becomes a useful tool in simplifying the shimming procedure.

Spinning the NMR sample tube averages the field inhomogeneities in the plane perpendicular to the spinning axis, but not along the axis. If the NMR operator could make a spherical sample and spin about the X , Y , and Z axes simultaneously, shimming might become a lot easier. However, no simple mechanical means of preparing and spinning the sample to average all three axes has yet been devised. The effect of spinning in all three axes simultaneously can be seen when starting and stopping spinning on large diameter tubes. The turbulence created by starting and stopping causes sample mixing along the spinning axis. If the NMR operator watches the lock level of a spinning sample and suddenly turns off the spinner, the lock level will actually rise while the sample is mixing from the turbulence. The same effect can be seen when starting to spin where the lock level goes up to a higher level and fades back down to a final value between the nonspin value and its highest level. This is because turbulence when the spinner starts causes vertical mixing of the sample. As the sample moves around with spinning and up and down with turbulence it is effectively being ‘spun’ in all axes simultaneously. The effect is most visible on large diameter tubes.

4.1 Artifacts of Sample Spinning

An undesirable effect of spinning the sample is the creation of spinning sidebands. Field inhomogeneity modulates the NMR signal at the spinning rate and produces small peaks on either side of the resonance signal. There are actually several types of spinning sidebands. Each type has some observable different characteristics, but they have a common characteristic of occurring at integer multiples of the spinning rate with a tendency to become smaller as the spinning rate is increased. These properties can be used to help identify these spurious signals. Spinning sidebands (SSB) can be of three general types as discussed below.

Off-Axis Inhomogeneity Sidebands: These are first- and second-order (sometimes more) sidebands (SSBs) which are in phase with, and usually present on both sides of, the main peak.

These signals average with the main peak and so do not tend to decrease with the acquisition of more scans. This type of SSB arises from off-axis gradients in the magnetic field and can be decreased or eliminated with shimming. Whether the sideband is first- or second-order depends on the geometry of the magnetic field inhomogeneity. In a conceptually simple model, if the sample is spinning through a linear off-axis gradient, it will produce first-order SSBs, offset from the main peak by the spinning rate. Examples of gradients of this type are X , Y , ZX , and ZY . If the sample is spinning through a second-order off-axis gradient, it will produce second-order SSBs, appearing at twice the spinning rate. Examples of gradients of this type are XY and $X^2 - Y^2$.

Phase-Modulation Sidebands: Another kind of SSB is a first-order (sometimes second) SSB present on both sides of the main peak and out of phase with the main peak. These do not have the same phase with each scan (not phase coherent with the main peak) and so tend to average out with multiple scans. They arise when the sample tube wobbles as it spins, which perturbs the probe’s tuning, and creates a phase modulation of the NMR signal. The resulting SSBs are sometimes referred to as ‘ Q -modulation’ sidebands, and are more apparent with higher Q probes. These SSBs have a phase relationship to the main peak related to the instantaneous position of the spinning tube. Because the spinning position is not usually related to the signal acquisition, the SSBs appear to have a random phase. Because signal acquisition from scan to scan is not synchronized with the spin rate, these SSBs have a different phase with each scan and do not average with the main peak. These SSBs are not improved by shimming. Improving these requires either much better symmetry while spinning, better sample tubes, or balancing the probe’s electrical circuit to reduce dielectric and capacitive effects. Another problem caused by tube wobbling while spinning is poorer scan-to-scan reproducibility, which is critical in many difference experiments such as inverse detection. These experiments are performed without sample spinning.

B_1 Inhomogeneity Sidebands: Another kind of SSB occurs on one side only at either twice or four times the spin rate. This SSB is in phase with the main peak and signal averages with the main peak. Since this type of SSB is worse in probes with poor B_1 homogeneity, they are believed to arise from the rf inhomogeneity of the probe. If the probe coil has two vertical bands, the SSB will be of second order (at twice the spin rate). If the probe coil has four vertical bands, the SSB will be a fourth-order SSB. Which side of the main peak the offending SSB appears on is determined by the sign of the magnetogyric ratio of the NMR nucleus, its spinning direction, and the direction the main field is polarized. This SSB arises from the sample spinning through areas of stronger and weaker rf pickup by the coil, which takes place near the coil’s bands when rf homogeneity is poor. Larger coils in both length and diameter tend to have lower rf homogeneity. These SSBs are not improved by shimming.

5 THE BASICS OF SHIMMING

5.1 Criteria For Shimming

Progress during shimming can be monitored in various ways, the most common being a swept NMR resonance, lock level,

and free induction decay (FID). Choice of the most useful method depends on the instrument and its current condition and need not remain constant throughout the shimming process.

Swept Signal: The swept NMR resonance is most commonly deuterium from the lock solvent which is swept by either field sweep or frequency sweep, but could be any NMR-active nucleus. To be used for shimming, the signal should have sufficient signal-to-noise ratio that the height and ringing pattern can be observed. The sweep repetition rate should be fast enough to give a real-time response as the shims are adjusted. One of the best uses for this method of homogeneity measurement is the initial adjustment of the shims from a raw magnetic field. It is also commonly used when the spectrometer has no internal lock. The swept response should be adjusted for pure absorption phase and the rf power adjusted to avoid saturation of the signal. The height of the initial signal response is used to determine the best response while shimming. The ringdown pattern can be used for the final adjustment of Z1 and Z2, but should not be overemphasized in the initial stages of shimming because varying lineshapes can produce better ringing, but less desirable lineshape and resolution.

Lock Level: The lock level is probably the most common method of adjusting homogeneity. The lock level can be displayed by an analog meter on the NMR spectrometer or digitized and displayed as a number or level on a computer display. The NMR lock nucleus must not be partially saturated with rf power and the phase of the NMR signal adjusted carefully. Care should be taken if the lock phase is adjusted by maximizing the lock level. An asymmetric NMR lineshape leads to a lock maximum at a phase that is not at pure absorption. Improper lock phase can lead to an asymmetric lineshape, or an asymmetric lineshape can lead to an improper lock phase. Care should be taken that whenever an even-order axial shim is significantly changed the lock phase is checked and possibly readjusted.

Another problem with using a deuterium lock level for homogeneity adjustment is the relative sensitivity to field inhomogeneities of the NMR lock signal and the signal under observation. If the nuclei under observation are protons, then the lock signal's sensitivity to inhomogeneities is one-sixth that of a proton (the ratio of the magnetogyric ratios of the nuclei). This is further complicated by a deuterium resonance usually being broader than its proton counterpart. In general, good shimming results can be obtained by using a lock solvent with a sharp lock signal to do shimming for basic lineshape and minimum spinning sidebands followed by a touch-up adjustment of Z1 and Z2 on the FID signal.

FID Shimming: Using the FID response is probably the most difficult method of shimming and is usually left for the final touch-up of Z1 and Z2. The shape of the FID reveals more information about the lineshape and resolution than a lock level, similar to the ringdown pattern from a swept signal. Some excellent examples of FID shape and resulting lineshape are given in an article by Chmurny and Hoult.⁷ Briefly, the longer the FID rings, the better the resolution. The closer the FID's shape to a perfect exponential decay, the better the lineshape. A FID that falls sharply to another level and then decays more slowly either has a poor lineshape displaying a substantial hump at its base or contains the resonances from two or more signals with different linewidths. Some NMR computer systems can integrate the total area of the FID and

yield a number indicative of the resolution similar to the lock level. FID shimming is the most sensitive method for shimming and has the advantage of using the observed nucleus as the shimming criterion. It removes all doubt that what the lock system 'sees' is not what the observe system 'sees'.

All three of the above methods for monitoring field homogeneity can be used successfully. The shimming sequences described later refer only to response. Except where otherwise indicated, the operator should choose his/her own method. It is probably best to use all of them in some combination during the shimming process.

5.2 Procedures for Shimming

If the shimming operation were a simple maximization of each shim gradient, then shimming would be quick and easy. However, several things prohibit this.

Shims have, by nature of their design, levels of interactions with other shims (see Table 1). Some shims generate some gradients of other shims. An example of this is that Z4 is expected to generate some Z2 and Z0. Because the construction of the shim sets does not meet the theoretical design perfectly, each shim also has the impurities of other shims. For example, when the Z4 gradient current is adjusted it not only generates a Z4 gradient and the expected Z0 and Z2 discussed above, but some unexpected Z3 and Z1 gradients.

As the shimming process progresses, the response being used to adjust the shims becomes more sensitive. As an oversimplified example, if the magnetic field has a 20% Z2 gradient and an 80% Z4 gradient, the adjustment of Z2 first will be insensitive (feel 'mushy' or unresponsive). Then after Z4 is adjusted, Z2 will be more sensitive and might adjust to a different value.

The shimming process can be caught at a local maximum. To avoid this the NMR operator needs to explore shim changes large enough to step over a local maximum and explore the next maximum before further progress can be obtained. Shimming N number of shims can be represented as an $N + 1$ dimensional surface. While it is not easy to visualize such a surface, it is easy to think of shimming any two shims as moving over a two-dimensional surface. The third dimension would be the response of the shimming criterion, such as the lock level. The goal is to find the highest spot on the entire surface.

5.3 Shim Interactions

Each pair or set of shims has an interaction relationship. This relationship determines how the respective shims need to be adjusted to minimize the possibility of being caught on a local maximum which is not the overall best maximum for the set of shims.

Zero-Order Interactions: Shims having no interactions (zero-order interaction) can be adjusted for best homogeneity by one simple adjustment. However, most shims have interactions that complicate the process. The other two types of shim interaction are called first-order and second-order interactions.

First-Order Interactions: First-order interactions are the type that allow a true optimization of magnetic homogeneity

by repeated optimization of the individual shims. After the complete set of shims is adjusted, readjustment of the first shim of the set leads to a different optimum. Successive iterations then lead to less and less change on readjustment until finally no further change is observed. The Z1 and Z2 shims have a first-order interaction. The iterative process can often be accomplished faster by noting the direction the Z1 shim is changing and moving slightly too far on the early corrections. The ability to make educated guesses based on a knowledge of the shims leads to a much faster shimming process.

Second-Order Interactions: In a second-order interaction, a given shim must first be moved and then others adjusted before any determination of improvement can be evaluated. Simply adjusting these shims successively does not necessarily lead to the best homogeneity. The process employed for second-order interactions is usually to change the shim a measured amount and reoptimize the set of related shims. If this leads to a better response, then the shim is changed further and the process repeated until the response starts to decline. If the initial response is worse, the other direction is tried.

A classification of each shim as to the type of interactions to be expected is shown in Table 1. The interaction order assigned to each shim is a general description of the expected type of response. It can often be noted that shims displaying a complex type of interaction in the early stages of the shimming process display a much simpler type of interaction as the homogeneity improves. This simplification process often yields zero-order interactions for most shims in the later stages of shimming. Under these conditions, the shims appear to 'drive' directly to their final positions with almost no interactions.

6 A NEW MAGNET

When an NMR instrument is first installed, the setup is usually done by a trained service engineer. The installation engineer has one of the most important roles in determining the instrument's future performance. If the superconducting magnet is properly set up and shim values determined for all the probes, routine operation of the instrument can be very easy. A list of these shim values should be stored in a safe place, so that they can be used as a known starting point in the event that problems develop in the future.

Making sure the room temperature shim assembly is installed in the correct position in the magnet is very important. Usually, the best position for the room temperature shim assembly is with its center aligned with the center of the superconducting shims, determined from the magnet manufacturer's data. This can be confirmed with a technique similar to that used to establish the center of the room temperature (RT) shims, described below. There are conditions where the center of the rt shims should not be coincident with the center of the superconducting shims. In general, these arise when a different area of the magnet has a better overall field shape (on- and off-axis) than the area around the center of the superconducting shims. However, when the center of the rt shims is not the center of the superconducting shims it is more often than not a mistake.

6.1 Field Centering

The interaction of different shims makes shimming a tedious process requiring many repetitive passes through the shimming

sequence. Shim interactions become much greater when the center of the shim set and the center of the sample are not coincident. Since the Z1 gradient has zero contribution to the field at its center ($z = 0$), it can be used to locate the center of the shim set. One or both of the processes described below can be used to ensure the probe and shim alignment. If the sample and shim alignment is unknown and the alignment process is not followed, the shimming sequences described later still optimize the field homogeneity, but there are considerably more shim interactions. These interactions make the shimming process more difficult than is necessary.

Most NMR systems do not allow the probe position and the room temperature shim assembly position to move independently. For this reason, if one of the following tests indicates that the probe center and the room temperature shim center are not the same, the problem probably resides in the placement of the probe coil in the probe. This is not usually an NMR operator adjustable parameter. If any of the tests reveal a misalignment, check several different probes and see if they are all misaligned. If the problem exists in only one probe, consider having the probe manufacturer check the coil placement. If all the probes are misaligned, something fundamental in the spectrometer installation or design is wrong.

Swept Lock: If the NMR spectrometer can display a swept lock signal, the easiest method of checking the probe and room temperature assembly alignment is to observe the swept lock display while adjusting the Z1 shim control. The first step is to display the swept lock signal. Then while noting the lock signal display position, adjust the Z1 shim current in one direction and then the other. If the probe is in alignment with the room temperature shim assembly, the lock signal should not move, but should become wider and shorter while staying in the same position. If it does move while becoming broader and shorter, the direction should change as Z1 is moved in different directions. If the peak moves then there is some degree of misalignment between the probe position and the room temperature shim alignment.

A value judgment is called for if the lock signal does change position with Z1 current. In general, if the peak moves less than it broadens then the misalignment is small and is usually best ignored. If the peak moves more than it broadens then corrective action, if possible, would make shimming easier.

6.2 Probe Coil Plot

If a swept lock signal is not available, an alternative, albeit slightly more involved, technique for determining the relative probe position and room temperature shim alignment is the effect of the Z1 current on a plot of probe coil response. While being more involved, this technique also gives more information which is useful for understanding the overall NMR instrument's operation. Place a drop of water in the bottom of an NMR tube, the smaller the drop the better. Also be careful to keep water from the sides of the NMR tube. Put this sample in the NMR spinner at a depth such that the drop of water is in the center of the probe's coil and insert the sample into the spectrometer. The sample should not be spinning. Set up the spectrometer for proton observation and acquire a spectrum with a sweep width appropriate for the experiment. What is appropriate comes with experience and you will know more

about how large a sweep width to use when the experiment is over, but for now use something like ± 2000 Hz. After doing the experiment you may want to go back and collect the data again using a different sweep width.

Process the spectrum using a magnitude calculation and whatever processing parameters are necessary to keep the computer scaling constant for the duration of this experiment (e.g. Bruker or Nicolet AI command). Take an integral of the entire sweep width and set up whatever integral corrections are necessary. If possible set this integral value to 100 and record all future integrals relative to this one. Record the integral value and the frequency position at halfheight on the integral line. An eyeball guess at the frequency position is usually more than good enough for this experiment. Now adjust the Z1 current in the positive direction by an appropriate amount. What is appropriate again comes with experience, but it needs to be a large amount and you should note that you are going to change the Z1 current the same amount in the negative direction next, so do not change the current more than you have available in the opposite direction. Now record the integral value and the frequency position of the halfheight of the integral with the Z1 current change in the positive direction and again with the same Z1 current change in the negative direction. You should now have three sets of two values:

Z Position	Z1 = +		Z1 = 0		Z1 = -	
	Freq.	Integral	Freq.	Integral	Freq.	Integral
0mm	0Hz	100	0Hz	100	0Hz	100

Do not be concerned at this stage if the frequencies or integral values are changing by small amounts. If they are changing by large amounts, make sure you have undertaken the measurements correctly by reproducing the values, but if they are changing by small amounts complete the data collection.

Now move the position of the water drop up 5 mm in the spinner and repeat the above experiment. Record the data and move the water drop position up in 5 mm steps until the water signal can no longer be observed. Then move the water drop 5 mm below the original position. Record the data and move the water drop position down in 5 mm steps until the water signal can no longer be observed. Plot the frequency versus Z position of the water drop for the three values of Z1 current.

Figure 1 NMR frequency versus position in the probe for different values of Z1

You should get a graph something like that shown in Figure 1. The three lines should cross at one point, but usually you get a small triangle. For this purpose, the center of the triangle is the center of the room temperature shim assembly.

Now plot the integral versus Z position when the water drop is at Z1 = 0. Note that the Z1 = 0 current value is not zero current but the starting value for Z0 on the shimmed instrument. You should get a graph something like that shown in Figure 2.

The plot of NMR signal versus water drop position allows one to see over what height of sample the probe coil is active. This should describe roughly a rectangular region. The center of this rectangular region should be the region on the previous graph where the Z1 current lines crossed. This method tells the NMR operator where the active coil region is located relative to the room temperature shim assembly. In addition, it tells the NMR operator how long the probe coil is, which is useful for determining how tall a sample is required for shimming in a particular NMR instrument. Techniques for shimming different sample lengths will be discussed later in Section 10. Another very important piece of information which can be seen from this plot is any possible probe coil lead pickup which can make shimming more difficult. If the plot is similar to that shown in Figure 2 with the ends approaching zero but with increased intensity further out, then coil lead pickup has been detected. This phenomenon comes from the probe coil's leads being at a high voltage potential and not being shielded from the sample. If this occurs, it is often the case that the lead pickup is occurring at a region of the rt shims that is not very homogeneous, which leads to lineshape problems.

The unshielded lead problem often reveals itself in another way. For a normal single resonance close to the carrier frequency, as the pulse length is increased past a 90° flip to a 180° flip, the signal should pass through a null. With lead pickup, most of the signal goes through a null but a small portion of it remains positive even when the rest of the signal is becoming negative with increasing pulse length. The small positive portion of the signal is coming from lead pickup. The sample seen by the leads is outside the main coil region and is seeing a much smaller effective field than the main region of the sample. The effective 180° flip for this region can be many times that for sample in the main coil region. Often, since this sample can be in a region of different field homogeneity and therefore have a different field value, the small peak which remains positive will be to one side or another of the main peak which is going through a null with a 180° pulse.

Figure 2 NMR signal integral versus position in probe

If either of these symptoms of probe coil lead pickup are observed, the probe should be modified to have a lead shield. This will lead to better lineshapes, pulse homogeneity, and solvent suppression.

7 A SHIMMING PROCEDURE

A shimming procedure⁸ follows. It should not be taken as a Gospel truth, but as a suggestion of where to start the learning process about the relationship of shimming procedures, your samples, your instrument, and the NMR data acquisition process in general as it relates to your laboratory. Not every instrument will shim the same, nor will every sample. Later discussions will talk about what to look for and do when this process is done. For this procedure the optimization processes are:

1. *Zero order*: This is a straightforward process of adjusting the control for the best response.
2. *First order*: Adjust one control, then the next control, then the next until all controls in the set have been adjusted. Repeat the process until no further response improvement can be obtained.
3. *Second order*: Note the current response level. Adjust a shim control from the current value by a defined amount (a rule of thumb would be enough to change the response to between 50% and 75% of the original value) to a new value. Optimize all other shims in the set with a first-order process. If the new response is better than the previous response, note the new response level and adjust the shim to a new value in the same direction and repeat the process. If the new response is less than the original response, adjust the shim control a defined amount in the opposite direction and repeat the process. Continue until the best value is clearly determined. This means it is necessary to go too far to make sure no further improvement can be made and then return to the optimum value. It is often useful in this process to plot the results of the shim of interest and the response value after the other shims have been optimized. The operator can then make sure that the changes being observed are real and significant and can better determine the optimum shim value. A typical plot for Z4 is shown in Figure 3.

7.1 First Stage

If the NMR spectrometer is in a state of unknown homogeneity or is known to have poor homogeneity, a simple

Figure 3 Z4 plot technique

optimization of certain shims is the first step in the shimming sequence. A swept NMR signal is the recommended method of judging the response for this operation:

1. Spin the sample (20–30 Hz) and adjust the Z1 and the Z2 shims interactively to produce the tallest swept signal response (first-order process).
2. Stop the spinner and adjust X and Y for the tallest swept signal response (first-order process).
3. Adjust X and ZX for the tallest swept signal response (second-order process).
4. Adjust Y and ZY for the tallest swept signal response (second-order process).
5. Adjust XY and X2 – Y2 for the tallest swept signal response (first-order process).
6. If any large shim changes were observed in the above process then the process should be repeated from step 1.

After the above procedure, the NMR instrument should be capable of a field/frequency lock. Any one of the three methods described above for measuring homogeneity can be used in the following sequence steps.

7.2 Spinning Shims

The adjustment procedure for the spinning shims should be conducted with the sample spinning at more than 10 Hz. Care should be taken to avoid a vortex, which leads to a false shim optimum, usually with Z2 being the most misadjusted. If the lock signal is being used for shimming, then ensure that the lock signal is not being partially saturated with rf power and that the lock phase is correctly adjusted. The lock phase should be checked and adjusted each time a large change is made in an even-order Z shim.

For second-order adjustments of Z3, Z4, and Z5 described below, it is best to make a plot of the response level versus shim setting. Start by noting the shim value and response level, then change the shim. Obtain data points far enough on both sides of the maximum to clearly define the optimum setting.

1. Use the first-order process to optimize Z1 and Z2.
2. Use the second-order process to optimize Z3. Change Z3 enough to degrade the response by 20–30%. Repeat the process in step 1.
3. Use the second-order process to optimize Z4. Change Z4 enough to change the response by 30–40%. Repeat the process in step 1, then adjust Z3 to give maximum response. If the Z3 shim changes considerably, then repeat step 1 again and readjust Z3 again for maximum response. If, after optimizing Z3, Z2, and Z1, the new response is better than the previous response, then continue in the same direction; otherwise, try the other direction.
4. The Z5 shim is difficult to adjust because it often has substantial Z1, Z2, Z3, and Z4 components. It therefore becomes a tedious iterative process involving adjusting all five shims. See Section 9 for a different approach to adjusting high-order shims.

7.3 Nonspinning Shims

Shims with X and Y components should be adjusted while the sample is not spinning. Changing the nonspin shims which have Z components causes changes in the spinning shim set.

If any of these shims change significantly, then the spinning shim sequence should be repeated after completion of the nonspinning sequence. With all shims involving a second-order process, the technique described under the spinning shim sequence of plotting the result and interpolating the shim position should be followed either on paper or mentally.

1. Adjust X and Y interactively using the first-order process for maximum response.
2. Use a second-order process to adjust ZX . Change ZX by an amount sufficient to lower the response by 10% and then adjust X for a maximum response. If the new response is better, continue in the same direction with ZX . If the response is less, try the opposite direction with ZX .
3. Repeat step 2 but using the Y and ZY shims.
4. Adjust XY and $X2 - Y2$ interactively using the first-order process for maximum response. If either XY or $X2 - Y2$ change significantly, then repeat steps 2 and 3.
5. Use a second-order process to adjust $Z2X$. Change $Z2X$ by an amount sufficient to decrease the response 30%, then maximize the response with ZX and then with X . If the new response is larger than the initial response, then continue with $Z2X$ in the same direction. If the response is less, then try the opposite direction.
6. Repeat step 5 but using $Z2Y$, ZY , and Y .
7. Use a second-order process to adjust ZXY . Change ZXY by enough to decrease the response by 20%, then maximize the response with XY . If the new response is larger than the initial response, continue with ZXY in the same direction. If the response is less, try the other direction.
8. Repeat step 7 but using $Z(X2 - Y2)$ and $X2 - Y2$.
9. Adjust $X3$ and X interactively for maximum response (first-order process).
10. Adjust $Y3$ and Y interactively for maximum response (first-order process).
11. If the nonspin shim settings have significantly changed, then the spinning shim sequence should be repeated. If there are significant changes in the spin set after optimization, repeat the nonspin set also.

7.4 Final Stage

After the spinning and nonspinning sequences have been conducted, the NMR instrument should be delivering less than 0.5 Hz linewidth with good lineshape and minimum spinning sidebands. This is all that is required for most NMR experiments. If better resolution is desired, then a first-order adjustment of $Z1$ and $Z2$ using the FID can be helpful. Maximize the response by adjusting $Z1$ and $Z2$ for maximum ringout of the FID. If the FID is not observable, then the swept lock signal ringout is the best second choice. The ringout of the FID or the lock signal is a very sensitive measure of resolution. Adjusting only $Z1$ and $Z2$ prevents changes in the lineshape.

8 SYMPTOMS OF INHOMOGENEITY

An examination of the NMR signal lineshape can often reveal which shim needs the most attention. In general, even-order spinning shims ($Z2$ and $Z4$) create asymmetric lineshapes when misadjusted. The odd-order spinning shims ($Z1$, $Z3$, and $Z5$) create symmetrical lineshape symptoms

when misadjusted. Also, in general, the higher the order the shim causing the problem, the further down the peak the symptom will appear. The lineshape problems to be expected are summarized in Figure 4.

Spinning sidebands were discussed in Section 4.1. The third-order nonspin shims, $Z2X$, $Z2Y$, ZXY , $Z(X2 - Y2)$, $X3$, and $Y3$, can create both spinning sideband problems and lineshape problems, usually very low at the base of the peak. An especially interesting symptom from two of these shims can be seen while adjusting the spinning shims. When the adjustment of $Z3$ changes the observed NMR signal from a broad-based signal with no spinning sidebands to a narrow-based signal with spinning sidebands, then the responsible shim is most likely $Z2X$ or $Z2Y$.

In the endless search for greater sensitivity, one approach has historically been to use longer coils in the NMR probe. As the active sample length increases, it becomes more difficult to optimize the field over the entire length of the coil. Also, the higher-order shim gradients become much more important with longer coils, making shimming more complex. Usually some degradation of lineshape is inevitable when longer coils are used.

The probe coil also contributes to resolution and lineshape problems by means of the magnetic susceptibility of the materials used in probe construction. This magnetic susceptibility has a tendency to bend the magnetic field, distorting the observed lineshape. The effect is greatest close to the source of the magnetic susceptibility. As the probe filling factors become better, the coil parts move closer to the sample, and the coil's magnetic susceptibility has a greater effect on lineshape and resolution. A typical probe induces magnetic gradients on the sample which look a lot like a $Z4$ inhomogeneity symptom. The process of creating these gradients and how to shim them is discussed in depth in Section 11.

9 THE $Z1$ PROFILE

One tool which can be used to help the NMR operator in the shimming process is the ' $Z1$ profile'. This can be thought of as an axial image of the sample in the probe. To obtain a $Z1$ profile, a large $Z1$ gradient, offset from its optimum value, is applied and the resulting lineshape examined. If the probe had no magnetic susceptibility and the magnet's field were perfect, then when a large $Z1$ gradient is applied the resulting lineshape resembles a rectangle as shown in Figure 4(a).

While this may seem a very uninteresting and undesired lineshape, it contains a lot of useful information. Imagine the NMR sample being composed of many discrete minisamples located along the axis of the NMR tube. When a $Z1$ gradient is applied to the sample, each of these minisamples has a slightly different frequency due to the slightly different $Z1$ gradient value at each position. There is no standard for NMR instruments as to which direction of $Z1$ gradient is generated with a positive current in the $Z1$ coil, so we cannot tell whether the left end arises from the top or the bottom of the sample. However, this image of the sample provides some positional information to work with.

The $Z1$ profile can also be used to see if the center of the probe's receiver coil is at the center of the room temperature shims. Take a $Z1$ profile with a positive $Z1$ offset value. Take another $Z1$ profile with a negative $Z1$ offset of the same size,

Figure 4 Lineshapes resulting from Z gradients

but in the opposite direction. Overlay the two $Z1$ profiles plotted on the same scale. If the two profiles are offset relative to each other, then the center of the probe's receiver coil and the center of the room temperature shims are not coincident. For NMR operators familiar with the $Z1$ profile technique, this method of determining the center of the room temperature shims is faster and easier than the plotting method discussed in Section 6.

The $Z1$ profile can also give information about other gradients present in the magnetic field. If the magnetic field has a $Z2$ gradient and a $Z1$ profile is taken, lineshapes as shown in Figure 5(a) would be obtained. Note that the shape is asymmetrical and that the top of the $Z1$ profile is a curve with the order Z^2 . With practice and when comparing with later examples of gradients, it is apparent that as the gradient

order increases, the outside edges of the $Z1$ profile are affected more than the center. In fact, with the higher-order gradients, the center of the $Z1$ profile is relatively unaffected. If a positive $Z1$ profile and a negative $Z1$ profile were taken with a $Z2$ gradient in the magnetic field, they would look identical. This is because the even-order Z gradients are symmetrical about the center of the room temperature shims.

If the magnetic field has a $Z3$ gradient and a $Z1$ profile is obtained, the result would resemble Figure 5(b). Here it is easy to note that the $Z1$ profile changed shape symmetrically. Note the drooping edges when $Z3$ is changed in one direction and the peaked edges when $Z3$ is changed in the opposite direction. Also note how far from the center the effects start taking place and that the two lineshapes have different widths.

As we move to higher-order gradients, it will be easy to see that the effect takes place farther to the outside edges.

With this example of a Z3 gradient with a Z1 profile, if the direction of the Z1 profile is changed then the positive and negative Z3 gradient lineshapes would interchange. This is different from even-order gradients which stay the same as the opposite Z1 profile polarity is taken. The fact that the Z1 profiles of Z3 gradients interchange with opposite Z1 profile polarity can be used to adjust the Z3 value to its correct position. The process would be to change Z3 until the plus and minus Z1 profile had about the same width. On many NMR systems obtaining the proper Z3 and Z4 values is a large part of the battle in the shimming process, and this technique makes finding the proper Z3 value relatively easy.

If the magnetic field has a Z4 gradient and a Z1 profile is taken, the results would resemble Figure 5(c). It can be seen that the change in the Z1 profile is again asymmetrical, but now there is a flat region near the center that is relatively unaffected compared to the ends of the Z1 profile.

If the magnetic field has a Z5 gradient and a Z1 profile is taken, the results would resemble Figure 5(d). It can be seen that the change in the Z1 profile is symmetrical. Again there

is a flat region near the center that is relatively unaffected compared to the sides of the Z1 profile.

Continuing the process with Z6, Z7, and Z8 gradients would give a set of profiles as shown in Figure 5(e)–(g). A pattern emerges from the complete set of Z1 profiles:

1. Even-order gradients (Z2, Z4, Z6, and Z8) produce asymmetrical changes in the Z1 profile.
2. Odd-order gradients (Z1, Z3, Z5, and Z7) produce symmetrical changes in the Z1 profile.
3. The higher the order of shim gradient applied, the farther from the center the significant effects are observed in the Z1 profile.
4. Odd-order gradients, in particular Z3, give different width profiles with opposite polarity Z1 profiles, while even-order gradients are unchanged with opposite polarity Z1 profiles.

There are similar effects that can be observed when shimming while looking at normal lineshapes instead of the Z1 profile:

1. An asymmetrical change in lineshape is seen when even-order Z shims are adjusted.
2. A symmetrical change in lineshape is seen when odd-order Z shims are adjusted.

Figure 5 Z1 Profiles with positive and negative Z gradients. For (a)–(g), see text

3. The higher the order of shim gradient adjusted, the lower down the peak the lineshape distortion is noticed.

From this study of Z1 profiles, another procedure of shim optimization emerges as a new shim tool. Normally the lowest order gradients (Z1, Z2, and Z3) are adjusted first, then based on lineshape criteria, the higher order gradients are adjusted. The low-order gradients are readjusted as necessary in this process. However, if the NMR operator applies a Z1 gradient to get a Z1 profile of the sample, the highest order gradients are adjusted *first* to get the most square and symmetrical ends on

the Z1 profile, then the center region is flattened with the lower order gradients. During the entire process, odd-order gradients are adjusted when a symmetrical change is desired. Even-order gradients are adjusted when an asymmetrical change is desired.

In general, when trying to shim using this technique, the goal is to make the squarest and flattest Z1 profile possible which does not change width with opposite polarity Z1 profiles. This applies even when the NMR probe has magnetic susceptibility problems. When you shim for the squarest and flattest Z1 profile, you will get the best lineshape when the

Z1 gradient is removed. If the NMR probe has very severe magnetic susceptibility problems (discussed further in Section 11), the Z1 profile will not be very flat at all. With probe magnetic susceptibility problems localized to specific regions of the probe's coil, the Z1 profile may have many peaks and valleys where it should be flat. Probes that have several regions of deep peaks and valleys will be very difficult to shim and will probably not produce a good lineshape when shimming has been completed.

The Z1 profile technique is not the one and only best way to shim, but is a useful tool which can be used as appropriate. It does seem to offer some advantages when trying to adjust the higher order gradients.

The Z1 profile can also be used to visualize the probe's B_1 homogeneity. After shimming is complete, apply a Z1 gradient. Take a spectrum with a 90° pulse and plot out the rectangular lineshape. This represents the probe coil's excitation picture. Now take another spectrum with a 180° pulse and plot it out with the same scale and position as above. This plot will have a region near the center of the initial rectangular region which is near zero intensity. This shows the area of the sample which is experiencing the 180° tip angle. The ends of the initial rectangular region represent the ends of the probe's coil. These regions will not be near zero because the ends of the coil receive less than a 180° tip angle. In probes with a good B_1 homogeneity, the region near zero will be a significant portion of the initial rectangular region. In probes with poor B_1 homogeneity, the center region will dip slightly below zero intensity with little or no flat region near zero. This is a picture of the sample receiving a 180° tip angle versus position in the probe's coil.

10 THE SAMPLE AND SHIMMING

The NMR sample and its preparation have tremendous influence on the quality of the spectra and the shimming process. These areas include end effects (magnetic susceptibility) of the sample, particulate materials in the sample, dissolved materials in the sample, and radiation damping.

End Effects: An often overlooked parameter in the shimming process is the magnetic susceptibility effect caused by the ends of the sample. The solvent-air interface generates field gradients which can create lineshape distortions if it occurs close to the 'active' region of the probe coil (the part of the sample which lies within the coil window). An empirical method of determining the active region of the probe's receiver coil is discussed in Section 6.2. The key question in this discussion is how far from the active area of the probe must the solvent interface be to avoid distortions. The answer depends on many variables, a few important ones being the height of the receiver coil, the diameter of the receiver coil, and the magnetic susceptibility of the solvent. The larger the diameter of the tube, the further away the effect from the solvent ends is detectable. For a 5 mm tube, the effects are easy to measure when the sample extends 1 cm above and below the active region of the probe's coil. The effects are difficult to measure when the sample extends 2 cm above and below the active region of the coil. This is more sample length than most NMR operators want to use. The shorter the sample used, the more difficult the shimming process will be, but less sample is required.

As a general rule, if the sample length used in the 5 mm probes is going to be longer than 2 cm above and below the active region of the probe's coil, the sample-to-sample variations of the shim values derived from the end effects of the solvent will be negligible. If the typical sample to be run on the NMR spectrometer is going to be within 1.5 cm above and below the active region of the coil, then the sample length should be tightly controlled and maintained the same for all samples. Then if the sample tube's position in the spinner is kept the same, a set of shim values can be developed and reused from sample to sample.

When a spectrum of a limited amount of sample is necessary, one can use a microsample probe or constrain the sample in a micro-cell. When the microcell is inserted in a 5 mm NMR tube, it is usually best to surround the microcell by the same solvent as used in the microcell such that the ends of the surrounding solvent extend more than 2 cm above and below the coil's active area.

Since deuteriochloroform is a common NMR solvent, another trick which has been used by many NMR laboratories is to take advantage of the fact that Teflon has about the same magnetic susceptibility as chloroform. The sample is then placed between two Teflon plugs. The total length of the sample and Teflon plugs is then maintained to be 2 cm above and below the probe's active region. This technique also minimizes the effects from the end of the solvent and makes shimming small samples easier.

Particulates: When an NMR sample is examined under a magnifying glass, one can often see little extraneous bits floating around. These particulates often have a very different magnetic susceptibility from the NMR sample. These perturbations on the magnetic homogeneity over the active volume of the probe cannot be compensated for by shimming because the particulates are moving about while the sample is spinning. The particles need to be removed by filtering the sample.

As surprising as it sounds, it is not at all uncommon for the particulates to be iron. Holding a small magnet to the side of the NMR sample can cause these iron particles to move to one side of the sample tube, as seen by examining the sample under a magnifying glass. Some samples with iron particles can be examined before putting them into the NMR spectrometer and appear clean. After shimming for a while with unsatisfactory results, the sample can be removed and examined under a magnifying glass and big particles can be seen. This comes about because the original sample had some very fine iron particles that could not be seen, but which coagulated after being magnetized in the magnet. It is often a good idea to look at the sample under a magnifying glass before expending a lot of time on a sample which seems difficult to shim.

Dissolved Material: In addition to having macroscopic particles in the sample, it is possible to have dissolved paramagnetic material in the sample. This will not be visible to the eye, but can cause dramatic broadening of NMR lines due to paramagnetic relaxation, which is a very efficient mechanism of T_2 relaxation. Even dissolved oxygen in the sample will cause broadening, which is why NMR resolution standard samples are always supplied degassed in sealed tubes.

Viscosity is also a cause of broadening of NMR lines because of the reduced correlation times for molecular tumbling. Slower motions are a more efficient mechanism of T_2 relaxation.

Radiation Damping: Another broadening phenomenon which can be observed under some conditions is called 'radiation damping'. When used in conjunction with NMR, this phenomenon is different from radiation damping when discussed by an electronics engineer. When discussed in relation to NMR, it is an additional relaxation mechanism arising from energy in the NMR sample being coupled into the probe's coil. Losses in the probe's circuit then provide a means for removing energy from the nuclei. This relaxation process is proportional to the strength and frequency of the nuclear signal, the sample coil filling factor, and the Q value of the probe's tuned circuit. This means that it is most likely to be observed on high-field instruments when observing protons in water solutions. The phenomenon can be seen with other samples such as CHCl_3 on 500 MHz and 600 MHz systems if the CHCl_3 sample is very concentrated ($>5\%$).

The presence of radiation damping is easy to detect. Run a spectrum of the sample under conditions where you suspect radiation damping and measure the linewidth of the signal. Then de-tune the probe off-resonance and run the same spectrum again. You will of course have a reduced signal intensity, but if the line becomes narrower, then radiation damping was present. Because the degree of relaxation the nucleus experiences by this mechanism is directly related to the strength of the NMR signal, it is possible that only the intense peaks in the spectrum show broadening.

11 PROBES AND SHIMMING

Ideally, probes should have little or no influence on the shimming process. However, many probes have one or more characteristics that make them nonideal. In general, the better the probe, the easier the shimming process. Major areas where probes can influence shimming are the materials used in probe construction, size (length and diameter) of the probe coil, and the rf homogeneity generated by the probe coil.

Each of these areas produces constraints and/or influences on the shimming process. An understanding of these influences and what the NMR operator can and cannot do makes shimming less frustrating.

Materials: The basic way probe materials can influence the shimming process is via the magnetic susceptibility of the probe materials. The area of the probe of major concern is the probe's coil because it is closest to the active region of the probe, the volume of sample which contributes to the observed signal. Other parts of the probe can influence the shimming process, but they are usually further away from the probe's active region and, because the effects fall off with distance, they have less influence. Because of the distance from the sample, the effect that these probe parts produce is a low-order gradient. Low-order gradients can cause the shim values of particular gradients to change, but they are usually straightforward to shim. The coil, however, is much closer to the probe's active region and has a complex geometric arrangement relative to the sample. Any magnetic susceptibility of the probe's coil changes the magnetic field profile in the active region in a complex manner related to the complex geometric pattern. The NMR operator is then faced with the prospect of trying to correct this influence with the shims.

As an example for discussion, consider a simple probe coil often referred to as a single-turn Helmholtz or coaxial cavity

Figure 6 Simplified drawing of a single-turn Helmholtz or coaxial cavity probe coil

as shown in Figure 6. If the coil material has a magnetic susceptibility, it perturbs the magnetic field producing a gradient whose geometry is related to the geometry of the coil. If the coil described were made of a material with nonzero magnetic susceptibility such as copper, the gradient profile generated along the Z axis through the center of the sample can be calculated and would look like the graph on the right of Figure 7. The vertical axis in this figure represents the position along the sample. Gradients are displayed as horizontal deviations from zero at the center. A perfect field would have a profile which is a straight, vertical line at the center of the plot, showing no gradient over the active region of the probe, which is the area between the top and bottom edges of the window. The deviation from ideality of the gradient profile shown would result in a distorted lineshape.

If it is assumed that only the sample within the window generates a signal, the calculated values of Z_0 through Z_4 gradients best able to correct this coil-induced gradient are shown in the upper right corner of Figure 7. If we apply these gradients to the induced field to correct them by shimming, then the result is shown on the graph on the left of Figure 7. Notice that there are residual field gradients not correctable with Z_0 – Z_4 . In this example, there are strong Z_0 , Z_2 , and Z_4 gradients induced. When using such a probe, the NMR operator would adjust these shim gradients to correct the coil-induced gradients. However, there are residual gradients that are not correctable by Z_0 through Z_4 . These residual gradients oscillate between a slightly positive and a slightly negative field value. This would result in a split field lineshape where the peaks would either be broader than necessary or split into a doublet. This type of lineshape would even result from perfectly compensating for the coil-induced gradients up to fourth order. The NMR operator would be very unhappy with a resulting lineshape where every peak is a doublet and might continue to shim, probably concentrating on the even-order shims. In general, the operator would probably move Z_2 a little one way and Z_4 a little the other way and then adjust Z_1 for the best lineshape. This process consists of misadjusting the shims to smear out the lineshape so

Figure 7 Magnetic field gradient induced by material with magnetic susceptibility of pure copper for a probe made from a single-turn Helmholtz or coaxial cavity probe coil: (left) after correction with Z0–Z4; (right) before correction

that it is not a doublet, but a more acceptable fat singlet. This results in shimming symptoms that many operators may have noticed: the resolution gets better while the lineshape distortions get worse. In extreme cases of this phenomenon, the NMR operator observes a very frustrating symptom. When the NMR instrument is shimmed the lines in the spectrum tend to split. About the only cure for such a problem is to deshimm the system to spread out the doublet to a broad singlet or use a different probe.

The actual shimming process to correct for the probe coil's magnetic susceptibility influence is more complicated from the NMR operator's point of view. Using the example of the typical single-turn Helmholtz coil made from a material with magnetic susceptibility one-fifth that of pure copper in a perfect magnetic field, the magnetic gradients induced by the probe on the sample would generate a lineshape as shown in the first frame of Figure 8. The user would look at this and try to correct the lineshape problem using Z4. Using only pure Z4, the user would get the result shown in step 2. This generates a lineshape which looks like Z2 needs adjustment.

Correcting with pure Z2 would give the result shown in frame 3 of Figure 8. This again looks like Z4 needs adjustment, but less than at the start shown in frame 1. Iterating back and forth between Z2 and Z4 would correct the lineshape with the final result shown in frame 4 of Figure 8.

While the result looks like an acceptable lineshape, its low-order lineshape, width at halfheight, and peak amplitude are all poorer than what would have been obtained with the same probe and sample in a probe with zero magnetic susceptibility components.

In the absence of magnetic susceptibility problems, as the operator changes the value of Z4, the hump in the base of the lineshape peak moves through the peak and appears on the opposite side. The time when the hump is totally under the peak results in the best resolution. In cases where the probe's

magnetic susceptibility is a problem, the lineshape hump looks like a Z4 problem, but is a magnetic susceptibility problem. The gradients induced in the sample by magnetic susceptibility of the probe coil perturb the sample near the ends of the coil more than in the center of the coil. This creates a gradient profile that looks like Z4. The actual profile is a much more complex function which, in its simplest form, contains Z2, Z4, Z6, Z8, etc. Since most NMR spectrometers do not have these as shimmable gradients, the best the operator can do is overcorrect the sample near the ends of the coil with Z4 and try to back-correct the sample near the middle of the coil with Z2. In the process of doing this, when the small hump starts to move under the peak, the resolution degrades. It is impossible to get the best resolution and no Z4 hump in these cases.

The susceptibility phenomenon is usually present more in lower-frequency probes than high-frequency probes. This is because the lower frequency probes usually have more inductance in the probe, meaning that the probe coil has more turns of wire and therefore larger amounts of the magnetically imperfect material. The lower frequency probes are also more likely to have a separate decoupler coil which also adds more material to the probe. However, the same ppm of magnetic susceptibility effects creates greater perturbation at high frequency. For this reason, lineshape problems produced by probe coil magnetic susceptibility are usually observed more with higher frequency probes such as proton. The addition of more probe coils, and therefore more materials in reverse probes and dual probes where one of the nuclei is proton, is one of the reasons that good lineshape performance in these probes is more difficult.

Today, all NMR probe manufacturers correct the probe coil's magnetic susceptibility to some degree. It is interesting to note that glass has a much greater magnetic susceptibility than the copper from which coils are commonly made. The insert and sample tube are effectively infinitely long uniform

Figure 8 Four steps in shimming a probe with magnetic field gradients induced by a probe coil with the geometry of a single-turn Helmholtz or a coaxial cavity probe coil with material of the magnetic susceptibility of pure copper

cylinders and, by virtue of this symmetry, generate no field gradients at the sample. When a hole is drilled in the center of an NMR probe insert (as in a CIDNP probe), this symmetry is lost and results in substantially degraded resolution. A cracked insert can also perturb lineshape. Poor quality NMR tubes which have nonsymmetrical wall thickness can create gradients to the degree that they deviate from being perfectly cylindrical. Because the resolution requirements become more stringent at higher fields, better quality tubes are necessary to obtain optimum resolution and lineshape. When no other reason can be found for poor resolution or lineshape, try transferring the sample to a different tube.

11.1 Magnetic Susceptibility Correction

There are several techniques used by probe builders to reduce problems with gradients induced by probe coil materials. One way is to correct the magnetic susceptibility of the probe material. A common way to do this is to use a copper–aluminum sandwich.⁹ Good, oxygen-free copper is diamagnetic (negative magnetic susceptibility) and aluminum is paramagnetic (positive magnetic susceptibility). The goal is to make a composite with close to zero magnetic susceptibility by adjusting the amounts of the component materials. Other plating techniques are also commonly used. The difficulty is that the magnetic susceptibility varies greatly with purity and measuring the magnetic susceptibility accurately for these materials is difficult.

Very few techniques can measure magnetic susceptibility at the absolute levels which cause very strong gradients in an NMR probe. A common way is to measure a large amount of the probe coil material in a very strong, very inhomogeneous magnetic field either by a change in weight or by a change in deflection as a function of field strength. To have the necessary sensitivity, a large sample of the probe coil material is necessary. This presents the additional problem that small point-to-point fluctuations in the magnetic susceptibility within the large sample of material are not detected. When these materials are used in a probe, point-to-point susceptibility fluctuations can be present all along the probe coil leading to field gradients and lineshape distortions.

Another method is to use the NMR spectrometer itself to measure the materials. This is usually done by placing a piece of the material to be tested at the top of a shimmed NMR system's probe coil.⁹ This will create a lineshape distortion which resembles a solids powder pattern. If the material is diamagnetic, the powder pattern is sloped in one direction and if the material is paramagnetic, the powder pattern is sloped in the opposite direction. If the material has no magnetic susceptibility, there is no lineshape distortion. This technique has the ability to test smaller samples more resembling the probe coil itself and in fact can be used on an actual probe coil. A limitation of the technique is that a good lineshape is needed to do the test well. The better a lineshape is to start with, the more sensitive the technique becomes. This technique ends up being a bootstrapping technique where

a good probe is used to make better materials, which are used to make better probes which allows one to make better materials.

Another technique to improve the situation of gradients induced by probe coil magnetic susceptibility is to change the shape of the coil window. Depending on several parameters such as the length of the coil and the height and width of the window, the shape of the window can change the type and magnitude of the gradients induced. Thus improvement in lineshape can be obtained just by changing the window shape, even if the materials in the probe coil are not magnetically compensated. In the previous discussion of the single-turn Helmholtz coil, the coil window was rectangular in shape. As the bands of copper at the coil ends become small compared to window height, the minimum influence from the coil's magnetic susceptibility will be observed with this rectangular shape. As the bands of copper at the coil ends become large compared to the coil window height, an ellipsoid window shape becomes better. The best shape depends on the ratio of the height and width of the window as well as the size of the bands at the top and bottom of the coil.

Another common problem which comes from probe coil magnetic susceptibility arises when the susceptibility at the top and the bottom of the coil are different. In this situation, a high-order even gradient, typically Z4, is used to correct the asymmetrical lineshape induced by the probe's materials. But the amount of correction required for the top region and the bottom region are different. Typically what happens is that, as the asymmetry is improved with the change of Z4, a different asymmetry is produced on the other side of the lineshape. With probes of this type, the 'best' lineshape does not occur at the settings which give the best width at halfheight. This produces a situation where shimming for the best response produces an asymmetrical lineshape. The NMR operator is then forced to use Z4 to produce the best lineshape and the remaining controls to produce the best width at halfheight. Shimming for the best response with Z4 does produce the best width at halfheight but not the best lineshape. This is a case that many NMR operators will recognize and makes shimming Z4 very difficult. It is also a case where automatic computer shimming will lead to the 'wrong' answer. What is happening is that Z4 is being used to destroy the field in the center of the probe's active region, but make the field values at the ends of the coil acceptable for lineshape. The NMR operator then tries to make the field in the center of the probe's active region as good as possible with lower order gradients. Here is an example of a situation where the use of a Z6 or Z8 shim would provide better results.

Size of the Probe Coil: The size of the probe coil, or its length and diameter, can affect the shimming process in three ways. The first is via the magnetic susceptibility of the probe materials and the induced, noncorrectable gradients as just discussed. As the coil length becomes larger at a constant window width, the NMR lineshape tends to split. This aspect ratio of the coil is very important when shimming with probes which have less than perfect magnetic susceptibility compensation for their materials. Having a longer receiver coil is also something many probe manufacturers try to do, since longer coils 'see' more sample and therefore have greater sensitivity.

If the probe's materials were perfect, then longer coils and larger diameter coils would still be more difficult to shim, but

only because it is always more difficult to make a magnetic field perfect over a larger volume than a smaller volume. The case of longer and larger diameter probes is a situation where a 'good' magnet is easier than a 'bad' magnet to shim. This also means that wide bore magnets are better than narrow bore magnets at a given sample volume. As the amount of sample decreases relative to the probe materials, the probe materials become more important to the shimming process than good or bad magnets. This is one reason why microsample probes are difficult to shim and not commonly used. As probe material compensation becomes better, microsample probes will probably become more useful.

12 COMPUTER SHIMMING

Many instruments provide automated shimming, commonly using computer-driven digital to analog converters (DAC) as one input to the shim power supply and a Simplex computer optimization routine to adjust the shim settings. Automating the shimming process can save wear and tear on the operator, provided a few precautions are taken.

1. Each shim should have equal control of the homogeneity. This is best done by setting the voltage from the DACs to the shim power supply such that an equal DAC step for each shim produces an equal depression of the lock level.
2. The initial step size for the Simplex search should be large enough to include the best value for each shim to be optimized by the Simplex routine.
3. The lock phase must be correctly adjusted if the Simplex routine is using the lock signal for measuring homogeneity.
4. The waiting period between measurements of homogeneity must be long enough to allow the NMR system time to respond. This is especially true if the lock signal is being used as a measure of homogeneity. The response time for a lock with deuteroacetone as a lock solvent can be several seconds as the homogeneity improves.
5. When the FID is used as a measure of magnetic homogeneity, a steady state must be established and maintained between the rf pulses before the FID can provide a valid measurement of the homogeneity. Because the time between adjustments may not be constant as the Simplex optimization proceeds, the best way to meet this condition is to avoid saturation.
6. The most sensitive method for adjusting the final values for Z1 and Z2 is by using the FID as the measurement of homogeneity.

In theory, the Simplex routines should be able to optimize the homogeneity regardless of the shim interactions. However, experience has shown that with second-order shim interactions, Simplex often fails to find the best values. In these cases, slower and less elegant computer routines following a shimming sequence similar to the manual one described can give better results. Also, the initial shimming steps must be large enough to ensure that the computer algorithm is not caught at a local maximum.

Some other algorithms for computer shimming have been explored. One called 'hypershims'¹⁰ searches in a circle to fully define where the valleys are before optimizing. The goal is to provide a more robust algorithm which does not get caught at a local maximum.

1 INTRODUCTION

Obtaining detailed structural information from NMR of solid samples is more complex than for liquids because of the absence of molecular tumbling in solids to average line-broadening interactions; hence, much greater probe bandwidths are required.^{1–4} The wide-line probe usually has spectral excitation bandwidth greater than 80 kHz (i.e., able to generate 90° pulses less than 3 μ s). To do this, it normally must withstand peak rf voltages in excess of 3 kV. Often wide-line probes are double-tuned (DT) to permit cross polarization (CP) and high-power decoupling for increased sensitivity and resolution. If $\pi/2$ pulse lengths below 2 μ s can be generated, multiple pulse line-narrowing techniques may be used to remove dipolar broadening,³ but this is generally possible only in single resonance probes where low inductance coils can be used effectively.

The most common solids probe is the cross polarization/magic angle spinning (CP MAS) probe, which adds high-speed sample spinning at the magic angle to the other capabilities of the DT wide-line probe for effective averaging of the chemical shift anisotropy (and perhaps dipolar broadening at very high speeds), thereby greatly improving resolution for spin- $\frac{1}{2}$ nuclei.⁵ Single resonance MAS probes can generate the short pulses needed for the combined rotation and multiple pulse spectroscopy (CRAMPS) line-narrowing technique for ^1H or ^{19}F . Large volume MAS rotors can achieve the rotational spin rate stability needed for slow MAS, where pulses are applied at precise rotor orientations to average out the anisotropic chemical shift broadening as with high-speed MAS, although sensitivity may be reduced. Commercially available extended variable temperature (X-VT) CP MAS probes permit experiments from 35 K to 650 °C.

When sufficiently large single crystals of the sample can be grown, high-resolution spectra and the chemical shift tensor can be obtained using a single crystal probe,⁶ which is similar to a wide-line probe but includes a goniometer and crystal orientation mechanism for rotating the sample about three perpendicular axes.

^aLoss tangent is approximate at 300 K, 30 MHz, and increases with temperature and frequency, especially in plastics and high- k dielectrics.

^bHigh purity, high density, with minor Y–Al–Mg–O glass phase.

Quadrupolar interactions require more complex motions for effective averaging.⁷ The dynamic angle spinning (DAS) probe allows the spinning axis to be changed rapidly while spinning the sample at high speeds. In another approach, known as double rotation (DOR), the sample is placed in a small spinner inside a larger spinner and spun about two intersecting axes simultaneously.

The short T_2 values (and often long T_1 values) in solids make sensitivity much lower than in liquids, and the requirement for high-power decoupling requires attention to efficiency at the proton frequency. In liquids probes, it is the sample coil that is most critical. For solids, it is the capacitors.

2 HIGH-POWER CAPACITORS

The special requirements of capacitors for NMR probes include the following: ultra-low magnetic susceptibility, high Q , high voltage, high current, ultra-low piezoelectric effects, and dielectrics devoid of unwanted NMR background signals. Losses in rf capacitors at a given frequency may be indicated by a capacitor quality factor Q_c , an effective series resistance [$\text{ESR} = (\omega C Q_c)^{-1}$], a loss tangent ($\tan \delta \cong \pi/Q_c$), or a loss factor, $k_d \tan \delta$, where k_d is the dielectric constant (relative permittivity). Direct current losses may be specified by a leakage resistance, but this usually has no relationship to R_p (the effective parallel resistance of a tuned circuit) above 1 MHz. Table 1 lists typical permittivity and loss properties of dielectrics frequently encountered in NMR probes.^{8–12}

Solids probes are usually designed for peak voltages of 2.5–4 kV, compared with ~ 1 kV for most liquids probes. Voltage breakdown strengths often tabulated for dielectrics are best ignored unless two important parameters are also specified: test material thickness and frequency. The frequency dependence is not easily characterized, but dc ratings of rf capacitors are typically four times the short-pulse rf ratings at 100 MHz. For very short pulses where heating is not much of a factor, the voltage rating at 10 MHz is typically only twice that

2 SOLID STATE PROBE DESIGN

Table 2 Typical Dielectric Breakdown Voltages

Thickness (mm)	$V_B, k_d > 30$ (V)	$V_B, k_d < 10$ (V)
0.1	500	1000
0.5	1200	2200
3.0	3000	5400

at 500 MHz, but with long pulses the voltage derates at least as the $\frac{3}{2}$ power of the frequency above a cutoff that is a function of Q_c/C . Table 2 shows typical rf breakdown voltages, V_B , for several thicknesses of low- k and high- k dielectrics at 30 MHz. Above 50–100 V, V_B is a square root function of thickness and shows relatively little variation within the two classes of rf dielectrics listed.¹¹ Dry air has an ionization V_B comparable to that of high- k dielectrics, but arc voltage in monatomic gases (He, Ne, Ar) is less by a factor of at least five (more for large gaps) because of the absence of low-energy rotational and vibrational relaxation modes.¹³ The additional rotational modes in polyatomic gases usually increase the breakdown voltage, except in the case of ionic gases such as H_2O .

2.1 Ceramic Capacitors

The standard COG (ceramic oxide glass) rf capacitor specification (formerly type NPO) requires a temperature coefficient of less than ± 30 ppm and $\tan \delta$ below 0.001 for the range -55°C to 125°C . For moderate-power applications up to 300 MHz, the COG formulation usually consists of fine-grained baria–neodymia–titania systems or magnesium titanate prefired with 6 mol% calcium titanate, but they are also made from mixtures of neodymium carbonate, titania, and barium titanate. A two-stage firing is generally required for multilayer capacitors so that the final firing temperature can be kept below 1150°C to allow the use of Pd–Ag electrodes. The ceramic precursors are prefired at a high temperature, then reground and mixed with a powdered glass binder with matched thermal expansion such as 36% CdO, 23% Bi_2O_3 , 25% PbO, 5% ZnO, 5% B_2O_3 , 5% SiO_2 , 1% Al_2O_3 .⁹ Alternate layers of ceramic/glass and metallization slurry are built up by a screening or spraying process.

Porcelains (magnesium–aluminum–silicates) are often used in the UHF range for high-power capacitors below 15 pF. Corning Pyroceram 9606 consists mostly of cordierite ($2\text{MgO} \cdot 2\text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2$), with lesser amounts of cristobalite and various magnesium titanates. Its low thermal expansion can cause problems with the metallization. Forsterite ($2\text{MgO} \cdot \text{SiO}_2$) is electrically almost as good as Pyroceram, easier to produce, and easy to metallize, but has poor thermal shock resistance.

UHF high-power capacitors above 30 pF are usually based on strontium titanate, which is not piezoelectric but may contain piezoelectric barium titanate impurities. High-power rf capacitors are often coated with a sealing glass such as $2\text{PbO} \cdot \text{SiO}_2$ (550°C) to keep out moisture,⁸ as it facilitates silver migration in the presence of an electric field.

The magnetic properties of ceramic capacitors are unpredictable, as most ceramics are slightly diamagnetic (bismuth compounds are very diamagnetic), palladium is extremely paramagnetic, and ferromagnetic nickel barriers are sometimes used in the terminations. A number of manufacturers are by now quite familiar with the stringent requirements of

NMR/MRI capacitors and offer ‘nonmagnetic’ chip capacitors with 500–1000 V rating (a 2.5×3 mm cube), but it is always necessary to screen them for magnetism using a small magnet (a 2-mm cube of high-energy neodymium–boron–iron) suspended from a string. Also, nearly 1% of new capacitors may be noisy in a double resonance circuit as a result of microgaps between the electrodes or terminations and the dielectric.¹⁴ Premature breakdown may be initiated by surface tracking and moisture in solder rosin.

At least four manufacturers (JFD, ATC, Murata Erie, and Tansitor Electronics) offer 3-kV multilayer ceramic rf capacitors in roughly a $3.5 \times 10 \times 11$ mm³ package. The JFD capacitors have generally been found to have the highest Q , but the difference is often not important. Some of the best NMR ceramic capacitors (when available, but once discontinued) are the 2-kV UV10 and UV17 series ($3.3 \times 6 \times 8$ mm³) by Murata Erie, as they have very low magnetic susceptibilities and a 2-kV rating in a small package. Moreover, for typical circuit values (reactance above 100 Ω), Q_c is usually greater than 3000 for capacitance below 150 pF at frequencies at least up to 50 MHz, and Q_c is usually greater than 1000 up to 500 MHz.

2.2 Piezoelectric Acoustic Ringing

While acoustic ringing is seldom a problem in liquids probes because of the longer T_2 s and the effectiveness of the Patt acoustic suppression sequence,¹⁵ piezoelectric-induced acoustic ringing¹⁶ of capacitors can obscure signals in solids probes requiring short recovery times. Subjecting a capacitor with ferroelectric impurities to a dc electric field in excess of 1 kV mm^{-1} , as may occur in a voltage withstanding test or from asymmetric rf breakdown, causes domain alignment and imparts a net crystallographic piezoelectric orientation to the ceramic. The ferroelectric is said to be ‘poled’, and may exhibit acoustic ringing. The polarization of ferroelectrics can be annealed out by heating above the Curie temperature (130°C for BaTiO_3 ; 180 – 300°C for lead–magnesium–niobates), but they can easily become poled again.

Grain size is usually under $4 \mu\text{m}$ for rf power COG capacitors in the 10–30 pF range, in which case Rayleigh scattering will normally keep acoustic decay times under a few μs above 30 MHz. However, grain size may exceed $100 \mu\text{m}$ in high-voltage (HV) capacitors above 150 pF and occasionally in low-valued capacitors, resulting in reduced acoustic absorption and acoustic decay times greater than $10 \mu\text{s}$ at frequencies as high as 45 MHz. On the other hand, acoustic ringing in bulk metals from the Lorentz interaction is seldom a problem above 15 MHz.¹⁷

2.3 Variable Capacitors

The double rotation (DOR) probe shown in Figure 1 illustrates the use of three common types of variable capacitors (air, quartz, and pressurized gas) and 3-kV ceramic chip capacitors (attached to the left of the quartz variable near the center of the photo). The Johanson 5000-series nonmagnetic, air-dielectric, trimmer capacitor (one is mounted on the upper circuit board near the center of Figure 1, just to the right of the central support post) is typical of that used in most liquids NMR probes and the high-frequency (HF) channel in solids probes with capacitive voltage division. It consists

Figure 1 DOR WB probe (Doty Scientific, Inc.)

of an alumina ceramic housing supporting several concentric, silver plated brass cylinders at the 'hot' end; a precision screw mechanism adjusts a similar intermeshing arrangement at the mount end. The minimum radial air gap is under 0.1 mm, and breakdown occurs at 500–700 V when new. With use, alignment deteriorates, and the voltage rating decreases. Care must be taken to avoid dissolving the internal lubricants (which are essential for an acceptable lifetime) with cleaning solvents. The capacitors may be sealed, but this is inconvenient; hence, their voltage rating also decreases with altitude and humidity or high concentrations of monatomic gases. These variable capacitors are manufactured using 300 °C Pb–Ag solder between the alumina and brass body parts, and they tolerate repeated overvoltages.

Also shown in Figure 1 (near the center, on top of a gas variable capacitor, just left of the central support post) is the JMC 7584, quartz-dielectric, 0.8–10 pF, variable capacitor. Its 2.5-kV rf capability allows five-times the tuning range of the above air variables, as tuning range is generally proportional to $(CV^2)^{1/2}$. Defective silver plating on the piston or sleeve has occasionally been found to produce noise at lower voltages in double resonance circuits.¹⁴ Impurities in the brass base and piston of the JMC capacitor are not controlled as carefully as in a similar capacitor by Voltronics, but the JMC capacitor is more robust which simplifies certain capacitive voltage division arrangements,¹⁸ and the magnetism is acceptable unless it must be very close to the sample. These capacitors

have been used successfully up to 400 MHz. They may lock up at high temperatures from the piston expanding or at low temperatures from the lubricants freezing.

The single component most synonymous with solids NMR probes is the Jennings CHV1 N-45 gas variable capacitor—the 22-mm diameter ceramic cylinder on the left side of the main circuit board in Figure 1. It is pressurized with about six atmospheres of CO₂ and SO₂ in its minimum capacitance position and may be adjusted from 1.5 pF to 45 pF using a pushrod mechanism. It has a peak breakdown voltage V_B of about 3.5 kV near the low end of its range (~ 10 pF) but V_B increases to about 5 kV near the high end as the gas becomes more compressed. The ceramic-to-metal seals are slightly magnetic, but this is seldom a problem as they are normally more than 20 mm from the sample. These variables have been used successfully for tuning purposes up to 220 MHz. With proper layout, they are usable on the low-frequency (LF) channels of multituned circuits with 500 MHz HF. These capacitors tolerate repeated overvoltages and are usable from –20 °C to 100 °C. If the external mechanical stop is not set properly, they may be easily damaged by pushing the adjustment rod beyond the specified limit.

Teflon variables with very low magnetism are available from Polyflon and Voltronics in a variety of sizes and ratings similar to the three described above, but Teflon does not tolerate the brief, inadvertent overvoltages which are unavoidable in most laboratories.

3 SAMPLE COILS FOR SOLIDS

Almost all solids probes use solenoidal rf coils for higher filling factor and Q than saddle coils. Standard oxygen-free, high-conductivity (OFHC) electronic-grade copper wire (C10100, 99.99%) has acceptably low iron content (less than 25 ppm, typically 4 ppm) for most solids coils at high fields. Optimum space between wires is half the wire diameter¹⁹ or perhaps a little less. An enamel coating does not usually cause a background problem with carbon experiments, but it should be removed using warm sulfuric acid if proton experiments are planned.

High- Q circuits are usually preferred—except perhaps for wideband. Coil length-to-diameter ratio is not critical, but values between 1.0 and 1.4 (depending on available wire sizes) are usually best, except for MAS. Larger ratios (1.4–3.0) give better S/N for MAS (more sample for a given speed and lower dielectric losses), but some manufacturers use short coils to achieve shorter pulse lengths and higher decoupling fields. Coil forms help stabilize tuning but reduce both filling factor and maximum voltage before the onset of arcing. If used, they should be of low-permittivity dielectrics for minimal electric field gradients and arcing.

Special or custom wire may be obtained from MWS Wire Industries, Westlake Village, CA. Gold flash (0.3- μ m plating) is often applied to prevent copper sulfates and chlorides (which have a large positive susceptibility due to antiferromagnetism) from forming on the wire surface, but it is critical to specify that the common practice of first applying a nickel strike (to minimize diffusion into the copper) be omitted or the wire will be very magnetic. The gold flash degrades the Q by about 1%. Silver plating does not improve Q (because of unavoidable defects) and does not provide the same degree of

protection against corrosion—even when the plating thickness is increased to 3 μm . Silver and its compounds are quite diamagnetic but often contain paramagnetic impurities.

High-purity copper coils for high resolution are often plated with the proper thickness of iridium or rhodium to cancel the

diamagnetism of copper.²⁰ Palladium can also be used for this purpose if it is plated only on the side that will be the external surface of the coil (where there is little current flow) so that the Q is not spoiled. Table 3 lists various properties, including volumetric magnetic susceptibility χ_v , for materials commonly

found in NMR probes. The desired plating thickness for foil is that for which the algebraic sum of the product of thickness and χ_v for the different layers is zero.

4 WIDELINE

The initial instrumentation for solids NMR borrowed extensively from radar and UHF transmitter technology, using fixed-frequency transmission lines as circulators and magic-Ts to isolate the multikilowatt transmitter from the low-noise preamplifier.^{2,3} However, it was soon determined that it was not difficult to deal with the phase transients from Q s of 50–200—an order of magnitude higher than initially thought. Pulse rise times could be as much as one-third the pulse length without serious difficulties.²¹ Hence, several hundred watts were sufficient except perhaps for low- γ nuclei. The cost savings of moderate power transmitters and the shift from transmission line traps to lumped elements facilitated the commercial solids probe,²² which is usually required to be multinuclear and reasonably user friendly.

For proton NMR it is still beneficial to damp the Q to about 100 by coating the coil with tin–lead solder (as proton linewidths are large and sensitivity is enormous) but care must be taken not to trap rosin in the coating, or backgrounds will be seen. Also, experiments on other nuclides with very broad lines may benefit from moderate Q -damping if samples larger than 0.1 mL are being used, since the increased bandwidth simplifies data collection. A number of accelerated ringdown schemes have been proposed,^{2,23} but the method seeing more use today appears to be overcoupling^{24,25} because of noise, reliability, and magnetism problems associated with other methods. Moreover, the recent availability of linear prediction often obviates the need for active damping (see *Fourier Transform and Linear Prediction Methods*).

The unbalanced, capacitively matched DT circuit (see *Probe Design and Construction*, Figure 6) is usually used for wideline probes to simplify multinuclear tuning. The HF tuning coil L_H (which may be a capacitively shortened $\lambda/4$ coaxial transmission line) is chosen to have an inductance such that its untuned reactance would be between 25 Ω and 60 Ω at the HF. Lead inductance is minimized subject to VT, high voltage, and multinuclear constraints. The total series lead inductance is then typically 25–40 nH.¹⁴ Maximum B_1/V_T , where V_T is the maximum total circuit voltage, is obtained for coil inductance L_S half of the total circuit inductance, but a somewhat higher value is usually selected for improved LF sensitivity with some sacrifice in HF efficiency and a slight reduction in maximum B_1 .

Minimum 90° pulse lengths have typically been 3 μ s, but recent successful demonstrations of wideline ^2H Hadamard NMR²⁶ may have a major impact on single resonance solids NMR. In Hadamard NMR, the spin system response to the application of a large number of pseudorandom pulses with flip angles as small as 0.1° (mW, μ s pulses) at periods on the order of tens of microseconds can be transformed into the equivalent NMR response from a single high-power pulse. A Hadamard wideline probe should benefit from a low- Q (~ 5) saddle excitation coil in combination with a moderate- Q (~ 100) solenoid receive coil. SNR for Hadamard appears comparable to Fourier transform (FT). (See also *Stochastic Excitation*.)

5 MAGIC ANGLE SPINNING

In 1958, Raymond Andrew²⁷ and co-workers showed that high-speed sample spinning at the ‘magic’ angle of 54.7° could be an effective tool in averaging out dipolar broadening. However, the required rotational rates for abundant dipolar nuclei (35 kHz for ^1H) appeared impossible, and the technique was largely ignored²⁸ for nearly two decades until Stejskal and Schaefer^{4,5} showed that more realistic rotational rates (3–5 kHz), capable of averaging chemical shift anisotropy, combined with high-power decoupling to remove the ^1H dipolar broadening, could be extremely effective in obtaining high-resolution ^{13}C spectra from solid samples.

Andrew used a conical bearing/drive surface which eventually achieved speeds in excess of 10 kHz using helium gas.²⁹ This spinner was based on the classic ultracentrifuge work by Beams³⁰ and depended on the Bernoulli effect to hold the sample spinner close to the drive jets. The stiffness of such a bearing is extremely low, which results in low-frequency oscillations, precession, and instabilities. Moreover, angular accuracy of 0.3° is sometimes required in MAS, which is an order of magnitude beyond the capability of the conical Bernoulli–Beams bearing. Lippmaa,³¹ Veeman, Pines, Eckman, and others introduced the double bearing cylindrical rotor to circumvent these problems, and Doty and Ellis presented an approximate analysis of the cylindrical air bearing optimization.³² [Note that typographical errors resulted in equations (9) and (12) in the referenced article³² appearing twice. The second equation in each case is correct. The first should be deleted.]

The high-strength ceramics⁸ that have recently become available are required to obtain high sensitivity (from high filling factor) and high spinning speeds simultaneously. Silicon nitride³³ has the highest strength-to-mass ratio of any available ceramic, which allows the highest surface speeds with low-density samples; but zirconia has higher strength, better toughness, and fewer defects, making it the preferred material for heavier samples—except perhaps at very high fields or high temperatures. Most commercial MAS rotors and stators are ground and lapped (using precision diamond tooling) from partially stabilized zirconia (PSZ) or hot isostatic pressed (HIPd) Si_3N_4 . As a consequence, these items are rather expensive. The press-fit turbine caps are usually machined from Vespel, as polyether ether ketone (PEEK) has poor wear resistance despite its other desirable properties. Zirconia turbines may be attached to a zirconia rotor by thermal interference fit. Other high-strength plastics and ceramics as listed in Table 3 are also used for special thermal or background considerations. Fiber-optics spin-rate detection is normally provided to allow precise, synchronous pulsing for the total suppression of sidebands (TOSS) technique.³⁴

5.1 High-Speed Air Bearings

The high mass of ceramic rotors requires more attention to rotor resonances than was required in the earlier designs using plastic rotors.³⁵ For stability throughout a wide speed range, it is advantageous to have the high bearing stiffness that comes from tight radial clearances. However, as the clearance is reduced, bearing frictional heating becomes more severe; moreover, the possibility of a ‘crash’ increases. A crash may

occur in a hydrostatic bearing when the rotor moves close enough to the stator to cause extreme choking around the perimeter of the bearing nozzles on the proximal side, at which point the stiffness changes sign and the rotor is driven into the stator. Pockets or recesses at the orifice exit may eliminate this crash mechanism,³⁶ but the reduced response time adversely affects stability at very high speeds unless the pockets are very small.³⁷

Highest spinning speeds have been obtained with the design illustrated in Figure 2, which has achieved surface speeds in excess of the speed of sound at room temperature for rotor diameters from 5–14 mm. Half of the bearing gas exits over the ends of the rotor forming an axial thrust bearing at each end, while half exits out the center of the stator. Allowing the gas to flow axially inward as well as outward (nearly) doubles the bearing stiffness (by nearly doubling effective area) and was probably the most significant innovation in the spinner by Langer et al.³⁸ which achieved a 40% increase in surface speed over previous designs.

Optimum bearing radial clearance for controlling Taylor vortices³⁹ in the air bearing at moderate speeds is proportional to $(\mu^2 d / c^2 \rho^2)^{1/3}$, where μ is the gas viscosity, d is the rotor diameter, c is the velocity of sound, and ρ is the gas density. Optimum clearance r_c for the control of whirl instabilities with minimum friction at high speeds fits the following empirical equation for typical NMR spinners:

$$r_c \cong k T^{0.25} d^{0.4} \text{ (mixed units)} \quad (1)$$

where T is the gas temperature (K), d is the rotor diameter in mm, and k has an approximate numerical value of 0.0027 for nitrogen and 0.0035 for helium with units of $\text{K}^{-0.25} \text{ mm}^{0.6}$; it is necessary to take into account the strain that will occur even in ceramic rotors at top speeds: 0.1% and 0.15% for silicon nitride and zirconia, respectively. Smaller clearances than given by equation (1) may be used if the additional heating can be tolerated, and larger clearances may be used with large rotors if other measures are taken to control whirl instabilities. Optimum bearing hole size is such that bearing

Figure 2 Supersonic sample spinner (Doty Scientific, Inc.)

mass flow at 0.3 MPa with the rotor in place is 60%–85% of the mass flow with the rotor removed. Short bearing hole sizes normally range from 0.13 mm for 3.5-mm rotors to 0.28 mm for 14-mm rotors, but slightly larger long bearing holes work better for VT.

With very small rotors, the bearing clearance becomes extremely critical—partly for manufacturing reasons and partly for fundamental reasons. To appreciate the fundamental limitation, consider the conical resonance frequency,³² which is approximately proportional to the square root of the quotient of the bearing stiffness and the rotor mass near the end of the rotor. In order for this resonance to scale as $1/d$, the stiffness must be linear with diameter (since the mass is cubic with diameter), which requires the radial clearance to be proportional to the diameter if the pressure is constant. But clearance cannot be linear with diameter or frictional power density on the rotor surface becomes unmanageable with small rotors. Hence, Nature does not like small rotors, and it is in fact fortuitous that 5-mm rotors can achieve supersonic surface speeds (21 kHz) under optimum conditions with nitrogen bearing pressures of 0.5 MPa. While 3.5-mm Si_3N_4 rotors have occasionally reached 27 kHz, they are fraught with instabilities above 24 kHz which are exacerbated by the large, axial Bernoulli effects from poor turbine efficiency.

5.2 Radial-Inflow Microturbines

To achieve surface speeds above 240 m s^{-1} it is necessary to use microturbines in a symmetrical fashion so that axial reaction forces are precisely balanced at all speeds (unless helium drive gas is used), since the load capacity of the axial thrust bearings is quite limited.⁴⁰ The reduced-diameter radial-inflow microturbines used in Figure 2 achieve order-of-magnitude higher isentropic efficiency than the earlier Peltier microturbines by (a) controlling flow separation over the blades, (b) operating at lower tip speed, and (c) reducing exhaust swirl.⁴¹ Inlet and exit angles are not particularly critical, but axial clearance over the blades is—unless the turbine is designed for a very low reaction ratio. A vaneless radial-inflow supersonic diffuser may be used with the larger sizes to obtain supersonic, nonseparated flow at the rotor entrance. The microturbines on a 14-mm rotor have 28 blades with 10-mm tip o.d. and produce 25 W shaft power each at 40% isentropic efficiency at 6 kHz. The 2.5-mm o.d. microturbines on the 3.5-mm rotor have only 12 blades and achieve approximately 10% efficiency at 22 kHz. Unlike large turbines, substantial efficiency losses occur in the nozzles (even with the 14-mm spinners) because of boundary layer effects. For an excellent treatment of turbine theory and design, the reader is referred to the text by Wilson.⁴²

5.3 Radiofrequency Circuits

Most MAS work requires CP and/or high-power decoupling. Hence, the circuit is essentially identical to that described earlier for the DT wideline probe except that lead inductance may be a little larger,¹⁴ necessitating somewhat higher sample coil inductance for high sensitivity. Maximum B_1 is usually 30% less than expected of a similar DT wideline probe, but many wideline experiments are still possible

with an MAS probe. For large samples at high fields, it can be beneficial to balance the HF channel for more efficient decoupling—especially at high temperatures. A modified form of the standard ^1H – ^2H high-resolution balanced decoupler/lock circuit may be adapted to the high-power requirements of solids.⁴³

Wu and Zilm⁴⁴ showed that high rf homogeneity is much more important than originally recognized for efficient CP at high speeds and that variable amplitude proton B_2 can greatly improve CP efficiency in the presence of large rf inhomogeneity. Leifer⁴⁵ recently presented an elegant method of optimizing rf homogeneity for six- and 10-turn solenoids. Many software packages using numerical methods are now available for general field calculations and optimizations, and a few are capable of properly handling nonuniform surface current distributions.⁴⁶

Single resonance circuits can efficiently use very low inductance coils (e.g., two-turn, 6-mm, 18-nH coils) to achieve the short $\pi/2$ pulse lengths ($1.5 \mu\text{s}$) needed for multiple pulse techniques to average dipolar interactions of abundant ^1H or ^{19}F nuclei.⁴ When combined with sample spinning at several kHz to average chemical shift anisotropy, the technique is called combined rotation and multiple pulse spectroscopy (CRAMPS). High resolution in CRAMPS requires extremely high B_1 homogeneity. Since wide conductors and leads are required with low-inductance coils (to limit lead voltage, if not losses), the current locations are not known and the method of Leifer and related analytical methods cannot be used to homogenize the field. However, the most difficult technical problem in making CRAMPS probes is usually that of eliminating proton background signals from hydrogenous contaminants in Teflon and even Kel-F.

Triple resonance circuits have been used occasionally for more than a decade,⁴⁷ but the development of the powerful rotational echo double resonance (REDOR) technique⁴⁸ for accurate distance determinations from weak dipolar couplings has recently resulted in a large demand for triple resonance MAS probes. The circuit shown in Figure 3 uses an inductively coupled HF tank to permit multinuclear tuning at both the middle and the low frequency with high efficiency and excellent isolation on all ports.⁴⁹ It has been used successfully for ^1H up to 500 MHz, and can easily be extended to quad resonance experiments such as RETRO.⁵⁰ Fixed frequency triple resonance MAS probes for REDOR experiments are expected to be available soon at 750 MHz.

6 GONIOMETERS AND SLOW MAS

The earliest applications of NMR to solids involved the study of single crystals, as relatively narrow lines are observed without multiple pulse or high-speed spinning techniques. These studies are necessarily limited to materials that can be obtained in single crystals of sufficient size (usually several mm^3) for acceptable S/N. The method requires the ability to slowly and precisely rotate the crystal about three orthogonal axes while observing the anisotropic chemical shift. The standard method for the past two decades has involved gluing a small crystal into a three-sided, 4-mm ‘semicube’.⁶ (Similar probes with larger coils have rotated sealed tubes to study oriented liquid crystals.) The sample may then be inserted into a precision holder inside the sample coil for 360° rotation

Figure 3 Doubly broadband, triple resonance circuit (Doty Scientific, Inc.)

about an axis perpendicular to B_0 in small increments at which spectra are collected. The semicube is then removed and reinserted for rotation about a second axis, and the process is repeated again for the third axis. The crystal orientation with respect to the semicube holder is determined using X-ray crystallographic techniques.

The sample holder axis may be inclined at the magic angle to permit slow MAS, which is a method of addressing the spinning sideband problem by applying pulses precisely at 0° , 120° , and 240° . There is renewed interest in this technique for obtaining high-resolution spectra from large samples of dilute systems. (See *Magic Angle Turning and Hopping*.)

Rotation has usually been accomplished using precision aluminum or brass bevel gears, but worm gears, belts, and flexible shafts have also been used. The early versions used a manual goniometer, but a stepper motor under computer control is now common. A DT multi-X circuit is usually used.

7 VARIABLE TEMPERATURE (VT)

Most CP MAS probes operate from -120°C to $+160^\circ\text{C}$, but XVT CP MAS probes are available for wider temperature ranges, and several methods⁵¹ have been used to cool the drive gas and circumvent liquefaction problems in pressurized nitrogen. Gay⁵² optimized the conventional high-resolution sample tube spinner to obtain rotational rates sufficient for many MAS applications (over 3 kHz for 5-mm tubes) with the advantages of greater independence of the sample temperature and spinning characteristics and the ability to spin long, sealed glass tubes at the magic angle. The MAS design of Bartuska et al.⁵³ also provides clear separation between the VT and the bearing gas.

One manufacturer (Doty Scientific) uses a low-temperature and a high-temperature CP MAS probe, as pictured in Figure 4 along with a standard CP MAS probe, to cover the range from 35 K to over 900 K. In these probes, the electronics are maintained near room temperature and positioned close to the sample to allow multinuclear tuning without excessive lead losses, although lead inductance is increased by about 30 nH over the standard probes. Another manufacturer (Bruker) offers

Figure 4 VT CP MAS, low-temperature CP MAS, and high-temperature CP MAS probes

a gas-levitated, laser-heated wideline probe for experiments to 1200°C .⁵⁴ Attempts to provide CP MAS down to 6 K have proven too difficult for commercial success thus far, but a number of research groups^{55,56} have performed wideline NMR experiments in the 0.03–3 K range.

Figure 5 DAS probe with fixed coil and belt-drive spinner reorientation

8 DYNAMIC ANGLE SPINNING (DAS)

High-resolution NMR spectra can be obtained from quadrupolar nuclei if the sample spinning axis can be dynamically reoriented such that the time average of the second and fourth spherical harmonic functions vanishes.⁷ The dynamic angle spinning (DAS) probe allows the spinning axis to be rapidly changed while spinning the sample at high speeds to accomplish the required averaging. One early design used

a pneumatic system to switch between two fixed angles, but a high-performance servo motor and precision encoder are now standard, as programming flexibility is needed to experiment with the various ‘magic angle pairs’ such as $[0^\circ, 63.43^\circ]$, $[30.56^\circ, 70.12^\circ]$, and $[37.38^\circ, 79.19^\circ]$.⁵⁷

Two basic approaches have been used: moving coil and fixed coil. The moving coil design has the rf coil mounted on the spinner stator and attached with flexible leads or sliding contacts.⁵⁸ The fixed coil design uses a small spinner assembly that can be rotated perpendicular to its spinning axis inside a large rf coil that is perpendicular to the external field and coaxial with the reorientation axis.⁵⁹ The first commercial DAS probes used a moving coil, but it was abandoned in favor of the fixed coil because of lead failures, as most DAS experiments are two-dimensional and require millions of flips. The fixed-coil design has inherently poor filling factor, but special spinners and coils are being developed to minimize this drawback.

High-torque, low-inertia servo motors with optimized linkage should permit axis reorientation under 5 ms if the air bearings supporting the sample rotor have sufficient stiffness and load capacity; but control limitations, linkage compliance, and structure vibrations have often resulted in settling times of 25 ms or more.⁵⁹ The currently available commercial DAS probe shown in Figure 5 uses a 21-mm diameter rf coil, 8 mm long, and offers a choice of three interchangeable sample spinners: 8.6-mm diameter by 12 mm; 7-mm diameter by 13 mm; and 5-mm diameter by 14 mm. The shortest reorientation times thus far with 8.6-mm rotors are about 15 ms. Half that time may be possible with the 5-mm rotors, but the filling factor is very small. One of the factors contributing to the engineering difficulties is that the motor must be positioned well below the magnet to operate properly, which requires a rather long drive linkage that still must allow easy insertion of the probe into the magnet. The other major technical problem is that rotors with small aspect ratio (length-to-diameter ratio) are required for good filling factor, but a large aspect ratio is needed for bearing stability during rapid reorientation.

9 DOUBLE ROTATION (DOR)

In the DOR technique, the sample is placed in a small spinner inside a larger spinner and spun about two intersecting axes simultaneously to accomplish the time averaging needed to remove dipolar and quadrupolar interactions. It usually comes as a surprise to the uninitiated that such a feat would be possible at high speeds, even though most have observed a football traveling through the air executing free precession—spinning about two axes simultaneously with no significant external torques acting upon it.

The requirement for no net torques on the inner rotor is given by the following:

$$f_1 = \frac{f_2(I_T - I_A) \cos \theta_2}{I_A} \quad (2)$$

where f_1 is the frequency of the inner rotor, f_2 the frequency of the outer rotor, I_A the *axial* moment of inertia of the inner spinner (rotor, sample, caps), I_T the *transverse* moment of inertia of the inner spinner, and θ_2 is the angle of the inner rotor with respect to the axis of the outer rotor.⁶⁰

In practice, the outer rotor is always inclined at the dipolar magic angle, 54.7° , and θ_2 is 30.56° . For stability, (a) f_1 must be a few per cent larger than given by the above, (b) the center of mass of the inner rotor must lie precisely on the axis of the outer rotor, and (c) the outer rotor must be dynamically balanced when the inner rotor is removed. The highest double rotation rates thus far are approximately 1800 Hz outer and 7000 Hz inner for 0.1-mL samples. The outer spinner assembly of a DOR spinner is shown in Figure 1, inclined at 54.7° . (The braid-reinforced lines entering each end of the assembly supply air to the inner spinner.)

1 INTRODUCTION

In the most general sense, any instrument for recording a nuclear magnetic resonance signal may be regarded as an NMR spectrometer. As such it can include devices as diverse as magnetometers used for the measurement of magnetic fields, instruments to measure *relaxation* times (either for fundamental physical studies or for applications to process analysis), instruments to study the details of the nuclear spin response in the frequency domain, and magnetic resonance *imaging* systems in which the frequency of the NMR response is associated with position within an object. As NMR spectroscopy developed, some of these applications required quite different instrumentation. In recent years, a number of the instrumental requirements for many of these applications have tended to converge. The aim of this article is to provide an overview of the components and operation of NMR spectrometers. The emphasis will be on spectrometers used for analytical applications, although differences for other applications will be indicated.

Since the function of any NMR spectrometer is to excite and detect nuclear spin responses, it must include certain components. This minimum set is: a magnetic field to polarize the spins, an rf system to generate the excitation, a coil or coils to couple the excitation to the spins and to receive the NMR response, a detection system to amplify and detect the spin response, and an output device for displaying the spin response. In addition, some form of control mechanism is required for these various components. For many applications, further components and features are included to condition the sample in some way, e.g. temperature control or sample spinning, to provide the information of interest.

A constant theme in the development of NMR spectrometers and the practice of NMR spectroscopy for analytical applications has been the quest for improving the *sensitivity* of the method. The nuclear magnetization, which is the origin of the NMR signal, is proportional to $\exp(-h\omega/kT)$. Thus, two parameters can be manipulated to control the available signal, namely the resonance frequency (expressed in radian

s^{-1}), ω , and the sample temperature, T . The operating temperature is usually dictated by the nature of the problem to be investigated, so the operating frequency is often the only fundamental parameter which can be varied to improve the available signal. An important aspect of the development of NMR spectrometers has been the continuing trend toward the use of higher magnetic field strengths to provide a higher resonance frequency for a given nuclear species. The available signal is proportional to both the nuclear magnetization and the resonance frequency. Thus for a given nuclear species, the available signal varies as the square of the NMR frequency. Noise considerations reduce the overall sensitivity slightly to $\omega^{7/4}$.¹ The gains from operating at higher frequencies are clearly very significant.

A further facet of spectrometer development for a number of applications has been to increase the resolution of spectral information. The use of higher magnetic fields has contributed here also and, in addition, experimental techniques have been extended to involve multiple irradiation, the study of a wide range of nuclear species and the use of multidimensional Fourier transform methods. For solid samples, which normally have very broad lines, a number of techniques have been developed to remove some of the interactions leading to that broadening. The development of NMR spectrometers has been intimately related to the development in techniques.

2 HISTORICAL BACKGROUND

2.1 Early Spectrometers

The earliest investigators^{2,3} used a continuous radiofrequency source to excite the spin response and a variable magnetic field to sweep through the resonance lines. This is the essence of the continuous wave (CW) NMR spectrometers. An equivalent operation of maintaining a constant field while sweeping the frequency was used a little later. In these methods the steady-state response of the spins to an rf excitation is recorded. Torrey⁴ and Hahn⁵ introduced alternative methods for recording the transient response to a pulsed excitation. The response was detected following the pulse as the spins relaxed towards equilibrium. The two methods evolved independently, with the CW methods focusing on the details of the resonance lineshapes while the pulse methods focused on the study of relaxation times.

The observation of chemically shifted resonances in nitrogen spectra by Proctor and Yu⁶ stimulated efforts to improve the homogeneity and stability of the magnets used in the experiments and led to the observation of chemically shifted resonances in proton spectra.⁷ This was the basis for the development of NMR spectroscopy as an analytical tool for chemistry and initiated a rapid growth in the development of CW NMR spectrometers. Pulse spectrometers developed less rapidly as their applications were much more limited.

In general, the nuclear spin response is very weak in comparison with the rf excitation. An important consideration for an NMR spectrometer is the isolation of these two signals so that the receiver is not overwhelmed by the excitation signal.

The design of the probe was an important factor. Purcell and his co-workers developed a bridge circuit^{2,8} to buck out

the majority of the transmitter signal. Bloch and his colleagues developed a crossed coil probe^{3,9} in which the direct coupling of the transmitter signal into the receiver was minimized by the orthogonal arrangement of two coils. Pulse methods originally used one of these two designs but, later, switching schemes which exploited the fact that the transmitter and receiver were active sequentially were developed.

A further important development was the use of modulation coupled with phase-sensitive detection at the modulation frequency.^{10–12} Modulation is usually applied to the magnetic field, although frequency modulation is also possible. For broad resonance lines, for which the linewidth is greater than the amplitude of the modulation, the output signal is proportional to the derivative of the resonance line. However, when the amplitude of the modulation is greater than the width of the resonance line, the response is more complicated. When the modulation frequency is much greater than the resonance linewidth, distinct sideband responses are generated. Excitation can then occur at a frequency

$$\omega_0 = \omega_t \pm n\omega_m = \gamma B_0 \quad (1)$$

where ω_0 is the resonance frequency at a magnetic field B_0 , ω_t is the transmitter frequency, ω_m is the modulation frequency, n is an integer, and γ is the magnetogyric ratio of the nuclear spins.

Several important features derive from this relationship. First, the transmitter and receiver frequencies can be separated by the modulation frequency. When field modulation is used, there is no radiofrequency signal at the receiver frequency in the absence of an NMR response. Separating the weak NMR response from the strong excitation then becomes much simpler. Second, narrow band detection methods may be used by phase detecting the signal at the modulation frequency. Third, the effective frequency of the excitation can be changed by changing the modulation frequency and the excitation amplitude by changing the modulation amplitude. Since the modulation frequency is usually a few kHz, this represents a much more convenient method of sweeping the excitation frequency than by variation of the radiofrequency itself.

An alternative to field or frequency modulation is pulse modulation, first proposed by Arnold in 1955,^{11,13,14} in which the spin response is detected in the periods between pulses used for excitation. A sequence of pulses of width t separated by an interval T has a frequency spectrum with components at frequencies

$$\omega_n = \omega_0 \pm 2\pi n/T \quad (2)$$

and amplitudes

$$A_n = \sin(n\pi t/T)/(n\pi t/T) \quad (3)$$

This method was not widely adopted for CW spectrometers but is used in some cases in more modern spectrometers, for example, in the field/frequency lock channel and for homonuclear decoupling in a high-resolution Fourier transform spectrometer.

2.2 Requirements for Resolution and Stability

The natural linewidths in liquid samples can be extremely small, so that an important instrumental development was

the improvement of magnet homogeneity and stability. Any variation of the magnetic field strength over the volume of the sample causes a smearing of the resonance lines and a consequent degradation of resolution. In addition to the improvement of the basic magnet performance, resolution was improved by spinning the sample^{15,16} and by the use of electric shims.^{17,18} Stability was enhanced by the introduction of flux stabilizers¹⁹ and field/frequency lock systems.^{20,21}

2.3 Double Resonance Methods

Double resonance methods were first introduced in the study of the interaction of electron and nuclear spins,²² and theoretically analyzed by Overhauser.²³ The first use of double resonance methods for purely nuclear spectroscopy was by Royden²⁴ for the detection of a weak resonance through its coupling to a strong resonance. Such ‘indirect detection’ techniques have become very important in modern high-field spectroscopy. Shortly after Royden’s experiments, the use of a second irradiation frequency within the spectral range of the observed nucleus was introduced^{25,26} as a method to aid in the analysis of spectra. An additional frequency could be added relatively easily to a spectrometer operating in the CW mode with modulation sidebands by the use of an additional modulation frequency. When the coupling of a different nuclear species was to be removed, a second radiofrequency channel was required. The concept of broadband decoupling was introduced in 1966 by Ernst²⁷ to remove all the couplings of one nuclear species from another.

2.4 Improvements in Sensitivity

Since NMR is an inherently insensitive technique, there has been a continual quest to improve the sensitivity of spectrometers. Methods employed have been to improve the signal, reduce the noise, and improve the signal processing methods.

Signal intensity has been improved by increasing the spin polarization or by using a larger sample. The use of a larger sample places a more stringent requirement on the uniformity of the magnetic field and has been rather limited. The sample volumes used for analytical applications have not changed dramatically from the earliest NMR spectrometers. Improvements in magnet technology, on the other hand, have occurred and NMR spectrometers now operate with superconducting magnets at field strengths up to 18 T.

Spectrometers have been built to exploit the sensitivity advantage available through coupling to electron spins in the sample.^{28,29} In some cases, the sensitivity can be improved by saturation of electron spin resonance transitions but the method lacks generality to be widely useful. By contrast, the sensitivity to be gained through the nuclear Overhauser effect in the study of nuclei such as ¹³C and ¹⁵N is extensively exploited.

Reduction in the noise associated with the detection of NMR signals has occurred through a number of factors. The introduction of modulation was a contributor in that it allowed the use of phase-sensitive detection at the modulation frequency and the avoidance of some of the low-frequency contributions to the noise. These gains more than offset a

reduction of the basic sensitivity by $\sqrt{2}$ because the signal was only present at one sideband while the noise was present at two. Ernst³⁰ recognized that this loss could be recovered by the use of quadrature detection. Improvements in probe circuits and receivers have had continual small effects on the overall noise performance.

A number of signal processing techniques have had a profound impact on the overall sensitivity of spectrometers. The advent of digital techniques allowed the easy summation of a number of separate recordings of the resonance signal. This technique, known as time averaging,³¹ allowed the possibility of much longer recording times without the introduction of noise due to very low-frequency phenomena, such as spectrometer drift. Since coherent signals add directly and random noise adds as the square root of the number of additions, the improvement in sensitivity provided by time averaging is proportional to the square root of the number of additions.

2.5 Fourier Transform Methods

A major improvement for high-resolution spectroscopy was the introduction of *Fourier transform* methods. The CW method of spectroscopy requires a sequential sweep through the resonance lines of a spectrum. For a complex spectrum containing many resonance lines, the total time to record the spectrum is therefore many times the time needed to sweep through a single resonance line. If all the lines could be excited and their responses recorded simultaneously, a significant saving in spectrometer time would be possible. The significance of this was recognized by Varian³² but the practical realization was made by Ernst and Anderson.³³ They used a short pulse to excite a wide range of chemically shifted resonances and digitized the subsequent free induction response of the spins. Fourier transformation of the response provided the spectral response. The time taken to record the free induction signal is independent of the number of distinct resonance frequencies and is approximately equal to the time required to sweep through a single resonance line. The time reduction afforded by this method compared with the CW technique is the ratio of the total range of the spectrum to the width of an individual resonance line. For a typical proton spectrum at 60 MHz (the frequency of the original experiments), this ratio is about 600. The time averaging method was immediately applicable so that the response could be summed 600-times in the time taken for a single spectral sweep.

At the time of the pioneering experiments of Anderson and Ernst, the data handling necessary for the Fourier transformation and the subsequent spectral display was a very time-consuming process, so that the potential benefits of the technique were not immediately realized. However, small computer systems were developing rapidly and it was soon practical to add a computer to a spectrometer. The introduction of improved algorithms³⁴ for the calculation of Fourier transforms also had a significant impact on the practicality of the Fourier transform method. Initially, the spectrometers were capable of operating in both the CW and pulsed Fourier transform mode, but by about 1974 instruments operating solely in the Fourier transform mode were available and, soon afterwards, dual mode instruments ceased to be

built. Detailed descriptions of spectrometers for liquids³⁵ and solids³⁶ applications were published in *Advances in Magnetic Resonance*.

The pulsed mode of operation meant that instruments designed for high-resolution applications now shared some similarities with instruments designed for solids applications. Initially the timing and pulse power requirements were very different but, over time, these differences have gradually diminished. Now it is common for a single instrument to be capable of a wide range of different experiments for both solids and liquids applications.

Spectrometers designed to study nuclei other than protons were relatively uncommon before the introduction of Fourier transform methods. With the Fourier transform technique, the study of insensitive nuclei, such as ^{13}C , became very practical and instruments were designed specifically to study ^{13}C NMR.

A number of alternative schemes for simultaneous, or near simultaneous, excitation of a spectrum were proposed shortly after the introduction of the pulsed FT method. *Stochastic excitation*^{37,38} used a pseudorandom noise source as the excitation. By correlating the spin response with the excitation, the spectral response could be calculated. It offered the advantage of lower peak power excitation but more complexity in data handling, and has received only minor attention. A second method involves a very rapid sweep through the spectrum. It was observed in the early days of CW spectroscopy that sweeping too rapidly through a resonance line caused 'wiggles' following the line. These were an annoyance in conventional CW spectroscopy but could be exploited, again by making a cross correlation between excitation and response, to produce a spectrum. This technique was dubbed 'correlation spectroscopy'³⁹ and is in use in a few laboratories and in some low-cost commercial spectrometers.

2.6 Additional Developments

In 1974, Jeener⁴⁰ introduced the idea of *two-dimensional* spectroscopy. This was exploited by Ernst and his co-workers^{41,42} and has extended the applications of NMR spectroscopy enormously. As computers have developed, NMR spectrometers have incorporated more computing power to provide control for the pulse sequences required for multidimensional spectroscopy, and also for the analysis of the data. The method has further been extended to three and four dimensions to provide even greater resolving power.

A different application of spectroscopy was spawned by the idea of Lauterbur⁴³ to introduce magnetic field gradients to the sample region. The concept was to couple the resonance frequency to spatial position within the sample by the imposition of one or more field gradients, and hence to be able to provide a spin density map of the sample. Ernst and co-workers⁴⁴ applied the ideas of multidimensional spectroscopy to the method and this has led to the development of magnetic resonance imaging systems. Such instruments share a great deal in common with a pulsed Fourier transform spectrometer for analytical applications. Coils to provide linear gradients along three orthogonal axes are provided and large magnets have been developed to allow the study of larger samples, in particular the human body.

3 MAGNETS FOR NMR SPECTROMETERS

3.1 Introduction

Except for magnetometers, which are used to measure an available magnetic field, the magnet is a key element of the spectrometer. For most NMR applications, the major considerations for magnets are field strength, field uniformity, and stability. The uniformity and stability must be sufficiently high that the inherent properties of the NMR responses can be observed. In liquid samples, the relaxation times can be many seconds, so that natural linewidths may be much less than 1 Hz. In solid samples, resonance lines are broadened to tens or hundreds of kHz by static dipole or quadrupole interactions, or chemical shift anisotropies. Even for the study of these broad resonances, the magnetic field should be uniform to about 1 part in 10^4 over the volume of the sample, whereas for high-resolution liquids applications the uniformity should be up to 1 part in 10^9 or better. For imaging applications the uniformity requirement is typically about 1 part in 10^7 . Stability must be commensurate with these values to avoid degrading the resonance signals over the duration of a measurement which, in some cases, may extend to many hours or even several days. For the most demanding applications, the basic uniformity of the magnet is improved by a number of means including shimming and sample spinning and the stability is improved by the use of field/frequency lock systems and the use of persistent superconducting magnets.

3.2 Magnet Types

For laboratory applications, three main types of magnets have been used for spectrometers. These are permanent

magnets, electromagnets, and superconducting magnets. The basic configuration of these three types of magnet is shown in Figure 1.

3.2.1 Permanent Magnets and Electromagnets

Permanent and electromagnets typically produce the magnetic field between two parallel pole faces. These are mounted on cylindrical pole pieces which are in turn connected by an iron yoke to complete the magnetic circuit. In the permanent magnet, the pole pieces are made from a material with a high remanence which is magnetized by passing a high charging current through energizing coils wound around them. A typical magnetic field for a permanent magnet for NMR applications is 1.4 T corresponding to a proton resonance frequency of 60 MHz. In an electromagnet the magnetizing force is provided by passing current continuously through coils around the pole pieces. Again, an iron yoke completes the magnetic circuit. Magnetic fields up to about 2.3 T, corresponding to a proton resonance frequency of 100 MHz, can be produced by an electromagnet. The limit on the attainable field is the magnetic saturation of the pole piece and the pole cap. In order to provide the field homogeneity necessary for NMR, the ratio of pole diameter to pole gap is fairly high (greater than 10) and the pole caps are carefully shaped.^{45,46} A typical 2.3 T electromagnet for NMR applications has a pole diameter of 12 in. and weighs about 2 tons. The electric power consumption is several kilowatts and water cooling is required for the magnet coils.

Electromagnets have also been used for imaging applications but in the form of multiple solenoid windings with no

Figure 1 Cross-sections of (a) permanent magnet, (b) electromagnet, and (c) superconducting magnet. For high-resolution applications, a permanent magnet is usually enclosed in a temperature controlled and magnetically shielded enclosure. An electromagnet usually requires water cooling of the coils and a superconducting magnet must be cooled in a bath of liquid helium

iron yoke. They are limited to the generation of a magnetic field of about 0.3 T.

3.2.2 Superconducting Magnets

Because of the high power consumption and limited magnetic field capability, the use of electromagnets, for most applications, has been superseded by superconducting magnets. Their configuration is generally in the form of a multilayer solenoid wound with a superconducting wire and maintained in a bath of liquid helium. Since the majority of NMR experiments are performed with the sample at or near room temperature, the cryostat for the liquid helium is designed with a room temperature access to the bore of the magnet. For spectroscopic applications, the bore diameter is between 50 and 100 mm. For imaging applications, the bore diameter is up to 1 m. Most cryostats also include a liquid nitrogen reservoir and thermal shields to provide cooling to minimize the loss of liquid helium.

To provide the homogeneity needed for NMR applications the superconducting solenoid is wound with additional turns toward the ends.^{47,48} The design of these windings is critical to the performance of the magnet. The type of wire used for a superconducting magnet depends on the field strength required. For fields up to 9.4 T (400 MHz for protons), niobium–titanium is used as the superconductor. The superconducting alloy is arranged as one or more filaments in a copper sheath. This type of wire is very ductile and can be readily wound into a solenoid. For higher magnetic fields, niobium–tin is used as the superconductor. This is a very brittle material and cannot usually be manipulated to wind a solenoid. Consequently the magnet solenoid is wound with a wire containing niobium and bronze and is subsequently heat-treated to form the niobium–tin superconductor. Only the inner portions of the magnet need be made in this way. The outer sections of the solenoid which experience lower fields can be wound with niobium–titanium. Magnets using niobium–tin can produce fields in excess of 20 T. The highest field magnet suitable for high-resolution NMR applications is currently 17.6 T (750 MHz for protons). Higher field high-resolution magnets are being designed.

The use of high-temperature superconductors has not yet had an impact on magnets for NMR spectrometers. However, it does appear that these materials offer the possibility of still higher magnetic field strengths when operated at liquid helium temperatures, or the possibility of intermediate field strengths when operated at higher temperatures with simplified cryogenic requirements.

Electromagnets and superconducting magnets can operate at different magnetic fields simply by changing the current through them. However, because of the stability and homogeneity requirements, most NMR spectrometers operate with a fixed magnetic field. Superconducting magnets are nearly always designed to operate in the persistent mode in which the terminals of the solenoid are connected by a superconducting link. The current leads used to energize the magnets can then be removed to minimize thermal losses into the helium bath. The superconducting magnet is effectively a permanent magnet as long as the cryogens are maintained. Operated in the persistent mode, a superconducting magnet may be sufficiently stable for some NMR applications (e.g. solids and imaging) without

any additional stabilization. For high-resolution liquids applications, it is still necessary to provide additional stabilization against long term drift and environmental fluctuations.

3.3 Shimming and Homogeneity Improvement

Magnet uniformity can be improved by ‘*shimming*’, a term which derives from the use of thin metallic shims placed between the pole pieces and the yoke of a magnet to adjust the alignment of the pole faces.

The magnetic field can be expressed as a uniform field plus a series expansion of orthogonal field gradients. Expressed in spherical coordinates, the field at a point (r, θ, φ) may be written as

$$B_0 = \sum_{l=1}^{\infty} \sum_{m=1}^{l-1} r^{l-1} P_{l-1}^m(\cos \theta) [a_l^m \cos(m\varphi) + b_l^m \sin(m\varphi)] \quad (4)$$

where $P_l^m(\cos \theta)$ are associated Legendre functions of order l and degree m . A significant improvement in magnetic field homogeneity was made by the introduction of ‘electric shims’.^{17,18,49} These consist of a set of coils, each one of which is designed to produce a particular field gradient. Gradients inherent in the magnet, either from the design or construction, can then be canceled by the appropriate adjustment of currents in the shim coils. The shim coil currents are adjusted by the operator, or by a computer, to optimize a parameter of the spectrum.

Superconducting magnets include a number of superconducting shim coils for correction of the lower order gradients. In addition, magnets designed for high-resolution applications also include a more extensive set of shim coils in the room temperature bore of the magnet.

An alternative to current shims is the use of passive shims,^{50,51} pieces of magnetizable material positioned within the magnet bore to modify the field distribution. This type of shimming is used extensively in imaging magnets where, once corrected, there is no further need to adjust the field homogeneity.

An early technique to improve resolution was to spin the sample about its axis.^{15,16} If the spinning speed is fast compared with the spread of resonance frequencies across the sample, field inhomogeneities perpendicular to the spinning axis are averaged. The inhomogeneities cause a field modulation in the spinning sample and modulation sideband signals (spinning sidebands) are generated. Sidebands arising from this mechanism can easily be reduced to less than 1% of the intensity of their parent peak, but are still an unwelcome annoyance in spectra. Spinning sidebands are also produced by inhomogeneities in the radiofrequency field of the probe and by small eccentricities in the spinning axis caused by imperfections in the sample tube and spinning mechanism. It is sometimes difficult to reduce these sidebands below 1%. With the introduction of multiple dimensional methods and techniques which rely on the cancellation of signals, the effects of sample spinning have become intolerable. To maintain field uniformity without the averaging effects of sample spinning, more extensive shim coil systems, which correct for many more field gradients, have been introduced. It is quite common for a shim system to include more than 20 gradient coils and up to 40. Fortunately, most of these only need to be adjusted

once at the installation of the magnet. In normal operation, only a few of the gradients require optimization.

To improve the resolution of an NMR spectrometer by operating at higher magnetic fields, the relative homogeneity of the magnet system must improve. This has proved to be possible by careful attention to construction details and by improved shim coil systems. The specified resolution of a commercial high-resolution spectrometer operating at a proton frequency of 600 MHz is approximately the same as that of a 60 MHz spectrometer of 30 years ago.

3.4 Magnetic Field Gradients

While improvement of the magnetic field homogeneity is an important aspect of the operation of NMR spectrometers, a number of important applications exploit the presence of field inhomogeneities. If a spin echo experiment^{52,53} is performed in the presence of a known linear field gradient, the self-diffusion coefficients of the sample can be measured. The measurement was first made with a static field gradient⁵⁴ but later with pulsed field gradients.^{55–57}

Magnetic resonance imaging relies on the use of magnetic field gradients to couple the resonance frequency with the spatial position within the sample. In the earliest experiments,^{43,44} the shim coils were used to provide the gradients. These are generally too weak to provide adequate gradient strengths, so additional coils are included to provide linear gradients dB_0/dx , dB_0/dy , and dB_0/dz . Most applications require rapid switching of the field gradients and eddy current effects must be avoided. This is done by shaping the current driving pulse to compensate for eddy currents or by the use of shielded gradients⁵⁸ which minimize the generation of eddy currents in surrounding structures.

In high-resolution experiments, a pulsed field gradient was first introduced to suppress undesirable transverse magnetization in a spin–lattice relaxation time measurement.⁵⁹ For this application, the ‘homospoil’ pulses were provided by pulsing the current to one of the magnet shim coils. More recently, the use of field gradients has become very important for the selection of coherence pathways^{60–62} and it is usual to include gradient coils as part of the probe assembly to allow more rapid gradient switching and to keep the coil physically as small as possible for the greatest efficiency.

4 PROBES

The *probe* is a critical component of an NMR spectrometer. It provides the coupling between the nuclear spins and the spectrometer by generating and responding to a radiofrequency magnetic field perpendicular to the polarizing magnetic field.

For a given field strength and sample size, the performance of the probe defines the sensitivity of the spectrometer.¹ The efficiency of the coupling of the probe coil to the sample determines the signal induced by the spin system while Johnson noise in the probe coil, and sometimes in the sample itself, is the major source of noise in a spectrometer. Two key probe parameters are the filling factor and quality factor (Q). The filling factor is a measure of the energy stored in the transverse magnetic field coupling to the sample, compared with the total magnetic energy stored in the resonant circuit.

The Q of the probe circuit is proportional to the ratio of the energy stored in the resonant circuit to the power dissipated through resistive losses. Thus, both filling factor and Q should be as high as possible for the maximum sensitivity. Other parameters of importance in the probe are the uniformity of the rf field and the ability to recover rapidly following a strong rf pulse. For some measurements, the probe may have to generate very high rf fields which require very high voltages across the coil; in others the rf may be applied for long periods, resulting in high power dissipation in the probe coil. In addition to the rf characteristics, the probe must also provide the required environment for the sample, for example, temperature control or mechanical rotation of the sample, or other special conditions. Some of these parameters and requirements are in conflict and hence many different probe designs have been developed to support the wide variety of NMR experiments.

For observation of a single nuclear species, the probe can be as simple as a single coil tuned to the resonance frequency by a capacitor and matched to a transmission line (usually 50 Ω) by capacitive or inductive coupling. However, many NMR experiments require the irradiation of the sample with more than one frequency. Unless the frequencies are very close together (for example, exciting different spectral regions of a single nuclear species), the probe coil must be multiply tuned to resonate at a number of different frequencies. Double tuning,⁶³ or even triple tuning, of coils is quite common. There is inevitably some degradation of performance compared with a singly tuned probe because inductive elements are used to provide the frequency separation, and energy stored in these inductances effectively reduces the filling factor. It is also common to use two orthogonal coils to generate fields which are each perpendicular to the polarizing field and yet have little mutual interaction. By combining the use of multiple tuning and orthogonal coils, a single probe can be designed to provide rf excitation and/or detection at four or five different frequencies.

In almost all modern spectrometers, the same coil is used for transmission of energy to the spins and reception of signal from the spins. In a pulse spectrometer, these two functions are separated in time, and switching between the two functions is accomplished external to the probe. In a CW spectrometer, where transmission and reception occur simultaneously, transmitter coupling into the receiver is minimized by the use of a bridge⁸ or a directional coupler. An alternative form of probe for CW measurements used two orthogonal coils, one for transmission and one for reception.⁹ The coupling between the coils was minimized by careful mechanical alignment of the coils and by manipulating the residual coupling with ‘paddles’,^{64,65} movable pieces of metal designed to modify the magnetic flux distribution in the probe.

For liquids applications, the sample is commonly contained in a thin-walled test tube. Typical diameters are 5 mm or 10 mm. In a permanent magnet or an electromagnet the axis of the sample is perpendicular to the magnetic field between the pole faces, and the probe coil can be a simple solenoid around the sample. In a superconducting magnet, the sample tube is parallel to the field and the probe coil must be split to provide a transverse field. Figure 2 shows these two configurations.

A vital consideration for liquids applications is the maintenance of field uniformity. The requirements for magnetic field homogeneity have already been discussed in connection with

Figure 2 Two common types of probe rf coils for high-resolution liquids applications: (a) solenoid coil used with permanent and electromagnets; and (b) saddle coil used with superconducting magnets

the magnet. However, without due care, the probe and the sample itself will distort the magnetic field and destroy the resolution of the spectrometer.⁶⁶ The problem arises from the magnetic susceptibilities of the sample and its container, and of the materials used in the construction of the probe. Volume susceptibilities of many diamagnetic materials are approximately 10^{-6} so that discontinuities in susceptibility can cause field variations of this magnitude. Such effects can be minimized by keeping any discontinuities away from the active sample volume and by maintaining cylindrical symmetry as much as possible in the design of the probe. For this reason, the NMR sample tubes are filled with sample to a depth greater than the active region of the probe. This, of course, requires an excess of sample and compromises the uniformity of the rf excitation and detection. Special attention must be paid to the probe coil itself. Its geometry is not simple and, if a high filling factor is to be maintained, it must be close to the sample. The magnetic susceptibility of normal metals, such as copper or silver, are sufficiently high to cause intolerable distortions of the magnetic field in the sensitive volume of the sample. Coils are therefore manufactured from special composite materials specifically designed to have very low susceptibilities.

For solids applications, rf field homogeneity and efficiency are much more significant than the perturbation of the B_0 homogeneity. Therefore, it is usual to use a solenoidal coil with the sample limited to a portion of its total volume. For some applications, e.g. CP MAS⁶⁷ and CRAMPS,⁶⁸ the sample must be rotated at a very high speed (many kHz) about an axis inclined at 54.7° with respect to the polarizing field.

A single coil generates an oscillating magnetic field, while the nuclear spins respond to and generate a rotating magnetic field. An oscillating field, which may be regarded as two counter rotating fields, is therefore wasteful of transmitter power and signal reception is less efficient. Probes can be built to produce a rotating field and regain this efficiency (a factor of two in reduction in transmitter power and a factor of $\sqrt{2}$ in sensitivity) by using two orthogonal coils driven by rf signals in relative phase quadrature.⁶⁹ They are used extensively in whole body imaging systems where high power must be used to generate fields over a very large volume and where, often, only a single frequency must be supported. In spectroscopic applications, where multiple frequency excitation is common, quadrature coils have not found widespread use.

5 SPECTROMETER ELECTRONICS

5.1 Introduction

The electronic portion of the spectrometer includes the radiofrequency section for the excitation and detection of the spin response, control systems for the rf and for the magnet, and digital electronics to manipulate the data. A block diagram of a typical pulse spectrometer for high-resolution liquids applications is shown in Figure 3. A spectrometer for solids applications would not require the lock system or the gradient coils. An imaging system would not require the lock system and would not usually have a second transmitter channel.

The elements of the rf system are: frequency synthesis; transmitter system; power amplification; coupling to probe; receiver system; and signal detection.

5.2 Frequency Generation and Transmitter System

The transmitter provides the rf signals to excite the spins. In a simple spectrometer designed to observe a single nuclear species, this can be a fixed frequency source with a fixed amplitude. In a CW spectrometer, variation in the excitation intensity can be achieved by varying the amplitude of the field modulation signal, and scanning through the spectrum is provided by sweeping the magnetic field or the modulation frequency. In a pulse spectrometer, the effective excitation of the spins is controlled by the amplitude and duration of the rf pulse.

A modern pulse spectrometer designed to satisfy a wide range of applications and to observe a wide range of nuclear species requires a more complex frequency generation scheme. It is common to use a crystal oscillator operating at a standard frequency, such as 10 MHz, to provide a stable source of rf from which all other spectrometer frequencies can be derived. The transmitter may include a general purpose frequency synthesizer so that the output frequency can be set to correspond to a wide range of nuclear resonance frequencies. It is also quite common to generate the transmitter frequency by mixing one or more frequencies. This offers several advantages. First, the gating efficiency in the transmitter can be improved by providing gates before the mixing which generates the final transmitter frequency. This is important to minimize leakage of the transmitter signal into the receiver. Second, one of the intermediate frequencies can be constant for all transmitter frequencies and can be used to control the characteristics (e.g. phase or amplitude) of the transmitter output. Third, the receiver often operates on the heterodyning principle with a portion of the gain at an intermediate frequency. Frequency generation for the transmitter and receiver can then share some common frequencies. A disadvantage is that each mixing stage introduces multiple frequency components, only one of which is required. Careful filtering or suppression of the unwanted frequencies is therefore necessary to maintain the required spectral purity of the transmitter output. A block diagram for a transmitter using frequency mixing is shown in Figure 4.

In almost all pulse spectrometers, some control of the rf phase is used. For the simplest applications, this may only require the phase to be controlled in 90° increments. The first

Figure 3 Block diagram of a typical two channel high-resolution NMR spectrometer

Figure 4 Simplified block diagram of a typical spectrometer transmitter

pulse experiment to require phase shifts was the modification to the Carr–Purcell *spin echo* experiment⁵³ proposed by Meiboom and Gill.⁷⁰ Now, many experimental methods have been developed to exploit the use of transmitter phase shifts. In some, the behavior of the spin system is modified; in others, spectrometer imperfections can be controlled. It is important to realize that the absolute phase of the rf in a pulse is usually not constant from pulse to pulse. That would require the pulse interval to be a multiple of the rf period. What is important is that the pulses have a fixed phase relative to a continuous rf source at the same frequency. Many experimental methods have been developed in recent years which require a variety of rf phase shifts. Therefore many modern spectrometers include a general purpose phase shift capability to provide any rf phase between 0° and 360° with a phase shift resolution of less than 1°. This is most easily provided by controlling the phase of a fixed frequency section of the transmitter. Phase changes are transferred to the transmitter frequency through the subsequent mixing stages.

Short pulses provide an excitation of a wide range of spectral frequencies. This was the prime motivation for the development of the pulsed FT method. However, there are many instances when selective excitation of less than the full spectral width may be required. A number of methods were developed to provide selective excitation by pulse

modulation.^{71,72} These experiments can also be performed by modulating the amplitude of the rf. These methods first found widespread use for imaging applications but have become common in spectroscopic applications. The use of amplitude modulation requires that the frequency generation scheme is linear, or that it can be linearized by calibration. Again, the use of a fixed frequency section of the transmitter provides a convenient place to provide amplitude control for the rf.

The inclusion of a flexible phase and amplitude control means that complex modulation of the rf may be employed to generate a variety of excitation profiles for a wide range of experiments.^{73–76}

5.3 Power Amplification

The rf signals provided in the transmitter are amplified to the appropriate level before coupling into the probe. In a CW spectrometer, the power required is quite low. The use of modulation reduces the effective field strength in the probe but, even so, a few watts is all that is required.

In a pulse spectrometer, the output power required varies greatly with the application, the nuclei being observed, the sample size, and the operating field strength. For the observation of proton spectra in liquids, a few tens of watts is often sufficient, while the observation of nuclei with lower magnetogyric ratios often requires several hundred watt pulses. Solids applications usually require pulses to be short compared with relaxation times and pulse powers of a kilowatt may be needed. In whole body imaging applications, the probe coils can be very large so that, again, kilowatts of pulse power may be needed to generate only a modest rf field.

For applications in which a constant amplitude is sufficient, the use of a nonlinear class C amplifier offers a number of advantages. In the absence of an rf input, there will be no output from a class C amplifier, so the effective gating of the rf source is improved. Further, there is no noise generated by such an amplifier when there is no input signal. Class C amplifiers are often inexpensive to build. Disadvantages are the difficulty of building a broadband amplifier and the difficulty of controlling the gain.

For well-controlled broadband amplification and for use with variable amplitude drive, a linear amplifier is used. These amplifiers are more expensive than class C amplifiers and have the disadvantage that they do generate noise output with no input signal. To overcome this difficulty, amplifiers must be actively blanked off by switching the bias of the output stage until an output pulse is needed.

5.4 Multiple Irradiation

In a modern spectrometer, the need for a second irradiation frequency is so prevalent and varied that a second transmitter channel is added. This channel usually has all the attributes of the first transmitter, namely the ability to adjust the frequency and to control the amplitude and phase of the rf source. A number of experiments have been developed which require the excitation of several nuclear species either simultaneously or sequentially. Therefore a spectrometer may be equipped with three or four transmitters to provide the necessary excitation frequencies.

Care must be exercised if irradiation from a second or third irradiation channel is used during the acquisition of an NMR response. If the irradiation is within the spectral range of the receiver, as in the case of homonuclear decoupling, time-share modulation is used. In a manner similar to an earlier scheme of CW spectrometers,^{13,14} the irradiation is pulse modulated with the receiver being gated off during the pulses and turned on during the interval between pulses. If the irradiation frequency is at a significantly different frequency, as in heteronuclear decoupling, frequency selective filters are used to prevent any overload of the receiver by strong rf signals.

5.5 Transmit–Receive Switch

Transmitter energy must be coupled into the probe and received signals must be coupled out. In a pulsed spectrometer these events occur sequentially and a switching circuit is used to direct the signals correctly. A simple, commonly used circuit⁷⁷ makes use of crossed diodes and quarter-wavelength lines (Figure 5) to effect the switching by the application of the rf itself. High voltages during the rf pulse excitation cause the diodes to conduct and act as short circuits. Those to ground in front of the preamplifier protect the amplifier from overload and also reflect energy so that all the transmitter power is delivered to the probe. During the receive cycle, voltages are so low that the diodes effectively act as open circuits. The transmitter is effectively isolated and all the signal energy is coupled to the preamplifier. Such a circuit is nonlinear in that a threshold pulse amplitude is required to switch the diodes into a conducting state. For applications requiring linear control of the rf level in the probe, a linear version of the same circuit can be built using PIN diodes,⁷⁸ which can be switched from a conducting state to a nonconducting state by the application of a dc control voltage.

5.6 Receiver and Detector

The receiver system⁶³ provides the amplification of the weak NMR signal with the minimum degradation and distortion, and detection of the rf signals for display and measurement.

Figure 5 A simple transmit–receive switch using passive diodes. The interconnections are transmission lines and λ is the wavelength at the radiofrequency of interest. Errors in choice of line length affect the efficiency of power transmission to the probe, not that of reception. A single length of line can therefore be used to cover a factor of two in operating frequencies

The total gain required in an NMR receiver system is typically between 60–100 dB. In a few applications this might all be provided at the NMR frequency. More commonly, the NMR signal frequency is amplified by about 20–30 dB and then converted to a fixed intermediate frequency (IF) by mixing with a local oscillator frequency derived from the transmitter. This provides a more stable receiver and allows most of the amplification to be at a fixed frequency. In some cases more than one intermediate frequency might be used. Phase detection at the final intermediate frequency provides the output signal or signals of the spectrometer. A block diagram of a receiver employing a single intermediate frequency and quadrature phase detection is shown in Figure 6.

For pulse applications, it is necessary to deactivate the receiver during transmitter pulses to prevent overload and subsequent slow recovery to optimum performance. In a receiver using an intermediate frequency, very effective disabling can be achieved by gating off the local oscillator signal. Additional gating of the preamplifier is also sometimes used but is not always necessary.

The output of a mixer contains both sum and difference frequencies of the two inputs, only one of which is at the desired frequency. The unwanted frequency is easily rejected by limiting the bandwidth of the following receiver stages. A more difficult problem is that of rejecting the so-called image frequency. For example, in the first mixer of the receiver, signals at two frequencies are converted to the IF, namely

$$\omega_1 = \omega_{LO} - \omega_{IF} \quad (5)$$

and

$$\omega_1 = \omega_{LO} + \omega_{IF} \quad (6)$$

While only one of these frequencies corresponds to the NMR frequency, ω_0 , any noise at the second frequency will be converted to the IF to the detriment of the overall signal-to-noise ratio. The image frequency must therefore be rejected, either by including a filter to eliminate it before the mixer or by the use of a single sideband mixer⁷⁹ which rejects signals at the image frequency by cancellation. In a spectrometer designed

Figure 6 Block diagram of a quadrature detection receiver using a single intermediate frequency

to operate over a wide range of NMR frequencies, a broadband single sideband mixer can be used whereas the use of a simple mixer may require the switching of several filters. At the final mixers of Figure 6, the image frequency is twice the IF and is simply rejected by limiting the bandwidth of the IF section of the receiver.

The bandwidth of the receiver must be sufficient to amplify all the signal components generated in the probe. The rf and IF sections of the receiver have relatively large bandwidths and the low pass filter following the final detector determines the overall frequency response. In a CW spectrometer, this is a very narrow band since the signal is the response at the excitation frequency. In a pulse spectrometer, the bandwidth must be sufficient to record the transient response. Many individual signal components might be included in that response.

The output of the final mixers is at a frequency, ω_s , equal to the difference between the NMR frequency and the transmitter frequency. As such it is equal to the precession frequency in a reference frame rotating at the frequency of the spectrometer transmitter. The output of a single detector corresponds to the projection of the rotating magnetization vector onto an axis in the rotating frame. By using two phase detectors driven by reference signals in quadrature, as shown in Figure 6, two outputs are provided representing the projections onto two orthogonal axes in the rotating frame. The two axes may not correspond to the x - and y -axes as defined by the transmitter excitation, but can be brought into correspondence, if necessary, by phase rotation of the reference signals relative to the phase of the transmitter. In applications where the signals are subsequently digitized, the phase rotation can be effected by manipulating the digital data.

The sense of rotation of the signals in the rotating reference frame can be distinguished by the phase relationship between these two detected signals. Hence, NMR signals at frequencies above and below the transmitter frequency can be distinguished. For accurate separation, the outputs of the

two channels must be exactly in quadrature and equal in amplitude. Imperfections can be canceled by accumulating multiple spectra excited with differing transmitter phases and by suitably combining the resultant responses.^{80,81}

Noise at frequencies above and below the transmitter frequency is similarly distinguished. With only a single detector, the noise components from either side of the transmitter frequency both contribute to the noise in the output, and the signal-to-noise ratio is degraded by $\sqrt{2}$. The use of quadrature detection in NMR receivers was first proposed by Ernst³⁰ for the improvement of the sensitivity of spectrometers then in use.

For all types of NMR spectrometer, the noise performance of the receiver is an important consideration. Signals may be degraded by the addition of noise or by the introduction of spurious signals. Any circuit element can be characterized by its noise factor⁸² which is the ratio of the signal-to-noise power at the output compared with the signal-to-noise power at the input. Noise factors are usually expressed in dB as noise figures although, in cases where the noise source and the receiver may be at different temperatures, the use of noise temperatures is more appropriate. A noise factor of 2 is equivalent to a noise figure of 3 dB and results in a loss of signal-to-noise ratio (which is normally defined in terms of voltage) by $\sqrt{2}$. Typical noise figures for a modern NMR receiver are between 1 and 2 dB. Any lossy components between the probe and the receiver degrade the noise figure by a factor equal to its loss. Special care is therefore taken to use low loss cables and to minimize any loss in filters and the transmit–receive switch.

In FT spectrometers, where a number of signals over a band of frequencies are amplified simultaneously by the receiver, linearity and dynamic range are other important parameters. Any nonlinearity in the receiver response can give rise to harmonic or intermodulation distortion which can result in spurious signals which fall within the pass band of the receiver and hence can be confused with real signals. Dynamic range is

important because the receiver must be able to handle the sum of all signals excited by a pulse at the start of a free induction decay and yet also record faithfully the response of individual components, which may be very weak, as the signals dephase.

5.7 Analog-to-Digital Converter

In most modern NMR spectrometers, the analog signal following detection is converted to a digital form for time averaging or other signal processing. The analog-to-digital converter (ADC) must have sufficient resolution and accuracy to make a faithful representation of the signal in the digital domain.⁸³ Linearity must be maintained by adjusting the receiver gain to limit the maximum signal intensity to less than the full scale response of the ADC. At this gain, the resolution of the ADC (number of bits) should ideally be sufficient such that the quantization steps are less than the noise associated with the signal. This may not always be possible to achieve for all types of signal but, typically, 16-bit ADCs are used in a pulsed FT spectrometer.

The sampling rate of an ADC must be twice the maximum signal frequency to prevent aliasing of signals. In a quadrature receiver system, each channel must be sampled at a frequency equal to the total spectral width. The filter bandwidth in each channel is set close to one-half the total spectral width.

Since noise voltage increases with the square root of noise bandwidth, there are advantages of operating with as large a bandwidth as possible, even if signals only occupy a relatively small bandwidth. The time domain signal-to-noise ratio is reduced so that, for an ADC of a given amplitude resolution, it is possible to reduce the spectrometer gain, and hence handle larger signals, without running into the quantization noise limit of the ADC. The large amounts of data generated by high speed sampling can be reduced by digital filtering following the digitizer.

5.8 Field/Frequency Lock System

For high-resolution applications in liquids NMR, the inherent stability of the magnet is often not sufficient to ensure accurate results. Therefore it is common to stabilize the field by making use of an auxiliary magnetic resonance signal from the sample. This concept of an internal lock was introduced in 1961.^{20,21} An error signal is generated from the dispersion mode signal of this second resonance signal.

In a CW spectrometer using field modulation techniques, the resonance used for stabilization can be a resonance in the spectrum itself, excited by a second modulation frequency. Spectrometers designed for proton spectroscopy used the signal of tetramethylsilane (TMS) as a reference and as a 'lock' for the field/frequency control. For spectrometers designed to study a variety of nuclear species, and for systems which operate in the pulsed mode, it has become common to use a deuterium resonance as the 'lock' signal. A deuterium compound is included in the solvent of the high-resolution sample and the spectrometer is equipped with a separate deuterium spectrometer for the excitation and detection of the deuterium resonance. This is essentially a simple CW spectrometer operating at a fixed frequency with an output which controls the magnetic field. The probe includes a coil

tuned to the deuterium resonance frequency. Sometimes this is a separate coil, orthogonal to the observe coil, but more usually one of the coils in the probe is doubly tuned to the deuterium frequency and another operating frequency.

In a pulsed spectrometer, the lock system usually operates with pulsed modulation in the time-shared mode, since this is very compatible with the rest of the control circuits of the spectrometer. Pulse repetition frequencies of between 10 Hz and 10 kHz have been used. The transmitter power is quite low (less than 1 W) since it is normal to operate the lock system below saturation to maintain the linearity of the control loop. The output of the lock channel is phase detected and the dispersion signal is used as the control signal feedback to the field offset coil of the shim coil system. The output is zero exactly at resonance and an error signal is generated if the field/frequency relationship changes. From the dispersion response, the sign of the signal depends on the sign of the deviation from resonance and hence provides the required control for a feedback loop.

When the field variation over the sample volume is greater than the natural linewidth of the resonance, the amplitude of the absorption signal will vary with field homogeneity. Thus the amplitude of the lock signal can be used as an indicator for the quality of the magnet shimming.

A drawback of the use of deuterium is its low magnetogyric ratio. This results in a relatively low signal sensitivity and a lower sensitivity to changes in field homogeneity. For these reasons, and when deuterium is to be observed, lock systems are sometimes used with other nuclei. Good candidates are ¹⁹F and ⁷Li.

5.9 Digital System

The majority of spectrometers include a digital subsystem to provide control of the spectrometer and processing of signals. In a modern spectrometer, this system may consist of one or more powerful computers with some specialized hardware for specific functions. The use of a computer as an integral part of a spectrometer became essential with the introduction of FT techniques. Prior to that, spectrometer functions were controlled by manual knobs. In a modern spectrometer, interaction with the spectrometer variables is via a computer interface. This provides greater flexibility and lower cost than manual control.

The functions of the digital system may be divided into several parts: instrument control; data acquisition; and data processing.

5.9.1 Instrument Control

The control system provides the interface between the user and the spectrometer variables.

Some of these functions are time-critical whereas others are not. The non-time-critical functions are generally handled by a general purpose computer whereas the time-critical functions require some dedicated hardware and possibly a dedicated computer system.

An increasingly important aspect is the control of pulse sequences. Much of the flexibility in a modern spectrometer has come about by the ability to implement a wide range of experiments through a versatile pulse sequence programmer.

This provides the control of all of the relevant parameters used in the excitation of the spin system, e.g. rf level, pulse durations, pulse intervals, phase of transmitter and receiver, field gradient pulses, and timing of data acquisition. In multidimensional experiments, one or more of the timing durations is incremented for successive elements in an array of acquisitions. The control system must provide this control and keep track of the data associated with each increment.

The increasing use of pulses modulated in phase and amplitude has led to the use of distributed control in which the modulation information is stored in a memory buffer and recalled when required as part of a pulse sequence.

5.9.2 Data Acquisition

Since data acquisition is intimately connected with pulse sequence control, the same computer system or timing circuitry provides control for each. Time averaging is usually performed in the time domain as an integral part of the data acquisition process. The time domain data can then be transferred to disk from whence it can be accessed for further processing. If a separate computer system is used for data processing, acquisition of new data can continue while previously accumulated data are being processed.

Increasing use is being made of sampling data at a high fixed bandwidth. Bandwidth is then adjusted by digital filtering and the number of data points reduced, commensurate with the final bandwidth, before storing to disk.

5.9.3 Data Processing

The stored free induction signal or array of signals can be manipulated in a number of ways. The data may be weighted as a function of time to provide improved sensitivity or resolution. Data points may be modified or added, for example by *linear prediction* methods,⁸⁴ to overcome instrumental deficiencies or to correct for truncated data. Fourier transformation is most commonly used to generate the frequency spectrum although other methods are also used.^{85,86} Following transformation, the phase of the data is adjusted prior to display. It is usual to display the data on a video terminal to allow convenient selection of scales and displayed regions before finally plotting the data.

6 AUXILIARY SYSTEMS

6.1 Variable Temperature System

Sample temperature is a critical parameter for many experiments, so that control of the temperature is often included as part of the spectrometer function. The most common form of control for temperatures between about -100°C and $+200^{\circ}\text{C}$ is to use a flow of controlled temperature gas (usually dry nitrogen or air) over the sample. A heater and temperature sensor in the gas stream are connected to a temperature control unit in the spectrometer. For extremely low temperature operation, more sophisticated systems using liquid helium are used. For high temperatures, furnace systems have been employed.

6.2 Pneumatics System

Gas bearings and drive are used for sample spinning. For high-resolution applications, the NMR sample tube is mounted in a turbine which can be rotated by a jet of gas. The turbine walls can also provide the gas bearing surfaces or, sometimes, the sample tube itself can provide the bearing surface. While sample spinning has lost favor for most multidimensional experiments, it is still used for simple high-resolution applications as a means for improving resolution. An optical detector is used to detect and measure the rotation rate. For many applications, the precise control of the spinning speed is not important and an open loop system is used. More sophisticated spectrometers provide closed loop control of the spinning speed using the spin rate detector to generate a feedback signal to control the flow of gas to the spinner.

For solids applications requiring magic angle spinning, the sample is packed into a small rotor which is supported by gas bearings and rotated at high speed (up to 20 kHz).

In a superconducting magnet, the sample is located in the center of the long, narrow magnet bore. It is quite common to use a pneumatic lift mechanism to eject the sample and to provide a gentle lowering of the sample into the probe.

6.3 Automation

Many applications of NMR require the measurement of a large number of samples on a continuous basis. Therefore, the integration of automatic sample-changing mechanisms has become important for these applications. Such systems include a holder (tray or carousel) for a large number of samples and a mechanism to move the samples individually to and from the magnet. Coupled with sophisticated software, the required experimental parameters can be established for each individual sample and a large number of samples can be analyzed completely unattended.

7 CONCLUSION

The basic structure of a pulsed NMR spectrometer is well suited to a wide range of applications. Future developments are most likely to be in the greater accuracy and convenience of implementing more complex pulse sequences and other aspects of spectrometer control through improvements in digital technology and software. Developments in magnet technology may lead to still higher magnetic field strengths or simplified cryogenic requirements through the use of new superconducting materials. Some of these improvements may open new applications for nuclear magnetic resonance. The probe will be one aspect of the spectrometer which will continue to develop specifically for a particular application.

1 INTRODUCTION

Superconducting quantum interference devices (abbreviated SQUIDS) can be used as sensitive magnetic flux-to-voltage converters. In this mode they can detect NMR signals, replacing the tuned coil in a conventional NMR probe. Their primary applications include low frequency studies (below a few megahertz), observation of large spectral widths (several megahertz), and measurements at ultralow temperatures (millikelvin regime).

In conventional detection of NMR, the signal is observed as a voltage induced in a tuned coil by a changing magnetization dM/dt (Faraday's law). This method is inefficient at low frequencies, where dM/dt is small. The SQUID, on the other hand, directly transforms changes in the magnetization ΔM , induced by spin transitions, into voltages. Thus, SQUID detection works sensitively down to very low frequencies.¹

SQUIDS can detect changes in both the longitudinal and transverse magnetization. SQUID measurements of the longitudinal magnetization have been used to obtain NMR,^{2,3} NQR,^{3,4} and EPR⁵ spectra and relaxation times. There are no restrictions on the methods used to excite the transitions: techniques employed include CW excitation,^{3,6,7} rf pulses,⁸ and acoustic fields.⁹ Applications of SQUID NMR spectrometers range from structural studies of solids⁴ to thermometry,^{1,10} study of enhanced nuclear moments,¹¹ and properties of superfluid ³He.^{8,12,13}

Changes in the transverse magnetization, that is, in the FID following an rf pulse, have been observed with SQUIDS both at high frequencies (30 MHz)¹⁴ and in the low frequency regime (<200 kHz).^{15–17} This application has great potential in that it could make use of the multitude of pulse sequences developed for high field NMR.

After sketching the principles of operation of a SQUID and the design of a SQUID spectrometer, we outline some applications of SQUID detection in NMR. We conclude with a summary of areas of future potential progress for the field.

2 HOW A SQUID WORKS

Here we briefly describe the principles of operation of SQUIDS. For a more detailed description of both operation and noise characteristics, see Meredith et al.¹ and Clarke.¹⁸

By combining the phenomena of fluxoid quantization in a superconducting ring and Josephson tunneling, SQUIDS convert changes in magnetic field into voltages that can be detected by conventional semiconducting electronics.¹⁹ Fluxoid quantization in a superconducting ring restricts the magnetic flux threading the ring to $n\Phi_0$, a multiple of the flux quantum $\Phi_0 \sum h/2e \approx 2 \times 10^{-15}$ Wb. Application of an arbitrary flux Φ causes the ring to generate a supercurrent of Cooper pairs such that the self-generated flux exactly cancels Φ . To detect these flux-induced changes the superconducting ring is interrupted by one or two Josephson junctions. A Josephson tunnel junction consists of two superconducting films separated by a thin insulating layer. When a current I is passed through the junction, the Cooper pairs tunnel through the barrier. No voltage V is developed by this supercurrent until I exceeds the maximum supercurrent I_0 that the junction can sustain. Depending on whether one or two Josephson junctions interrupt the superconducting ring, one distinguishes between rf and dc SQUIDS, respectively. Direct current SQUIDS are normally operated by fixing the dc bias current across the SQUID at a constant value larger than the supercurrent I_0 . Since the amount of current that travels as supercurrent through the ring depends on the flux threading the SQUID, the voltage changes periodically as a function of the applied flux with a period Φ_0 . To obtain an output voltage that is proportional to the input flux even when the applied flux is less than Φ_0 or corresponds to many Φ_0 , one uses a feedback circuit in which the SQUID acts as a null-flux detector.

The rf SQUID, on the other hand, consists of a superconducting loop interrupted by a single Josephson junction. The prefix 'rf' implies that the device is biased with a radiofrequency modulated flux. Both types of SQUID have been incorporated into NMR and NQR spectrometers.

3 DESIGN OF A SQUID SPECTROMETER

Despite the multitude of applications and experimental techniques exploiting the high sensitivity of a SQUID, the basic features of the spectrometers and their problems are similar. We therefore describe in some detail a particular spectrometer which uses a dc SQUID to detect the changes of the longitudinal magnetization.^{3,20}

The probehead of this spectrometer is shown in Figure 1. The commercial dc SQUID (Model DBS, Biomagnetic Technologies, Inc.) operates in the flux-locked mode as a linear flux-to-voltage converter. To protect the SQUID from direct rf irradiation, the SQUID is embedded in a superconducting niobium tube (shown on the left-hand side of Figure 1), and is spatially separated from the sample environment (shown on the right-hand side of Figure 1). A superconducting flux transformer transfers the changes of magnetic flux from the sample into the SQUID. The transformer consists of two coils of equal inductance, and shunt resistors. The pickup coil holds the sample, which has a volume of roughly 100 mm³. The second coil, the coupling coil close to the SQUID, feeds the flux change of the pickup coil into the SQUID itself. The shunt resistors in parallel with the coils at the bottom of the probehead act as a low pass filter to prevent rf from being transferred directly into the SQUID.

Changes of magnetic flux in the sample are induced by rf excitation of spin transitions. In this spectrometer, two

Figure 1 Cross section of the low-temperature part of the SQUID spectrometer. (Reproduced by permission of the American Institute of Physics from C. Conner, J. Chang, and A. Pines, *Rev. Sci. Instrum.*, 1990, **61**, 1059)

Helmholtz saddle coils wound orthogonally to the pickup coil emit a linearly or circularly polarized rf field to the sample (of microtesla magnitude). The exact orientation of these coils with respect to the pickup coil is one of the main factors in minimizing rf influence on the SQUID. The rf circuit is not tuned to a specific frequency, thus allowing a wide range of frequencies to be observed. Also, since the SQUID detects the slowly changing magnetization of the sample parallel to the static magnetic field, the resonance frequencies do not determine directly the sensitivity of detection. A small static magnetic field (up to about 10 mT) can be trapped in a lead tube surrounding the rf coils, the pickup coil, and the sample.

In this apparatus the probehead is immersed completely in liquid helium, giving a constant temperature of 4.2 K. The SQUID feedback circuit rests on top of the cryostat; this circuit, the cryostat, and the probehead are placed inside a cage made of copper mesh to shield them from external rf fields. The rest of the spectrometer, consisting of the rf transmitter, the remaining SQUID electronics, and the receiver is situated outside the copper cage. The rf irradiation is generated by a computer-controlled frequency synthesizer. The signal obtained from the SQUID is passed through the feedback unit to the SQUID controller (BTi Model 40). The signal is amplified, filtered, digitized, and finally transferred to a computer for storage and analysis.

4 APPLICATIONS

Early experiments using SQUIDS as part of NMR spectrometers concentrated mainly on studying the physical properties of systems. For example, Meredith et al. took advantage of the low excitation powers needed for the SQUID-based spectrometer to measure temperatures in the millikelvin regime, by

determining relaxation times T_1 of a bundle of copper wires and using the Korringa relation $T_1 T = \text{Constant}$.^{1,10} Similarly, the low power requirements of the SQUID, together with the wider accessible frequency range (10 kHz to 1 GHz) allowed NMR and EPR relaxation studies of Ce^{3+} in cerium magnesium nitrate at temperatures down to 10 mK with the same spectrometer.⁵ The wide available frequency range was also important for studies of the hyperfine-enhanced nuclear moment in TmPO_4 ,¹¹ for which an effective field 77.9 times stronger than the applied magnetic field was found. Pickens et al. presented NQR spectra and the first measurements of magnetic-field-dependent nuclear spin relaxation rates in a bulk metal (^{121}Sb and ^{123}Sb).⁹ These experiments were performed using a SQUID spectrometer to detect the change of static susceptibility caused by transitions driven by acoustic energy. Webb studied the difference between the static and dynamic susceptibilities of superfluid $^3\text{He-B}$ at ultralow temperatures (1.2 K to 2 mK) and various pressures.^{12,13}

Besides investigating the physical problems outlined above, SQUID spectrometers are valuable tools for obtaining answers to a wide range of chemical questions. Examples discussed below include studies of rotational tunneling in methyl groups to characterize local environments, and various quadrupole resonance experiments.

4.1 Rotational Tunneling of Methyl Groups

The tunneling frequencies of methyl groups have been used to characterize the local methyl group environments and correlate them with macroscopic properties.² The ground state rotation eigenfunctions of hindered methyl groups split into *A* and *E* symmetry states. The energy difference between the *A* and the *E* levels, denoted as the tunnel splitting $h\nu_T$, depends on the hindering potential given by the environment. The Pauli principle dictates that transitions between the rotational states are coupled to changes in the spin states. Unfortunately, transitions between the pure *A* and *E* states, which contain information about the environment, are symmetry forbidden in both high and zero magnetic fields. The SQUID experiments detect these transitions by applying a small magnetic field, resulting in Larmor frequencies of only a few hundred kilohertz. For methyl groups attached to sp^3 hybridized carbon, the similar size of the proton Larmor frequency, the dipole-dipole coupling constant between the protons, and the tunneling frequencies render transitions between the *A* and *E* symmetry species observable. The spectra (an example is shown in Figure 2) show maxima at the proton Larmor frequency ν_0 and twice the Larmor frequency $2\nu_0$, with their tunneling sidebands $\nu_0 \pm \nu_T$ and $2\nu_0 \pm \nu_T$. A systematic study of the dependence of the tunneling frequencies on the chain length of a series of carboxylic acids, and comparison to macroscopic properties like the heat of fusion, has led to a deeper understanding of subtle differences in crystal packing and its consequences for physical properties.²

4.2 NQR: Longitudinal Magnetization

NQR transitions provide chemical and structural information about the environment of the nuclei studied. In pure NQR the transition frequencies are sharply defined by the local electric

Figure 2 The proton SQUID NMR spectrum of solid hexanol in a magnetic field of 13.5 mT at 4.2 K. One frequency sweep each, from low to high frequencies and in opposite directions, were added. The insert shows the resonance at the Larmor frequency (reduced by 1/10th). The transitions at the Larmor frequencies $\nu_0 = 574$ kHz and $2\nu_0 = 1147$ kHz are flanked by the tunneling sidebands $\nu_0 \pm \nu_T$ for a tunneling frequency $\nu_T = 145 \pm 3$ kHz. (Shown at the 33rd ENC, Asilomar, 1992, by B. Black, G. Majer, U. Werner, and A. Pines, reproduced in part by B. Black, Ph.D. Thesis, University of California, Berkeley, CA, 1993)

field gradients at the nucleus studied. However, low signal intensities due to low quadrupole transition frequencies, which can differ by several megahertz in the same sample, pose problems. These difficulties have been addressed by using a SQUID based spectrometer, both by detecting the longitudinal and transverse magnetization.

Studying NQR through the change in static susceptibility differs significantly from NQR experiments that observe the transverse magnetization either with a SQUID or a conventional detection scheme. The difference arises from the quenching of the magnetic moment of the quadrupolar eigenstates in zero field. This quenching is the result of time reversal symmetry of the quadrupole Hamiltonian.²¹ For half-integer spins, the eigenstates with magnetic quantum numbers m and $-m$ ($m \neq 0$) are degenerate. For integer spins the eigenstates are either degenerate (for $\eta = 0$, where η is the asymmetry of the quadrupole interaction) or a superposition of equal contributions of the states with magnetic quantum numbers m and $-m$. In either case, exciting a transition between the pure quadrupole eigenstates with linearly polarized rf does not change the static susceptibility, and therefore no signal is induced in the SQUID. Any magnetization induced by a circularly polarized radiation is rapidly quenched by cross relaxation between the $\pm m$ manifolds. These difficulties are avoided by applying a small magnetic field to lift the degeneracy of the eigenstates and suppress cross relaxation. A frequency sweep using linearly polarized radiation through one of the resonances first excites one manifold at its resonance frequency, thereby creating a signal in the SQUID. Upon further increase of the frequency, the resonance of the corresponding negative manifold inverts the magnetization change again. Thus, the spectra resemble a square shape, possibly distorted by relaxation effects between the two resonance transitions.^{4,22} This technique has been applied to a number of ^{27}Al , ^{10}B , and ^{11}B containing compounds in single crystals, and in polycrystalline and amorphous samples.^{4,22}

Using circularly polarized radiation selectively excites transitions among either the $+m$ or the $-m$ manifold, depending on the sense of polarization.²² The spectra show the sharp change of magnetization followed by the relaxation decay back to the equilibrium value. One peculiarity of this technique and other NQR measurements with a SQUID is that the sign of the observed changes in magnetization depends on the sign change of the magnetic quantum number of the transitions induced, an effect not observable by non-SQUID NMR.⁹

For integer spins, the application of a magnetic field either splits degenerate eigenstates or redistributes the weights in the superpositions of Zeeman states making up the quadrupolar eigenstates. These effects may still not be sufficient to create an observable signal in the SQUID. A study of the NQR of ^{14}N interacting with the weak electric field gradients in amino acids and small peptides^{23,24} shows that the NQR transitions can be observed via cross relaxation of the ^{14}N polarization to adjacent proton spins. Properties of this technique such as the magnetic field dependence, additional signal enhancement by double irradiation, as well as application to studies of the changes of the nitrogen environment by mixing optical isomers and by combining amino acids into small peptides, are given in Werner et al.^{23,24}

4.3 NQR: Transverse Magnetization

Pure NQR transitions can be detected with a SQUID by observing the FID after a rf pulse, or a spin echo created by a two-pulse sequence. The echo and a spectrum obtained by Fourier transformation for ^{14}N in NH_4ClO_4 at 1.5 K are shown in Figure 3.^{16,17} The signal, a sum of 16 000 transients, shows an FID after the second pulse and the formation of a spin echo after 5 ms. For display, the echo signal was demodulated with a frequency of 35 kHz. The spectrum shows the FT of the echo obtained with a pulse spacing reduced to 4 ms. The sharp peaks at 17.4, 38.8, and 56.2 kHz are the lowest directly detected ^{14}N NQR transition frequencies. Note that these are the absolute frequencies, not those demodulated from a Larmor frequency as is done in high field NMR. The peak at 10.6 kHz was attributed to magnetoacoustic resonance of the input circuit. The three transitions allow determination of the ^{14}N NQCC $|e^2qQ/h| = \chi = 63.3$ kHz and an asymmetry parameter $\eta = 0.550$. The absence of proton zero field NMR lines and of splittings of the ^{14}N NQR in the experimental results suggest motional averaging.

Finally, a SQUID acting as a tuned rf low noise amplifier at liquid helium temperatures was used to detect pulsed NQR at 30.686 MHz of ^{35}Cl in NaClO_3 .^{14,25} The long ring-down times after an rf pulse of the circuit, due to the high quality factor $Q = 2500$, was reduced using a Q spoiler consisting of a series array of Josephson tunnel junctions.

5 CONCLUSION

Detection of NMR and NQR signals using a SQUID has proven advantageous for studies at low frequencies, over large spectral widths, and at ultralow temperatures. Further technical developments should make these techniques even more widely applicable. For example, current SQUID spectrometers that

Figure 3 (a) FID after second pulse and spin echo of NH_4ClO_4 at 1.5 K. For display purposes, the real-time signal has been demodulated with 35 kHz. (b) FT of the spin echo. The inset shows the energy level diagram of ^{14}N in the presence of the electric field gradient of NH_4ClO_4 . (Reproduced by permission of The American Physical Society from M. D. Hürlimann, C. H. Pennington, N. Q. Fan, J. Clarke, A. Pines, and E. L. Hahn, *Phys. Rev. Lett.*, 1992, **69**, 684)

detect the FID following an rf pulse with untuned circuits are limited by the feedback electronics to frequencies below 200 kHz. An increase in the spectral width and improved stability against rf pulses would open up the possibility for a variety of otherwise very difficult, if not impossible, single- and multi-dimensional NMR and NQR experiments at low magnetic fields using multipulse sequences. Whether detecting longitudinal or transverse magnetization, recent results show that SQUID spectrometers are becoming valuable tools for obtaining answers to a wide range of chemical and physical questions.

1 INTRODUCTION—NMR AND STRUCTURE OF METALS

The Knight shift refers to the relative shift K in NMR frequency for atoms in a metal (e.g. sodium) compared with the same atoms in a nonmetallic environment (e.g. sodium chloride). The observed shift reflects the local magnetic field produced at the sodium nucleus by the magnetization of the conduction electrons. The average local field in sodium augments the applied resonance field by approximately one part per 1000. In nonmetallic sodium chloride the local field is negligible in comparison.

Conduction electrons¹ in a metal are delocalized, meaning that no electron is uniquely associated with any particular atom more than another but all exist in eigenstates within an energy band, whose highest occupied state lies at an energy E_F , the Fermi energy. At lower energies the electron wave functions tend to be mainly s states, while at higher energies there are increasing admixtures of higher (p , d , ...) states. For s states the probability density at the nucleus ($R = 0$) is high, and since each electron carries a spin and magnetic moment μ_B , the contact interaction momentarily produces a local magnetic field at the nuclei, as the electron moves through the lattice.

The local hyperfine field in atomic sodium is approximately 39 T. This is an atomic property, independent of external fields. The average contact hyperfine field in a metal is zero, in zero applied field, because the nucleus is exposed to equal numbers of spin-up and spin-down electrons. In an externally applied magnetic field the conduction electron system acquires a magnetization proportional to the magnetic susceptibility of the conduction electron system. The appropriate susceptibility χ_p is the temperature independent Pauli paramagnetism. Because the electron magnetic moments parallel to the applied field have the lower energies, the parallel orientation is more favorable than the antiparallel, and consequently the number of parallel moments is greater, hence the paramagnetism. The

fractional change in field, or observed resonance frequency, is²

$$K = \Delta B/B = \Delta\nu/\nu = (8\pi/3)\chi_p V_0 P_F \quad (1)$$

where χ_p is the Pauli susceptibility per unit volume, V_0 is the volume per atom in the metal, P_F is the average value of the s electron probability density at $R = 0$, B is the applied magnetic field, and ν is the observed resonance frequency. The average P_F is taken for electrons at the Fermi energy E_F . The local field of p electrons is usually 10% or less of the contact interaction, and produces small anisotropic shifts in noncubic metals (c.f. Section 2.3). The anisotropic effects vanish in cubic metals. In noncubic metals the effects are relatively small, but yield valuable information concerning electronic and crystal structures.

To summarize some typical parameters: the hyperfine field per electron in a free sodium atom is 39 T; the corresponding contact hyperfine field in metallic sodium is smaller, ~ 30 T, mainly because of p admixtures in the wave functions at the Fermi surface; the small Pauli susceptibility reflects the small number of unpaired spins; the average local field is 1.1×10^{-3} T for an applied field of 1 T; and equation (1) gives $K = 0.11\%$.

Values of K have been measured for most of the metallic elements, and recorded results range approximately from $K = 0.026\%$ (Li) to 2.7% (Hg). The measurement of K is a sensitive means for probing, noninvasively, electronic and geometric structures of metallic systems in solids and liquids, and has been of value in studying phase transitions in metals, alloys, intermetallic compounds, and superconductors.³

2 LATTICE STRUCTURE AND DYNAMICS

2.1 Effects of Pressure, Volume, and Temperature

It is evident from equation (1) that insofar as the parameters χ_p , V_0 , and P_F depend on pressure, volume, or temperature, K is affected by, and is a measure of, these variables. Compressing a specimen effectively changes the volume per atom and P_F , while heating affects the volume, the lattice dynamics, and electron-phonon interactions as well. Although the Pauli susceptibility is essentially independent of temperature, other contributions to the susceptibility are temperature dependent, and NMR shifts have corresponding temperature dependences (c.f. Sections 3.1 and 3.2).

In order to find the intrinsic temperature dependence, one can measure K versus T at constant P , and K versus V at constant T , also knowing the thermal expansion coefficient and compressibility. With so many variables, the end results are useful, but may not be as precise as one would wish. Bloembergen has pointed out⁴ that P_F is nonlinear with respect to volume, and χ_p depends on lattice vibration frequency via spin-lattice relaxation.

Recently, Götz and Winter⁵ have considered the volume dependence of K for the alkali metals lithium and sodium, for which many experimental data exist. They pointed out that the theoretical analysis requires the inclusion of orbital plus exchange and correlation terms (c.f. Sections 3.1 and 3.2). While they were able to arrive at good agreement with the experimental results for lithium, the result for sodium is less clear. The work serves to illustrate the fact that the theoretical problems are more elaborate than was believed at first.

2.2 Anisotropic Shift

For noncubic crystals K becomes a function of crystal orientation with respect to the applied field.⁶ We can perform and analyze NMR shift experiments in crystals with axial symmetry, for example, introducing the axial shift K_{ax} , which depends on hyperfine magnetic fields at the nucleus generated by p electrons. These fields are generally 10% or less of the contact hyperfine fields, but valuable structural information may be obtained.⁶

For crystals of axial symmetry, the anisotropic part of the NMR shift is a function of the angle θ between the principal symmetry axis and the applied magnetic field.

$$K_{\text{ax}} = q_F \chi_p (3 \cos^2 \theta - 1) \quad (2)$$

The shape of the p electron charge distribution and its dipole field at $R = 0$ are included in the function q_F in equation (2). For an axially symmetric crystal the total NMR shift is the sum of equations (1) and (2).

For a single crystal specimen the NMR appears at frequencies varying between extremes at $\theta = 0^\circ$ and 90° . A polycrystalline sample shows a broadened lineshape between the above extremes, with the largest intensity near $\theta = 90^\circ$, and the frequency of minimum intensity appears at higher frequency for positive q_F . For nonaxial symmetry, the corresponding extended analysis is straightforward.⁶ Experimental results are also interpreted in terms of crystal structure and electronic band structure (s-p admixture).

2.3 Quadrupole Coupling

An analysis similar to the above can be made for nuclei with the quadrupole moment Q in a noncubic environment. The first-order quadrupole interaction frequency is

$$\nu = e^2 q Q / h \quad (3)$$

where q is the local electric field gradient at the nucleus, which depends on crystal structure ($q = 0$ in cubic symmetry). For a first-order interaction in a specimen with nuclear $spin - \frac{3}{2}$ the spectrum consists of a pair of satellites astride the central NMR resonance and split by $\pm e^2 q Q / 4h$. More complete discussions, including second-order quadrupole effects, are available.⁶

3 ORBITAL AND CORE POLARIZATION SHIFTS, SPIN RELAXATION

3.1 Orbital Paramagnetism

Several other factors contribute to the total NMR shift in metals. Beyond the Pauli term in equation (1), there is the orbital (Van Vleck) paramagnetism, and also the core polarization by d electrons. Each of the above effects is associated with a respective magnetic susceptibility, and may be summed as follows:

$$\chi = \chi_p + \chi_v + \chi_d \quad (4)$$

The Pauli term χ_p predominates in light monovalent metals, while the second and third terms generally make large contributions in heavy and transition metals. The first two are nearly independent of temperature in the normal state. The last tends to be paramagnetic and temperature dependent for transition metals with narrow d bands and low Fermi temperatures.

The orbital paramagnetism χ_v is a second-order effect in solids analogous to the Van Vleck temperature independent paramagnetism in molecules.^{7,8} It arises because of the mixing of filled and unfilled orbitals in the same band. It appears that the contact term χ_p for vanadium is approximately cancelled by the negative χ_d term, and small compared with the orbital χ_v term.⁹ This conclusion is consistent with the fact that the NMR shift in vanadium is minimally affected by the transition to the superconducting state (the predominant orbital hyperfine field is not related to electron spin pairing—see Sections 3.2, 4.3, and 6.1).

The orbital susceptibility can be estimated⁸ in several ways, one of which can be expressed as

$$\chi_v \sim 2\mu_B^2 N / E \quad (5)$$

where N is the number of d electrons per unit volume, and E is the average energy separation of the mixed states.

3.2 Core Polarization

The third term in equation (4) represents the temperature dependent paramagnetic d states. Although the direct hyperfine interaction of d electrons is small, s electrons (either in a filled shell or in an s band) couple¹⁰ with the paramagnetic d electrons and produce hyperfine fields which can be comparable (or of opposite sign) to the direct s electron contact interaction. For example, in platinum the predominant contribution¹¹ to K derives from core polarization, which is calculated to be negative, resulting in a large observed negative shift, $K_{\text{Pt}} = -3.5\%$.

A recent band structure Green's function analysis¹² points out that equation (4) implies independence among the several terms, while in fact the terms are not strictly independent, and it is in principle necessary to include spin-orbit and exchange correlation effects in the calculations. It is also clear from their results and comparison of several calculations with equation (5) that the latter provides useful but imprecise estimates for susceptibilities and shifts. The theoretical results support the previous interpretations for the observed shifts in vanadium⁹ and platinum.¹¹

3.3 Diamagnetism of Conduction Electrons

In addition to the terms in equations (1) and (4), the contribution of the Landau diamagnetism by the conduction electrons is significant. When a magnetic field is applied to the conduction electron system, the levels split so that the average energy of the system increases, corresponding to a diamagnetism of one-third χ_p ,¹³ with a correction factor involving the electron effective mass:

$$\chi_L = -(\chi_p/3)(m/m^*)^2 \quad (6)$$

This χ_L term appears to be significant but relatively small in most metals, and is believed to be mainly responsible for the large negative $K = -1.25\%$ in solid bismuth, which is characterized by a very small effective mass. By contrast, liquid bismuth behaves more like an ordinary metal, since $K = +1.4\%$ in the liquid. A further interesting observation is the oscillation of K as a function of applied magnetic field, in analogy to the de Haas–van Alphen effect.

3.4 Korringa Relation

An important means of directly relating metallic properties to NMR experiments depends on the Korringa relation,⁴ which is based on the fact that the nuclear spin relaxation rate $1/T_1$ varies directly as temperature T and the square of the density of states $[N(E_F)]^2$ at the Fermi surface, while K is simply proportional to $N(E_F)$. In abbreviated form the Korringa relation is expressed

$$K^2 T_1 T \sim S \quad (7)$$

The Korringa product factor S on the right-hand side of equation (7) includes the magnetogyric ratios of the electron and nucleus. Equation (7) permits an independent evaluation of K in cases where χ is uncertain. The order of magnitude of S is generally unity when K is dominated by the contact interaction, as is true for the alkali and simple metals. For transition metals, where $S \gg 1$, equation (7) must be used with caution, noting also that the measured T_1 may include a contribution produced by fluctuating nuclear quadrupole interactions. The orbital paramagnetism χ_v depends on the average density of states over the conduction band and should not be included in a calculation involving equation (7), since χ_p and K depend simply on $N(E_F)$.

3.5 Overhauser Effect

The contact hyperfine interaction which produces the Knight shift, as well as relaxing the nuclear spins, acts reciprocally to produce a magnetic field on the conduction electrons because of the large nuclear polarization. This interaction produces a shift in the ESR, and a large enhancement of the NMR intensity, the Overhauser effect.¹⁴ The magnitude of the intensity enhancement is easily a factor of 10 or more. Under conditions of maximum NMR intensity enhancement, the ESR is saturated, and the frequency of the ESR is shifted (the Day shift).

4 STRUCTURES OF ALLOYS

4.1 Metallurgical Phases in Simple Binary Alloys

The classical treatment of alloys was based on thermodynamic analysis, crystal structures, and the average electron–atom ratios. Further local information is obtained by measurements of the Knight shift. Alloys of cadmium in silver include an α phase (face-centered cubic) with up to $\sim 40\%$ cadmium, followed by a mixed α and β phase (41–49%

cadmium), then a β phase (body-centered cubic) (49–51% cadmium), followed by the phases γ , ϵ , η (pure Cd). The mixed phases are characterized by two NMR lines with K values appropriate to the respective adjacent pure phases.^{6,15}

In the α phase of silver–cadmium alloy, K_{Cd} decreases linearly from 0.59 to 0.53% at the β phase boundary. The silver shift drops linearly from 0.52 to 0.46% in the α phase, as predicted,¹⁶ but was not observed at higher concentrations because of low signal strength.

Analysis of the local electronic structure, as seen by the solute atom in the alpha phase may proceed on the basis of equation (1), using χ_p (solvent), and P_F (solute, modified to include s–p character of the solvent).

The average electron density is reduced by long range charge density oscillations in space, which are induced by the perturbing solute atoms.¹⁶ The net result is a decreasing average charge density at solvent atoms with increasing solute concentration. Since the charge density oscillates with relative positions of solute and solvent atoms, the average reduction of the K shift is accompanied by a resonance line broadening.

4.2 Intermetallic Compounds

These are alloys with definite stoichiometries. Depending on the constituents and temperature, intermetallic compounds may be metallic conductors, semiconductors, or superconductors (c.f. Section 6). It was found⁹ that K for vanadium is strongly dependent on temperature in the superconducting intermetallic compound V_3Ga . Just above the transition temperature T_c the vanadium shift $K_V = +0.45\%$, changing to $+0.65\%$ for $T \ll T_c$. Correspondingly, the gallium shift K_{Ga} changes from -0.8 to -0.2% . In both cases the average hyperfine field becomes more positive as the negative core polarization shift decreases. These results raise a number of interesting questions, such as what are the charge density patterns of the band electrons.

4.3 Alloys with Dilute Magnetic Impurities

The scattering of conduction electrons by impurity atoms is considered in Sections 4.1 and 5.3. Long range spatial charge oscillations and indirect spin couplings¹⁷ between distant electrons and nuclei result in long-range variations in local fields, and polarizations which couple with host atoms as well as other impurities. NMR shifts and line broadenings are observed, in addition to resolved satellites for the NMR resonance lines.¹⁸

4.4 Muon Spin Resonance

Just as the conduction electrons probe the atom cores, the muon spin rotations, prior to their decay, provide signals measuring the local magnetic fields near the decay sites.¹⁹ Knight shifts of from 10 to 100 ppm are observed for μ^+ at frequencies of a few megahertz in fields of a few kilogauss. Muon spin resonance techniques have the advantages of fast timescales and no complications by quadrupole interactions.

5 ELECTRONIC STRUCTURE OF MESOSCOPIC PARTICLES

5.1 Energy Levels

The energy spectrum of electrons confined in a finite volume is, in principle, discrete. In macroscopic metals, however, the spacing of the energy levels is very much smaller than the lifetime broadening of the levels, and, therefore, the continuous energy spectrum is a good approximation. The broadening caused by electron–phonon interactions and/or electron–electron interactions diminishes as the temperature is lowered, and typically becomes of the same order as thermal energy at 1 K. Thus, in small particles with an energy spacing larger than 1 K we would expect anomalies in electronic properties at temperatures below 1 K. The spacing is evaluated as

$$\delta = [N(E_F)\Omega]^{-1} \quad (8)$$

where $N(E_F)$ is the density of states at the Fermi level and Ω is the sample volume. In ordinary metals, Ω is $(10^4 \text{ pm})^3$ for δ to be 1 K.

Fröhlich was the first to point out anomalies in the thermodynamic properties in particles, assuming that the levels are equally spaced.²¹ Kubo took a more realistic level distribution, i.e. a random distribution. Kubo also put emphasis on the charge neutrality of particles because a single electron imbalance brings a large charging energy.²² Shortly after, Gorkov and Eliashberg suggested that the level distribution is not random but has statistical correlations, in analogy to the level distribution in heavy nuclei.²³ These correlations are the results of the symmetries of Hamiltonians governing the system.

Let $P(E) dE$ be the probability of finding the next level between E and $E + dE$. It can be shown that, in the limit of small E ,

$$P(E) = E^{n-1}/\delta^n \quad (9)$$

where n is the number of random variables. Four cases are possible:

1. case 1, $n = 2$: elements of the Hamiltonian matrix are real.
2. case 2, $n = 3$: in high magnetic fields where the elements are complex.
3. case 3, $n = 5$: with a strong spin–orbit interaction, where spin and orbital states are not separable.
4. case 4, $n = 1$: with a large Zeeman energy, where the levels of up and down spins are no longer correlated.

These discrete and correlated levels modify the electronic quantities such as spin paramagnetism, nuclear spin–lattice relaxation time, orbital diamagnetism, and specific heat. So far, the first two have been investigated both theoretically and experimentally. The specific heat is very difficult to measure accurately. There is a prediction that the orbital magnetization can be both positive and negative, and will fluctuate with a large amplitude when a magnetic field is swept,²⁴ but no experiment has been reported.

Figure 1 Temperature dependence of χ_{even} and χ_{odd} , with $\eta = (h/\tau_{\text{so}})^{27}$

5.2 Magnetism

The spin paramagnetism of small particles shows characteristic behaviors. For case 1, the spin susceptibility of a particle with an odd number of electrons, χ_{odd} , is Curie-like as $T \rightarrow 0$ because there is an electron that has no partner with opposite spin. The susceptibility of a particle with an even number of electrons, χ_{even} , tends to zero as $T \rightarrow 0$, as all the spins are paired with opposite ones. In case 2, χ_{even} revives because of the mixing of up- and down-spin states. The behaviors of χ_{even} and χ_{odd} are calculated with a finite strength of the spin–orbit interaction. The results are shown schematically in Figure 1. All anomalies in susceptibility vanish when $k_B T > \delta$.

The spin magnetization is nonlinear when the magnetic field is as high as $2\mu_B H \geq \delta$, because the level correlation is diminished.²⁵ Thus, when $2\mu_B H \geq \delta$, the spin magnetization will take a normal Pauli value.

Nuclear spin–lattice relaxation in metals is governed by the Korringa process, the relaxation time, T_1 , being inversely proportional to the temperature, reflecting the continuous energy spectrum of electrons. In small particles this process is strongly suppressed, because it is not always possible to conserve the energy through the process which involves a mutual flip of electron and nuclear spins and a change in electron orbital state.

5.3 Small Particles and Alloys

The first quantitative experiment of the Knight shift in small copper particles was reported by Yee and Knight.²⁶ The samples were particles that are formed on substrates at early stages of vacuum deposition. This method has been used for all the experiments described in this article. The distribution width of linear sizes of particles in each sample is about 20%

Figure 2 Temperature dependence of shifts in copper particles.²⁶ Particle diameters: $\circ$, 2.5 nm; $\bullet$, 4.0 nm; $\square$, 10.0 nm; $\triangle$, 11.0 nm

of its mean value. In Figure 2 the results of the Knight shift are shown for several samples. The temperature dependence and the size dependence of the residual shifts at $T = 0$ agree quantitatively with theory.²⁷

The spin–lattice relaxation time in copper particles was measured, and extraordinarily enhanced T_1 values were observed, as expected.²⁸

The suppression of the Knight shift anomaly in high magnetic fields (case 4) was confirmed in 10.0 and 6.0 nm copper particles.²⁹ The suppression was observed when $2\mu_B H \geq \delta$.

The spin scattering by magnetic impurities destroys the effects of level discreteness. To establish a kinetic energy level in a particle, an electron has to ‘see’ all the boundary conditions, i.e. it has to ‘sweep’ the whole volume of the particle. It can be shown that the time necessary for this travel is $\tau = \Omega/\pi v_F \lambda_F^2$, where v_F and λ_F are the Fermi velocity and the Fermi wavelength, respectively. If an inelastic scattering takes place before τ , the level cannot be sharp. The above expression for τ is equivalent to $\tau\delta = h$. This consideration can help interpret the results of the Knight shift of ^{63}Cu in particles of copper–manganese alloys.³⁰ The suppression of spin paramagnetic susceptibility disappeared when the manganese concentration was increased so that the spin scattering time is shorter than h/δ . The anomaly in T_1 also vanished.³¹

The strength of the spin–orbit interaction can be modified by alloying a heavy element in particles. The Knight shift was measured in copper particles alloyed with gold.³² As the concentration of gold increased, the Knight shift recovered the bulk value. Although this change is the same as that in copper–manganese, a substantial difference was observed in T_1 . The value of T_1 stayed very long even after the shift was completely recovered. This is because the spin scattering is inelastic while the spin–orbit scattering is elastic, the phase memory being retained in the latter.³¹

6 KNIGHT SHIFT IN SUPERCONDUCTORS

6.1 Spin Pairing

According to the BCS theory of superconductivity, the Knight shift quickly vanishes below the transition temperature,

because of spin–singlet pairing.³³ NMR experiments were intensively carried out to check the validity of the theory. However, in some superconductors of heavy metals the shift did not vanish but stayed finite when $T \rightarrow 0$. Soon after, it was recognized that this was a size effect. To measure the shift, samples of reduced dimension (thin films or fine powders) were used, in order to increase critical fields of superconductors of the first kind and to let the rf field penetrate the samples. The reduced dimension makes the mean free path shorter, and enhances mixing of up- and down-spin states due to spin–orbit interactions. Thus, for the same reason as for the residual Knight shift in normal heavy metal particles, the shift remains finite even when $T \rightarrow 0$.³⁴

6.2 Contributions to Shift

In transition metal superconductors the Knight shift consists of three contributions: the s band spin polarization, the orbital (Van Vleck) polarization, and the core polarization induced by non-s spin polarization. The first two are positive in sign, and the last is experimentally negative, although it can take both signs in principle. The three contributions can be resolved by observing the temperature dependence of the shift in the normal state. What is suppressed in the superconducting state is the first and the last polarization, while the orbital part does not change (cf. Section 3). A great deal of data has been accumulated for various superconductors.³⁵

6.3 How Small is a Superconductor

In the 1970s, the order parameter fluctuation in superconductors with reduced dimensions was exhaustively studied. Measured Knight shifts in aluminum particles smaller than the coherence length and penetration depth³⁶ agreed with microscopic theories for the critical region of temperature.³⁷ The result for aluminum particles is shown in Figure 3.³⁶ The theories were based on a grand canonical treatment, which is hardly applicable to small particles with a large charging energy, and does not take the discreteness of energy levels into account. As expected, substantial deviation takes place when the particles are smaller than 10.0 nm, in which δ is larger than the superconducting energy gap, Δ .³⁸

The residual Knight shift in tin particles as a function of particle size demonstrates the competition among three energy parameters, i.e. δ , Δ , and h/τ_{so} , where τ_{so} is the time within which the spin direction diffuses by an angle π due to spin–orbit interactions.³⁹ These energies are proportional to d^{-3} , d^0 and d^{-1} , respectively, d being a linear size. Therefore, Δ dominates in the bulk, and the shift vanishes. As the size is reduced, h/τ_{so} surpasses δ , and the shift (of particles with even number electrons) revives. With a further reduction, δ becomes the largest, and the shift disappears again. The experiment in tin particles with d ranging from 2.5 to 60.0 nm³⁸ clearly demonstrates this competition (Figure 4). The shift exhibits a peak at around 10.0 nm which corresponds to $\delta \sim \Delta$.

It is interesting to know how many atoms are necessary in small particles for superconductivity. Unfortunately, the level discreteness and the superconductivity modify the Knight shift (in particles with an even number of electrons) and T_1 in the same direction. A reliable way to judge the superconductivity

Figure 3 Temperature dependence of shifts in aluminum particles³⁶

Figure 4 Size dependence of residual shifts in tin particles³⁸

is to see if there is a sharp decrease in T_1 at an expected critical magnetic field for superconductivity. The results show that particles are superconductive even when $\delta \geq \Delta$. The observed critical fields support microscopic theories of pair breaking.^{39,40} Much smaller particles of aluminum with $\delta \sim 65$ K still exhibit superconducting features as long as T_1 is involved.⁴¹

6.4 High T_c

Since the discovery of high- T_c oxide superconductors, NMR has been used extensively to clarify the mechanism. The Knight shifts and relaxation times were measured for most of the constituent elements, such as ^{89}Y , ^{137}Ba , ^{63}Cu , and ^{17}O , in 'YBCO', yttrium barium copper oxide.

The main interest is to identify the nature of pairing, i.e. s wave or d wave pairing.⁴² Recently, there has been considerable debate on this question, which appears not to be settled as of March 1994. A complete understanding of the mechanisms operating in high- T_c materials still seems remote.

1 INTRODUCTION AND BACKGROUND

1.1 The Beginning of NMR in Metals: Investigators and Material

The discovery of the resonance of nuclei is so recent that the number of subspecialties that have developed is astounding. In large part it represents the number of working scientists during the intervening years. In addition, the time period is one during which solid state physics, polymer physics, and more recently the biological sciences have seen unprecedented advance.

The discovery of the fact that proton resonance could be observed with relative ease if the required conditions were understood led two independent groups to construct apparatus to search for, and to find, the phenomenon in the same year. Fortunately, nuclear physics had a long history of research culminating in a burst of activity in the early 1940s. Tables of nuclear moments were available and there was an immediate spread of NMR to a host of elements in the Periodic Table. Pound saw the Cu metal resonance from the wire of his rf spectrometer¹ and Knight² soon after found that Cu metal and the corresponding isotopes in CuCl were at different frequencies in the same external magnetic field. Nuclear magnetic resonance in metals was thus launched only two years after the first nuclear resonance observation of hydrogen. The latter required the knowledge and skill of brilliant scientists, each of whom received a (shared) Nobel prize. Reading the Nobel prize acceptance speeches is rewarding, as is the study of the papers of Purcell et al. and Bloch et al. published in *Physical Review* in 1946.

Workers in the field of NMR in metals require an interdisciplinary background strong in physics, especially the theory of the solid state, and also well-developed in metallurgy. The latter subject remains one in which few phenomena are derived a priori, and the words 'experience' and 'art' are sometimes necessary to describe the methods successfully used in specimen preparation. Complex studies that purport to demonstrate a correlation between an NMR result and a particular aspect of the behavior of a metal or alloy should assume from the outset that the physical property under investigation must be measured on a batch of material prepared

for the study, and that the NMR must be conducted on samples from the same batch. An example study might be the rate of internal oxidation measured using resistivity or susceptibility together with NMR absorption line parameters. Correlation of NMR results with mechanical properties (rather than electrical) is usually more difficult.

1.2 Metals and Nuclei

The metallic state has several familiar but different characteristic mechanical and electrical properties when compared with other solid types. If we consider the four classic types of solids, metallic, ionic, covalent, and molecular (or van der Waals),³ the metals are known to be highly ductile, good electrical and thermal conductors, and different in their magnetic properties from ionic and covalent solids. The underlying reasons for the physical properties of metals lies almost entirely in their electronic structure. In solids which are primarily ionic or covalent the bonding potentials are largely central or directional, respectively. Metals by contrast are held together by nondirectional atomic potentials. Nearly all metals have one atom per lattice site, and thus have structures in which the atoms lie on the points of a Bravais lattice.⁴ Not surprisingly most metals have lattice structures in which the atoms are arranged as closely packed spheres [face centered cubic (fcc) and hexagonal close packed (hcp)]. The next most common structure among metals is body centered cubic (bcc). Of the roughly 50 metals in the Periodic Table about 36 are close packed and 14 bcc. Nearly *all* of these metals have at least one isotope which is useful for NMR, i.e., it has nonzero nuclear spin I , and thus a nonzero nuclear magnetic moment $\mu = \gamma_I \hbar I$, where γ_I is the nuclear gyromagnetic ratio and $\hbar = \text{Planck's constant divided by } 2\pi$. The majority of metals have more than one isotope of $I > 0$ (i.e., from among $I = \frac{1}{2}, 1, \frac{3}{2}, 2, \dots$). Isotopic abundance is a crucial factor in considering the feasibility of observing the nuclear resonance of a particular metal.

In addition to a magnetic dipole moment μ , a majority of nuclei have an observable electric quadrupole moment Q . In brief form there are two restrictions that limit the observability of electrical multipole moments:⁵ (a) No odd (l odd) electrical multipole (2^l -pole) moments can exist, and (b) for a nuclear spin I , it is impossible to observe a nuclear multipole moment of order 2^l greater than that corresponding to $l = 2I$. (The result of these restrictions is that we can expect to observe no dipole, octupole, $\dots$ electrical moments; and that for $I = \frac{1}{2}$ we can observe no multipole greater than dipole, for $I = 1$ we can observe no multipole greater than quadrupole, for $I = \frac{3}{2}$ we can observe no multipole greater than octupole, for $I = 2$ we can observe no multipole greater than hexadecapole, and so on.) We distill from these statements that $Q = 0$ when $I = \frac{1}{2}$ and that for $I \geq 1$, Q may be and usually is nonzero. The hexadecapole and higher existing moments have not been observed, probably because of their minute interaction energies. These conditions apply to all nuclei; however we enumerate them here because, since metals constitute over half of the Periodic Table, it is prudent as a first step for the experimentalist to ensure that a suitable isotope is available for any projected study. Usually tables list all relevant data.⁶ An additional useful fact is that the nuclear spin I is half integral

if the nuclear mass number is odd, and integral if its mass number is even.⁵

The above fundamental nuclear properties must be known if a metal is to be usefully probed. The observed magnetic dipole and electric quadrupole interaction energies are vector and tensor products, respectively, of the moments and the corresponding interaction parameters.

2 EXPERIMENTAL DETAILS

2.1 Specimen Preparation

Sample preparation is unquestionably one of the most important steps in any experimental study of metals or alloys. The metallurgical techniques necessary to prepare an alloy in a well-known state must be known and used. The characterization of metallic specimens after they are made is literally impossible. The only hope of understanding the NMR results is to have complete knowledge of the history of the alloy. The final step in preparation is usually reducing at least one and sometimes two or three dimensions of the sample to a size smaller than the skin-depth of the rf field in the specimen. At this point the metal is usually heavily cold worked and to some extent oxidized. A protective oxide layer may be very thin; a nonprotective oxide layer continues to grow if oxygen is present. The quantity of specimen in one powder particle of the total specimen is small (approx. 10–100 μg). The question of whether to anneal the specimen or not depends on having knowledge of the consequences of each alternative; there is no general answer and the choice depends upon the nuclear resonance and the materials aspects of the situation. Even the considerations involved are too numerous to introduce here. The nuclear spin, the annealing temperature of the metal or alloy, and the diffusivity of oxygen (or nitrogen, ...) at a proposed temperature are usually dominant factors.

The need to subdivide the metal was understood from the beginning; the *skin depth* or *depth of penetration* δ of the rf field into the metal depends on the frequency ν , and the resistivity ρ of the metal. The quantity δ plays a dual role in the experimental results; not only is it the distance into the metal at which the rf field strength falls to e^{-1} of its value at the surface, but a phase shift is introduced which mixes the absorption (imaginary or χ'') and dispersion (real or χ') components of the nuclear susceptibility χ .⁷ If the rf field does not penetrate the metal then it is the outer layer only (measured by δ) that contributes to the magnitude of χ . The *filling factor*, which is the ratio of the volume of sample in which the rf field energy is stored, to the total volume in which the rf field energy is stored, can also be greatly decreased. The ideal situation for nonspinning samples is to have the detector (receiver) coil just full of subdivided specimen, no particles of which are in electrical contact with any other and all of which are roughly of dimension $\delta \approx 5 \times 10^{-3}(\rho/\nu)^{1/2}$ where δ is in centimeters, ρ is in microhm centimeters, and ν is the frequency in megahertz.

The method of separation of the particles of specimen is chosen entirely on the basis of appropriateness. The temperature, state of the sample, and composition of sample often suggest materials such as mineral oil, any inert inorganic compound containing no active nuclei, e.g. Al_2O_3 when NMR

of V is observed, sheet mica, and so on. A minimum of 'filler' should be used to accomplish the particle separation; beyond that there is simply a loss of sample, filling factor, and signal.

The specimen may be either a pure metal or alloy. It is exceedingly difficult to handle metals of 99.9999% purity (usually called 'six 9s pure') or greater, without decreasing their purity. Fortunately the impurity is often on the surface only and it can be tolerated, or in some circumstances and with some risk, etched away. If during the preparation, a mechanical process such as filing, rolling, drawing, or swaging is used, the sample will be work hardened (cold worked) in addition to being contaminated. Work hardening is caused by mechanical imperfections in the lattice, primarily high densities of dislocations that comprise a three-dimensional 'forest'. The effects of mechanical and chemical imperfections will be discussed below.

2.2 Sample Containment and Conditions Used

Preparation of specimens for use at low temperature depends upon the detection technique being employed. Commonly a small thin-walled glass vial will be used to confine the specimen. For various reasons it is advisable to seal (tip off) the vial leaving the specimen under vacuum or an inert gas. Some of the same considerations apply to high-temperature NMR. A large number of experiments have been done on liquid metals.⁸ The separation of particles (spheres) and the choice of filler material is more difficult because of the likelihood of increased reactivity of sample with filler.

Finally it is interesting to note that many studies of the temperature dependence of the Knight shift were done in the solid state with the thought that the results would be approximations to volume-dependence measurements. Certainly the change in volume with temperature is a straightforward concept, but the intrinsic temperature dependence is less easily measured. The exact equation,

$$\left. \frac{\partial \ln K}{\partial T} \right|_p = \left(\frac{\partial \ln K}{\partial \ln V} \right)_T \left(\frac{\partial \ln V}{\partial T} \right)_p + \left. \frac{\partial \ln K}{\partial T} \right|_V \quad (1)$$

shows that obtaining the explicit temperature dependence of K on T at constant V requires use of the first term on the right, obtained from the pressure dependence of K at constant T and the compressibility $(\partial \ln V / \partial p)_T$, together with the coefficient of thermal expansion $(\partial \ln V / \partial T)_p$.⁹

2.3 Experimental Apparatus and Data

Early workers in the field usually used one of two or three types of nuclear resonance detection. A single-coil technique introduced by Pound¹⁰ was used almost exclusively by those working with or near him. Bloch used a cross-coil apparatus; students and others in his laboratory favored it. The 'Pound box' (a marginal oscillator) detected only the nuclear absorption χ'' , and was capable of sweeping over wide frequency regions with ease. The crossed coils, transmitter, and receiver, were constructed and adjusted in a way that made frequency change infeasible. An rf bridge technique was favored by many for its single coil capability and ease of use. For each method mentioned the rf field was applied

continuously so these were all used for steady-state NMR detection.¹¹ Audiofrequency modulation of the magnetic field B_0 and phase sensitive detection of the demodulated rf were commonly used to detect and display the derivative of χ'' or, for crossed coils, of a mixed χ'', χ' signal. For metals the separation of χ'' and χ' into pure components of χ is not straightforward. A bulk (1.27 cm $\times$ 1.9 cm) Al single crystal study illustrates the procedure under ideal circumstances.¹²

Pulsed nuclear resonance apparatus¹³ has proved to be almost universally superior to the steady-state methods. There remain pitfalls when the samples are metallic, and these are compounded if sample spinning is introduced. The skin effect and classical Eddy currents¹⁴ must be taken into account, or conversely, the sample prepared so as to make their effects negligible.

The data obtained from most magnetic resonance experiments eventually emerge in the form of absorption lineshape, width, amplitude (relative to a reference), and position (with respect to a reference). These are the quantities from which physical information, the goal of the work, is extracted. The interaction between the conduction electrons and the nuclei allows us to use the nuclear resonance as a probe of the charge density distribution. The association is not easy because of the complexity of the electron–nuclear, and electron–electron interactions; however problems with the theory are revealed as concepts of the electronic structure of the metal are refined. The number of locations in the lattice that can be probed are few, but when NMR is compared with other experimental approaches used to obtain data on this scale it has achieved a very impressive record.

2.4 NMR Lineshape in Powdered Metal Samples

In view of the fact that most NMR in metals is done on particles (or filings, foils, thin wires) with individual external dimensions of about 0.001" (0.0025 cm) it is clear that the sample comprises crystallites of at most that size or smaller. The results obtained from algebraic solutions of nuclear interactions are for single crystals and include the crystal orientation, as necessary, in keeping with the crystal symmetry. A number of such averaging calculations can be handled using no more than cylindrical symmetry and an average over all angles θ of the symmetry axis with respect to the magnetic field. This procedure is sufficient to treat hexagonal and tetragonal metal lattice structures as well as a large number of cubic, hexagonal, and tetragonal alloys. The absorption distribution $I(\nu)$ for an isotropic orientation distribution of crystals having axial symmetry is obtained by a transformation from crystallite orientation density to resonance amplitude at frequency ν ($B_0 = \text{constant}$). The calculation entails deriving $I(\nu)$ using $I(\nu) d\nu = \sin \theta d\theta$,¹⁵ and thus $I(\nu) \propto \sin \theta (\partial \nu / \partial \theta)^{-1}$. Derivations of NMR lineshapes (powder patterns) and the phenomena associated with structures of lower symmetry or causing low symmetry have been published.^{6,15}

2.5 Some Sources of Line Broadening in Stationary Samples

The implicit assumption has been made that the NMR resembles a Dirac δ function $\delta(\nu - \nu_0)$. There are at least three

sources of broadening in a stationary sample that contribute to the *linewidth* independently of its definition. The applied magnetic field is always inhomogeneous; the sample has nuclear dipoles and in the absence of atomic diffusion nuclear dipole–dipole interactions are a source of broadening; an internal field of totally classical origin is present because each metal particle has an internal field $B_{\text{int}} = \chi_m B_0$, where χ_m is the magnetic susceptibility of the metal. (This source can be significant in transition elements with large χ_m .) Lifetime or T_1 broadening is seldom a contributing factor to the linewidth of metals. T_1 and T_2 are the longitudinal and transverse relaxation times, respectively of the vector nuclear magnetization $\mathbf{M}$ in the stationary reference frame. M_z approaches its maximum equilibrium value in the direction of the external polarizing field; M_x and M_y decay toward zero through dephasing. These relaxation times appeared in Bloch's phenomenological equations describing the behavior of steady-state nuclear magnetization. The Bloch equations do not apply to solids in general, but the nomenclature has been carried over to the parallel quantities describing the behavior of $\mathbf{M}$. A brief, qualitative discussion of this topic appears in Schumacher.¹¹

3 PRINCIPAL THEORETICAL CONCEPTS

3.1 Introduction

The theory of NMR per se is presented in many books and papers. The interpretation of NMR in metals has been an especially active field because of the continuing interest in understanding the electron–electron interactions, which ultimately determine our understanding of the metallic state. Although high-temperature superconductors now attract much research (including NMR), for decades metals displayed properties and posed puzzles that were unique. Both type I and type II superconductivity and ferromagnetism have been thought to have their origin in the electron–electron and electron–phonon interactions in metals.

One of the tools that confirmed the Bardeen–Cooper–Schrieffer theory of superconductivity was NMR,⁶ and repeatedly it has shown its ability to reveal, on the atomic scale, electron distributions that cannot be otherwise obtained or can be obtained only with greater difficulty using another technique.

3.2 Electron–Nucleus Interactions

The topic of NMR in metals is one that can appear to lead to such complexity that it is intractable. Fortunately, however, all of the electron–nuclear interactions encountered can be formulated within the framework of quantum mechanics. It is helpful to understand the elements of the problem and the barriers to obtaining solutions in agreement with observation. Many of the difficulties can be identified in one statement: the potentials are not accurately known. The dense electron plasma is not completely understood; the chemical and other point imperfections (e.g. substitutional solutes, foreign atoms, vacancies and interstitial solutes) distort the lattice so that the positions of the surrounding atoms are not accurately known, and the potentials of the imperfections themselves are

perturbed self-consistently; higher dimensional imperfections such as dislocations (one-dimensional, 1D), grain boundaries, twin planes, and stacking faults (two-dimensional, 2D) are difficult to characterize in the metal and have received less attention than impurities and vacancies.

The above group of chemical and mechanical imperfections scatter conduction electrons and generate charge density fluctuations $\rho(\mathbf{r})$, which produce or perturb the following interactions: (a) hyperfine, (b) the electron–dipole nuclear–dipole, (c) indirect nuclear-spin exchange coupling via the conduction electrons, and (d) nuclear quadrupole. The magnitudes of the energy level shifts to which these give rise are usually related to the magnitudes of the nuclear dipole and/or electric quadrupole moments, and the external magnetic field. The derivation of all of the concepts to be included below and many more are explained in rigorous and elegant form by Slichter.¹⁴ A brief introduction to the application of NMR to pure metals and to alloys follows. Examples are offered of the way such studies are approached in terms of the information it is reasonable to expect. They are presented as models to help associate the atomic structure of a metal to the fundamental properties of a nucleus, which make it useful as a probe of that structure. Atomic structure includes lattice structure with imperfections and the total electronic structure. Nuclear properties include γ , I and Q as well as the mass and charge. Such quantities as isotopic abundance, and the bulk properties of the metal, both liquid and solid, are known.

3.3 Conduction Electrons and Scattering

The electronic structure of metals in its most exact form is responsible for the distinctive character of their NMR spectra. The electron energy levels of agglomerated metal atoms resemble those of any other solid when there is no overlap between wavefunctions, i.e. the inner levels are atomic in nature. The outer (conduction) electron orbitals of metals have significant overlap and the free atom energy levels are broadened into bands that may be 1–10 eV wide. Since each atom of a pure metal is identical to each other atom, and is neutral, no shift of charge from one atomic cell to another is expected. Rather, all conduction-electron wavefunctions are delocalized and exist over the volume of the bulk metal. For the alkali metals, which have highly s-like outer electrons; the valence bands are half-full. All metals in fact have only partially filled conduction (valence) bands and thus at $T = 0$ K have empty states within about 10^{-21} eV of the topmost filled energy level. Presentations of band theory (i.e. the energy distribution of electrons in solids and metals in particular) appear in the solid state literature.¹⁶ Of special interest are the transition metals in which s–d interactions are prominent; the s- and d-bands at the Fermi surface overlap and are partially full. Throughout the Periodic Table admixed orbitals can be expected for the conduction band. The greatest opportunity for systematic study is within the rows.

The s wavefunctions ψ_s play a crucial role in one of the useful applications of NMR in metals. The outer s radial wavefunctions $\psi_s(r)$ have the form $R_{n,s}(r) e^{-Zr/\sigma}$, where $R_{n,s}$ is a polynomial in r , n is the principle quantum number ($n \geq 1$), Z is the screened nuclear charge,¹⁷ r is the distance from the center of the nucleus, and σ is the screening radius. Since $\psi_s(r)$ is finite at the nucleus there is a magnetic interaction

between the nuclear magnetic dipole moment μ_I and the electrons in the metal. The magnetic field at the nucleus is $B = B_0 + \Delta B$, where B_0 is the field that would exist at the site of the nucleus in the absence of the metal (the ‘external’ or ‘applied’ field) and ΔB is the difference found by measuring $B - B_0$. The quantity of interest $\Delta B/B$ is known as the Knight shift K .² The quantity B_0 is usually obtained by using identical nuclei in an insulating diamagnetic solid, from a solution containing the isotope of interest, or the application of any other method by which it can be accurately measured. The medium used becomes the *reference*. The Fermi contact interaction in an atom has the form $E_a = a \mathbf{I} \cdot \mathbf{S}$ where a , the hyperfine coupling constant, is $(16\pi/3)\gamma_I\hbar\mu_B|\psi_s(0)|^2$. Here γ_I is the nuclear gyromagnetic ratio, μ_B is the Bohr magneton, and $|\psi_s(0)|^2$ is the outer s-electron concentration at the nucleus. In a simplified discussion⁴ it is found that $\Delta B = (a\chi_s M/g\mu_B\hbar\gamma_I)B_0$. A form more often used is

$$K = \Delta B/B = (8\pi/3)\chi_s\langle|\psi_A(0)|^2\rangle_{\text{FS}}M \quad (2)$$

where χ_s is the conduction-electron spin susceptibility per unit mass (also called the Pauli paramagnetism), M is the mass of the atom, and $\langle|\psi_A(0)|^2\rangle_{\text{FS}}$ is the probability density at the nucleus of the metal A atom of those electrons at the Fermi surface (FS) averaged over the FS. Earlier in this paragraph it was shown that $|\psi_s(0)|^2 \approx R_{n,l}^2(0)$. The Knight shift can, in principle, be used to measure the conduction-electron density for FS electrons at the nucleus, but the value of the s conduction-electron susceptibility χ_s is extremely difficult to measure accurately, and the experiment has been accomplished only rarely.¹⁸ The experimental determination of $\langle|\psi_A(0)|^2\rangle_{\text{FS}}$ and its comparison with calculated values is of fundamental interest; however, many applications of NMR to metals do not require knowledge of χ_s . There are experiments in which it can be made to ‘cancel out’ or in which relative differences in ΔB are important in themselves.

The conduction electron component χ_s of the magnetic susceptibility is assumed to be a bulk electronic property. According to equation (2) the Knight shift at the solvent lattice sites *around* an isolated solute atom at the origin will be different from the Knight shift K_0 of the pure solvent if the charge density is changed by the solute. The value of the quantity $\langle|\psi_A(0)|^2\rangle_{\text{FS}}$ is different in pure A than it is if a B atom is in a neighboring site. The perturbation caused by B of the charge density in A is effective over several lattice spacings and is spherical; consequently the n_i atoms in shell i at distance r_i from the B nucleus all experience the same change. The word ‘shell’ is used in the sense that the i th shell contains n_i atoms all at r_i . (Note that the solute atoms in a dilute alloy are often referred to as ‘impurity’ or ‘foreign’ atoms.)

The above physical description of a solute atom B located on a lattice site of the solvent A suggests treating the system from the point of view of scattering on an atomic scale. Conduction electrons with velocities ranging from near zero to the Fermi velocity v_F at the top of the band impinge on the B atom and are scattered by it. The scattering potential $V_B(r)$ can be computed using atomic wavefunctions, but a simple approach that demonstrates the effect is to use the spherical square well. Electrons in states below the Fermi surface cannot be scattered because all nearby momentum states are filled. Only electrons at the FS can be scattered: an integral of the scattered charge

over all states in the band shows that the only contribution is from electrons at the FS, and that the scattered electrons produce an oscillatory charge-density wave $\delta\rho(r_i)$ around the solute.¹⁹

The conduction-electron density at nuclei surrounding the scattering center is $\rho(r_i)$, the sum of ρ_0 ($\langle |\psi_A(0)|^2 \rangle_{\text{FS}}$ for the pure solvent) and the spherical wave $\delta\rho(r_i)$. An expression for $\delta\rho(r_i)$ is derived using the method of partial waves found in most standard texts on quantum mechanics.²⁰ Since $\delta\rho(r_i)$ is oscillatory and has a complicated dependence on r at short distances (several lattice spacings) expressions for it must be evaluated using the complete solution without simplification.²¹ An asymptotic approximation valid as $r \rightarrow \infty$ is $\delta\rho(r) \propto r^{-3} \cos(2k_F r + \theta)$, where θ is a function of the phase shifts η_l determined by the scattering potential. The asymptotic value for $\delta\rho(r)$ is never of use because: (a) even for a low solute concentration ($C_B \approx 0.01$) there is significant overlap among the charge density waves from the randomly distributed solutes and (b) the value of $\delta\rho(r)$ at large r is very small compared with other sources of linewidth. In summary, the effect of foreign atoms in a solvent matrix when the solvent nuclear spin I is $\frac{1}{2}$ is to cause a spectrum of resonance lines. Each line derives from the n_i solvent atoms in shell i . An example of such a study employing silver as the solvent and Group I, II, III, IV and V solute atoms demonstrated the presence of charge density waves.²²

4 PURE METALS WITH NONZERO μ_I

4.1 Initial Considerations: Lattice Symmetry and Nuclear Properties of Isotope(s)

The primary concern is the point symmetry at each lattice site, assuming an imperfection-free lattice. Of the 14 space lattices only three are cubic (yet these include many metals), four (trigonal, tetragonal and hcp) have three, four and sixfold axial symmetry respectively, and the balance have lower symmetry. There are thus three possible types of lattice symmetry to be combined with the nuclear and electron moments and the electron charge distribution; this is a closed set of possible combinations.

4.2 Pure Metals with $I = 1/2$

For nuclei of spin $I = \frac{1}{2}$ energy level changes are caused by the contact interaction and the nuclear–dipole electron–dipole interaction at a distance.^{15,23} The former has been discussed above (Section 3.3), the latter results from the non-s spin distribution in lattices with axial or lower symmetry. If for example a p_z orbital in a tetragonal lattice contained more charge than the $p_x = p_y$, then in the presence of a magnetic field the electrons near the top of the Fermi sea would produce a magnetic field at the nucleus with the axial symmetry of the spatial electron distribution. This *anisotropic Knight shift* has been observed in several metals with noncubic symmetry.⁶ The resulting powder pattern lineshape (because of the polycrystalline sample) is peaked by an integrable infinity at one end and falls off abruptly at the other, since the range of symmetry axis orientation (with respect to $\mathbf{B}_0$) is from 0 to

180°, with the usual weighting factor of $\sin \theta$ for an isotropic orientation distribution. The number of crystallite orientations near $\theta = 90^\circ$ is infinitely greater than those near zero degrees. Since this anisotropy gives rise to a broadening mechanism proportional to the external field it is clearly linked to the electron polarization via the Pauli susceptibility; equation (3) gives the shift for a single crystal orientation θ ; it is

$$\frac{\Delta B}{B} = \mu_B^2 V_0 N(E_F) Q_K (3 \cos^2 \theta - 1) \quad (3)$$

where

$$Q_K = \int \psi (3 \cos^2 \theta - 1) r^{-3} \psi \, dV \quad (4)$$

The distribution of electron dipoles is contained in the conduction band wavefunctions ψ and the band structure determines $N(E_F)$. An s wavefunction would cause the integral to vanish so we have secondary evidence for the mixing of orbitals at the FS. Other factors important in pure metals with nuclei of $I = \frac{1}{2}$ are the *core polarization* (the polarization of inner s electrons simply because of the necessity of orthogonalizing all electrons in the atomic cell) and the *orbital contribution*.²³ The average value of the orbital magnetic moments is nonzero because currents are produced in the inner shells by the static magnetic field.

Another interaction depends upon the conduction-electron spins to couple nuclei. *Indirect coupling* describes the indirect spin–spin interaction between two nuclei i, j via the electron gas.²³ The wavefunction is in contact with both nuclei through their hyperfine interactions. This indirect exchange would be zero in the absence of s electrons; however it can be a dominant source of line broadening (and is expected to be if the hyperfine interaction is large). Large hyperfine interactions accompany large (massive) nuclei, and it is roughly true that the Knight shift and indirect nuclear coupling increase with increasing nuclear mass. The relationship is only approximate because of the many other contributing factors, not the least being the fraction of $\langle |\psi_A(0)|^2 \rangle_{\text{FS}}$, which is s-like.

Pure metals with $I = \frac{1}{2}$ but which are highly paramagnetic, may exhibit nuclear linewidths reflecting (i.e. increased by) the inhomogeneity δB_0 of the static field B_0 within the particle (unless the particles are all shaped and oriented so as to ensure that the demagnetizing factor is identical in each). The additional field is of the order of $\chi_m B_0$, where χ_m is the bulk measured volume magnetic susceptibility of the metal.⁶ A further contribution to the susceptibility, small in the simple metals but significant in transition metals, is the Van Vleck contribution χ_{VV} .²³ Shifts and linewidths found under the conditions of this section are of the order 0.1–1 mT.

4.3 Pure Metals with $I \geq 1$

The magnitudes of shifts and contributions to the absorption linewidth considered in Section 4.2 are likely to be totally overwhelmed by quadrupole splitting of the magnetic resonance if the lattice symmetry is other than cubic. The nuclear electric quadrupole moment Q is a measure of the shape of the nucleus and thus its charge distribution. Since magnetic resonance is the topic of interest we assume a high (1–10 T) magnetic field is present and the quadrupole perturbation is said

to take place in the high-field regime; the electric quadrupole interaction energy is much smaller than the nuclear magnetic dipole resonance energy $h\nu_0$. The magnitudes of the electric field gradient, the quadrupole moment, and $h\nu_0$ can vary over a sufficiently large range for both first- and second-order quadrupole perturbation to be frequently required in analyzing data. A comprehensive and authoritative monograph on this topic has been published.²⁴ In addition, the subject is covered in all works on NMR in metals and in the 'high-resolution' literature.²⁵ The information gained is interesting and useful, and there are more nuclei with $I \geq 1$ than with $I = \frac{1}{2}$ by almost a factor of 3. A concise yet moderately transparent expression for the quadrupole energy is the Hamiltonian,

$$\hat{H}_Q = \frac{1}{6} \sum_{j,k} V_{jk} Q_{jk} \quad (5)$$

The way in which the field gradients $V_{jk} = (\partial^2 V / \partial x_j \partial x_k)$ multiply the second rank tensor components Q_{jk} is reminiscent of other stress tensor-matter tensor interactions. The quantity Q , a scalar, is defined as the quadrupole moment of the nucleus, and is determined in the standard way of evaluating n -pole moments through knowledge of the charge distribution. By convention, the charge e is not included, and $Q = \frac{1}{2} \int (3z^2 - r^2) \rho(\mathbf{r}) d^3\mathbf{r}$, where $\rho(\mathbf{r})$ is the expectation value of the nuclear charge density for the state $m = I$. The expression requires knowledge of the probability density of the protons in the nucleus: Q is in fact a measured quantity, tabulated for many nuclei. (The accuracy to which Q is known is generally much lower than for the nuclear gyromagnetic ratio γ ; however, it should also be admitted that the reason nuclear scientists began to study shieldings, electron-nuclear interactions, and so on, was because they were a nuisance in accurately determining γ .) An extensive literature has developed in the pure metal, $I \geq 1$ subset;²⁶ there is opportunity for systematic study because so many transition and rare earth (f shell) metals are hcp.

Early in the work on quadrupole interactions it was pointed out by Sternheimer (cf. Ref.²⁴ p. 341) that a factor contributing to V_{ij} is $-\gamma_\infty V^*_{ij}$. The charge distribution of an atom is distorted by the quadrupolar field of its nucleus and by the electric field gradient caused by the other atoms in the lattice. Surrounding atomic cells appear to be ionic because the mobile charge tends to distribute uniformly over the lattice; the remaining ionic lattice should be summed to derive the $V^*_{ij} \rightarrow q_{\text{latt}}$ contribution to q from the lattice. The literature frequently uses a standard notation that incorporates these and other factors into the expression for the total field gradient q , given by

$$q = q_{\text{latt}}(1 - \gamma_\infty) + q_{\text{loc}}(1 - R_Q) \quad (6)$$

Here q_{latt} is discussed above, $-\gamma_\infty$ is the Sternheimer factor (which may be as large as 100 in heavy atoms) required to correct for the charge redistribution in the atoms caused by q_{latt} . The local field gradient from sources inside the atomic cell q_{loc} is also a sum of terms. Schumacher²⁷ provides a particularly good introductory treatment of the basic features of this topic.

4.4 Pure Metals with $I \geq 1$, and Mechanical Imperfections

The majority of the strain in a metallic lattice is the result of dislocations. An early experiment¹⁵ in which the resonance intensity of the untreated filings of Cu was compared with the intensity of annealed filings showed the effect of lattice distortion dramatically, since the satellite lines from the first order broadening were almost totally removed from the region of the central $I = \frac{1}{2} \rightarrow -\frac{1}{2}$ line; the intensity of the latter was decreased to about one-half of the absorption intensity in annealed Cu. A more careful analysis showed the slight narrowing of the Cu absorption line caused by the elimination of the contribution of the group of 'like' spins in regions of high lattice distortion. Dislocation pinning is very strongly dependent upon other imperfections, including grain boundaries and dislocations on other slip systems which cross the primary. When we use the concept of 'annealing temperature', for which there is a clear definition, the impurity content is the greatest unknown. By producing fine filings or heavily rolled or drawn Cu the dislocation density may be as high as 10^{12} cm^{-2} . This may be reduced to 10^6 – 10^8 cm^{-2} upon annealing. Even at 10^{12} cm^{-2} the majority of nuclei are not within several lattice spacings of a dislocation core.

5 ALLOYS

5.1 Solvent Nuclear Spin $I = 1/2$

5.1.1 Alloy Types and NMR

An alloy ordinarily is assumed to be any number of metals put into a perfectly inert container and melted under a vacuum or inert gas, then solidified under equilibrium conditions. The alloy specimens used for NMR should be very thoughtfully made; if called 'dilute' they usually consist of at most one or two elements present in minor concentration (0.1–10 at.%) in addition to the solvent. These are called binary or ternary alloys and may or may not be single phase.

Several compilations of phase (or equilibrium, or constitution) diagrams exist, and journals publish newly determined diagrams, updates, and extended work.²⁸ For elements and compounds of more than passing commercial or academic interest, individual monographs are devoted to the binary alloys of a single element. A four-volume work published by ASM characterizes intermetallic compounds, classifies them by structure type, and incorporates all dimensions and atom locations within the unit cell.²⁹ Similar collections of the literature of ternary alloys are available.

There are instances of the application of NMR to concentrated binary alloys with compositions ranging from 0 to 100 at.% B in an A–B alloy. Over this composition range, at room temperature, one can expect to encounter several solid solutions and/or intermetallic compounds with two phase regions separating them.⁶ The results obtained resemble those of an X-ray study of a binary system. It is seen, however, that X-ray diffraction studies are better in almost every way, when they are feasible. (For metals this means essentially always.) However, NMR is not a universal approach, but is useful

only for special felicitous choices of nuclei. Important factors include the spin and the magnitude of the dipole moment.

5.1.2 Solvent NMR in Dilute Substitutional Random Solid Solution (DSRSS)

This subject has been discussed above in the context of Section 3.3 for simple metal A–B alloys. The substitution of a paramagnetic species causes very long range spin density waves around the magnetic site acting as a scatterer.

5.1.3 Solute NMR in DSRSS

Many references have been made to the charge density waves scattered from a solute atom. If the solute B nucleus has spin $\frac{1}{2}$ it is possible (other conditions being favorable) that the solute resonance absorption will be observable. The B site is a center of symmetry, and it is possible to evaluate $\langle |\psi_s(0)|^2 \rangle_{B,FS}$ with the wavefunctions, theoretical techniques, and computing capabilities available.

5.2 Solvent Nuclear Spin $I \geq 1$

5.2.1 Solvent NMR in DSRSS

For DSRSS the scattering of electrons from solute atoms is unchanged from the foregoing description. Each impurity atom is imagined to be isolated and, by definition, on a site of the solvent crystal lattice. The solvent band structure and scattering process are unchanged. Here the similarity in treatment ends. Surrounding the solute are spherical charge density waves; these cause potential waves and electric field gradients that ripple out from the solute. Consider the $n_1 = 8$ nearest neighbors of a solute in a bcc lattice: Over the volume of a near neighbor (nn) cell the electric field changes and the quantity $V_{ij}^s(r_1)$ results at the nucleus. In addition, because of the presence of $V_{ij}^s(r_1)$, the electron orbitals in the nn cell are polarized. Crudely, this latter effect is the Sternheimer factor introduced earlier.

If the magnitude of V_{ij} at $r_1 = \sqrt{3}a_0/2$, where a_0 is the bcc lattice constant, is such that the quadrupole interaction energy, $\chi = e^2qQ/h$, is roughly equal to or within an order of magnitude greater than the unperturbed ($q = 0$) linewidth, a set of first-order satellite lines would in principle appear in the powder pattern of the NMR of the powdered DSRSS alloy.⁶ In practice, the distribution of both shifts and symmetries leads to a broad distribution of absorption at the solute concentrations used. A large number of measurements of q_i at several r_i have been done using more dilute solutions.

Because of the number of energy levels associated with the nuclear spin I , for integral I (i.e., $I = 1, 2, \dots$) there is no $m = \frac{1}{2} \leftrightarrow -\frac{1}{2}$ transition. For half-integral spin ($I = \frac{3}{2}, \frac{5}{2}, \dots$) the $m = \frac{1}{2} \leftrightarrow -\frac{1}{2}$ transition is unperturbed and becomes the central $m = \frac{1}{2} \leftrightarrow -\frac{1}{2}$ line of the first order quadrupole split line structure. Carter et al.⁶ illustrate the various patterns.

In second-order perturbation the remaining central ($m = \frac{1}{2} \leftrightarrow -\frac{1}{2}$) transition is shifted with respect to the unperturbed ($q = 0$) absorption. (Since first-order perturbation theory is no longer valid, but the higher $m \leftrightarrow m - 1$, $m \neq \frac{1}{2}$ transitions are very far removed, there are no longer observable satellites.)

The digression into high-field quadrupole perturbation was necessary to complete even a brief description of the many experiments in which q is the primary quantitative information obtained. A rather sweeping summation of the topic would state that in a large majority of DSRSS studies, the NMR absorption of an $I \geq 1$ solvent is either broadened, decreased in magnitude to an asymptotic limit, or decreased in magnitude to a very small value near zero. There is so little absorption left in the region of the original line that it can no longer be detected.

5.2.2 Solute Nuclei of $I \geq 1$ in DSRSS

Although many such studies exist, the principal interest in the results and the way in which the electronic structure interacts with the nuclei have been described. A study that involves the combined effects of nuclear quadrupole interaction, anisotropic Knight shift, dipolar broadening, and an inhomogeneous Knight shift distribution at the solute sites,³⁰ can serve as an example of a more complex system; the solutes Al and V were dissolved in hcp Ti in concentrations of 1 at.% and 2 at.%. A semiquantitative analysis of the Ti lattice wavefunction as it joins the localized orbitals in the Al and V cells is carried out. The substitution of Al on an hcp Ti site decreases the Knight shift of Al to near zero. The $3s^2$ orbitals probably lie below the Fermi surface of Ti.

5.2.3 Further Considerations

Very large segments of material have been omitted from this entry. Each is as significant as the material included, and the choice of topics presented is merely slanted toward the most basic considerations of nuclear interaction and the simplest aspects of metals and alloys, stressing their electronic structure in real space. It is clear that other electronic properties are very closely related to this area. For example, the electronic specific heat is directly proportional to $N(E_F)$, a factor in $(\Delta B/B)$. The residual resistivity (that part related to solutes in DSRSS) involves electron scattering processes, one aspect of which invokes the same phase shifts as appear in the evaluation of the solvent Knight shift in DSRSS using the method of partial waves.

6 NUCLEAR RELAXATION AND ATOMIC DIFFUSION: NUCLEAR RELAXATION IN $I = 1/2$ SYSTEMS

The discoverers of NMR worried about this topic. It is easy to see that in order to absorb net energy, a spin in a lower level must be excited into an upper level. How long can this go on? Experience shows that if the incoming photon density is not too large, it can go on forever, but if the magnitude goes beyond some critical level, the net photon absorption decreases, the populations of the upper and lower level approach equality and net absorption approaches zero. The strong implication is that there exists a mechanism by which nuclei in the upper energy state return to the lower state and lose the required energy to the lattice, a passing electron, a paramagnetic impurity, or by another process that can absorb the required energy $h\nu_0$. The spontaneous loss of energy to a large reservoir is described by

the relaxation time T_1 . In metals T_1 is determined most often by collisions with passing conduction electrons; the calculation of T_1 was done by Korringa who found that the temperature $\times T_1$ product is a constant in this case. Since nuclei relax via the contact interaction, T_1 is found to be directly related to the Knight shift.²³

Another type of relaxation occurs because of the static dipole–dipole interactions among the nuclei. The transverse dipolar relaxation time T_2'' is calculated from the nuclear moments and their lattice locations in terms of the second moment of the dipolar field.³¹ (If all lattice sites are occupied by nuclei with magnetic dipole moments then a field caused by all of the other dipoles is present at each site.) If the nuclei move through the lattice the average field at any nucleus will decrease and the more rapid the motion the narrower the resonance line. Accurate measurement of the linewidth as a function of temperature measures the activation energy of diffusion for this motional narrowing.¹⁴ The mean time between atomic jumps has also been measured for Al using a pulse technique.³²

1 INTRODUCTION

Paramagnetic systems are materials with positive magnetic susceptibility, normally associated with unpaired electrons. Chemically, paramagnetic systems of relevance for this article are dilute aqueous or organic solutions of free radicals and transition metal ions or their complexes, including metalloproteins. The presence of unpaired electron spins has a profound influence on the NMR spectra of such solutions. The origin of the effects is to be found in the large value of the electronic magnetic moment, about 650 times that of the proton.

The influence of the paramagnetic species on NMR spectra of liquids may be two-fold. First, the nuclear spin relaxation rates are enhanced. The paramagnetic relaxation enhancement (PRE) is caused by random variation of the electron spin–nuclear spin interactions, which opens new pathways for longitudinal as well as transverse relaxation. The PRE is most often studied for $I = \frac{1}{2}$ nuclei, but oxygen-17 applications are not uncommon. Second, the NMR signals may be shifted, provided the relevant electron spin–nuclear spin interaction has a nonzero average. Paramagnetic complexes in solution often contain exchangeable ligands, and the exchange phenomena (see *Chemical Exchange Effects in Biological Macromolecules*), together with the intrinsic relaxation rates and shifts, contribute to the observed lineshapes and line positions. The paramagnetic effects have been used for several decades by chemists and biochemists as a source of structural, thermodynamic, and dynamic information. Applications of this type have been described in numerous books, recently by Bertini and Luchinat¹ and by Banci et al.² A more recent application of PRE is the use of paramagnetic compounds as contrast agents in MRI (see *Contrast Agents in Whole Body Magnetic Resonance: An Overview* and *Contrast Agents in Magnetic Resonance: Operating Mechanisms*).

2 THEORY

The theory of nuclear relaxation in paramagnetic systems contains many intricate points, described some years ago in a review article.³ Here, we concentrate on the most important issues and begin by formulating the relationships between the

measured macroscopic PRE and the microscopic quantities. We then proceed with the theory for relaxation times for nuclei residing in the ligands in paramagnetic complexes and conclude the theory section by a brief discussion of intermolecular relaxation.

2.1 The Macroscopic and Microscopic Quantities

The PRE experiments are often performed with a considerable excess of a ligand (e.g. solvent) over the paramagnetic centers (e.g. transition metal ions). The type of information obtainable from PRE measurements in solution depends on the relative magnitudes of the exchange rates, the intrinsic relaxation rates, and shifts. The set of equations relating the relaxation, shift, and lifetime properties of the nuclei in paramagnetic complexes to the observables of the NMR experiments has been derived by Swift and Connick⁴ and by Luz and Meiboom.⁵

$$T_{1P}^{-1} = \frac{P_M}{\tau_M + T_{1M}} \quad (1)$$

$$T_{2P}^{-1} = \frac{P_M}{\tau_M} \left[\frac{T_{2M}^{-2} + (T_{2M}\tau_M)^{-1} + \Delta\omega_M^2}{(T_{2M}^{-1} + \tau_M^{-1})^2 + \Delta\omega_M^2} \right] \quad (2)$$

$$\Delta\omega_P = \frac{P_M\Delta\omega_M}{(\tau_M/T_{2M} + 1)^2 + \tau_M^2\Delta\omega_M^2} \quad (3)$$

T_{1P}^{-1} , T_{2P}^{-1} , and $\Delta\omega_P$ are the excess (see Section 3) spin–lattice relaxation rate, spin–spin relaxation rate and shift measured for the ligand in solution, while the properties with index M refer to the ligand in the paramagnetic complex. τ_M is the lifetime of the ligand in the complex and P_M is the mole fraction of ligand nuclei in bound positions.

2.2 The Modified Solomon–Bloembergen Equations

The nuclear spin relaxation in a paramagnetic complex arises through the electron–nucleus hyperfine interaction (see *Electron-Nuclear Interactions*) between the nuclear spin I and the electron spin S . The hyperfine interaction consists of two parts. The first term is the dipole–dipole interaction between the nuclear magnetic moment and the electron spin of the electron outside of the nucleus; the second term is the scalar interaction or Fermi contact coupling between the nuclear magnetic moment and the spin of s electrons at the site of the nucleus. Each of these terms can be modulated by random processes and can contribute to the nuclear relaxation rates. The dipole–dipole part of the hyperfine interaction is modulated by reorientation of the spin–spin axis, by changes in the orientation of the electron spin (electron spin relaxation) and by ligand exchange. The scalar interaction part remains unaffected by reorientation of the molecule and is only modulated by electron relaxation and ligand exchange.

These qualitative ideas are reflected in the set of equations for nuclear relaxation rates in paramagnetic complexes, known as the ‘modified Solomon–Bloembergen equations’:

$$\begin{aligned}
T_{1M}^{-1} &= (T_{1M}^{SC})^{-1} + (T_{1M}^{DD})^{-1} \\
&= \frac{2}{3} \left(\frac{A}{\hbar} \right)^2 S(S+1) \frac{\tau_{e2}}{1 + (\omega_S - \omega_I)^2 \tau_{e2}^2} \\
&\quad + \frac{2}{15} \left(\frac{\mu_0}{4\pi} \right)^2 S(S+1) \hbar^2 \gamma_I^2 \gamma_S^2 R^{-6} \\
&\quad \times \left[\frac{\tau_{c2}}{1 + (\omega_S - \omega_I)^2 \tau_{c2}^2} + \frac{3\tau_{c1}}{1 + \omega_I^2 \tau_{c1}^2} \right. \\
&\quad \left. + \frac{6\tau_{c2}}{1 + (\omega_S + \omega_I)^2 \tau_{c2}^2} \right] \quad (4)
\end{aligned}$$

and

$$\begin{aligned}
T_{2M}^{-1} &= (T_{2M}^{SC})^{-1} + (T_{2M}^{DD})^{-1} = \frac{1}{3} \left(\frac{A}{\hbar} \right)^2 S(S+1) \\
&\quad \times \left(\tau_{e1} + \frac{\tau_{e2}}{1 + (\omega_S - \omega_I)^2 \tau_{e2}^2} \right) \\
&\quad + \frac{1}{15} \left(\frac{\mu_0}{4\pi} \right)^2 S(S+1) \hbar^2 \gamma_I^2 \gamma_S^2 R^{-6} \\
&\quad \times \left[4\tau_{c1} + \frac{3\tau_{c1}}{1 + \omega_I^2 \tau_{c1}^2} + \frac{\tau_{c2}}{1 + (\omega_S - \omega_I)^2 \tau_{c2}^2} \right. \\
&\quad \left. + \frac{6\tau_{c2}}{1 + \omega_S^2 \tau_{c2}^2} + \frac{6\tau_{c2}}{1 + (\omega_S + \omega_I)^2 \tau_{c2}^2} \right] \quad (5)
\end{aligned}$$

where

$$\tau_{ei}^{-1} = \tau_R^{-1} + \tau_M^{-1} + T_{ie}^{-1} \quad (i = 1, 2) \quad (6)$$

$$\tau_{ei}^{-1} = \tau_M^{-1} + T_{ie}^{-1} \quad (7)$$

τ_R is an isotropic rotational correlation time of the complex, T_{ie} ($i = 1$ or 2) is the electron spin relaxation time, and S is the electron spin quantum number, $A/\hbar$ is the isotropic scalar coupling constant, μ_0 is the permeability of vacuum, R is the distance between the nuclear spin and the electron spin (considered as a point dipole), and γ_S equals $g_{\text{eff}}\beta/\hbar$, where g_{eff} is the effective g factor of the electron in the complex under consideration and β is the Bohr magneton. ω_S and ω_I are the electronic and nuclear Larmor frequencies. The electronic Larmor frequency is so much larger than the nuclear Larmor frequency that the latter can be neglected in the terms involving the sum and difference frequencies, and some of the terms in the dipole–dipole parts of equations (4) and (5) can be brought together. Note the peculiar dual role that the exchange can play in the PRE: in equations (4)–(7) the τ_M acts as a correlation time, while its role in equations (1)–(3) is that of a relaxation time.

The modified Solomon–Bloembergen equations were first presented in the papers by Connick and Fiat⁶ and by Reuben et al.⁷ The formal derivation of the equations is fairly complicated and was in fact published much later.⁸ It is based on the Redfield relaxation theory for the nuclear spin and involves two critical assumptions. The first one is that the

electron relaxation (which is a motion in the electron spin space) is uncorrelated with molecular reorientation (which is a spatial motion influencing the dipole coupling). The second assumption is concerned with the description of the dynamics in the electron spin space. It is assumed that the electron spin system is dominated by the electronic Zeeman interaction. Other interactions lead to relaxation, which can be described in terms of the longitudinal and transverse relaxation times T_{1e} and T_{2e} . This point is elaborated on in Section 2.3. In this sense, one can call the modified Solomon–Bloembergen equations a ‘Zeeman-limit theory’. If the second assumption is fulfilled, then the scalar interaction parts in equations (4) and (5) become analogous to the equations describing scalar relaxation originating from the modulation of the nuclear spin–spin coupling, with the hyperfine coupling constant $A/\hbar$ replacing the J coupling constant. The first assumption does not directly influence the scalar interaction term, but the failure to fulfil it will lead to an additional interference (cross correlation) term between the dipole–dipole and the scalar interactions. The validity of both the above assumptions is questionable in many cases of practical importance.

Apart from these two main assumptions, equations (4) and (5) contain several additional approximations, the most important of which are the following:

1. The electron spin is assumed to be a point dipole centered at the metal ion. The validity of this assumption can be tested by ab initio quantum-chemical calculations, which indicate that it is reasonable for protons but may cause errors for heavier nuclei, in particular if the atoms where they reside are involved in bonding with the paramagnetic metal center.⁹
2. The electron g tensor is assumed to be isotropic. The effects of deviations from this assumption were first investigated by Sternlicht.¹⁰
3. It is assumed that the reorientation of the nuclear–electron spin vector can be described by a single correlation time, τ_R . This amounts to neglecting the effects of internal motion and anisotropic reorientation.
4. It is assumed that chemical exchange is uncorrelated with the remaining motions in the lattice. This assumption seems to be easy to fulfil. We return to the exchange effects in Section 3.1.

2.3 The Bloembergen–Morgan Theory for Electron Spin Relaxation

As one can see in equations (4) and (5), the magnitude of the PRE for the ligand nuclei depends on the energy level splittings and the relaxation behavior of the electron spin system of the transition metal ion in the magnetic field. For discussing the splittings, the spin Hamiltonian formalism, developed originally for the interpretation of ESR spectra,¹¹ normally constitutes an appropriate framework. The spin Hamiltonian is an operator involving only nuclear and electron spin operators and parameters characterizing the spin system under consideration. Neglecting the terms containing only nuclear spins and the hyperfine coupling to the ligand nuclei, the spin Hamiltonian can be written:

$$\hat{H}_S = \hat{S} \cdot \mathbf{g} \cdot \hat{B}_0 + \hat{S} \cdot \mathbf{D} \cdot \hat{S} + \hat{S} \cdot \mathbf{A} \cdot \hat{I}_M \quad (8)$$

$\hat{S}$ is the electron spin operator. The first term describes the electron Zeeman interaction and the second the zero-field splitting (ZFS) interaction, which only has to be considered for systems with electron spin quantum number $S \geq 1$. The last term corresponds to the hyperfine interaction with the metal nucleus, if it has nonzero spin ($\hat{I}_M$ is the nuclear spin operator for the metal). The molecular parameters are the three second-rank tensors: the g tensor $\mathbf{g}$, the ZFS tensor $\mathbf{D}$ and the hyperfine coupling tensor $\mathbf{A}$. The combined effect of the electrostatic interactions and spin–orbit coupling renders the Zeeman interaction anisotropic and makes the average effective g value (equal to one-third of the trace of the g tensor) different from the free electron value of 2.0023. The effect of the g tensor on ESR spectra is similar to the effect of the shielding tensor in NMR.

The zero-field splitting tensor also has its origin in the intermingling of the electrostatic and spin–orbit interactions. In addition, the dipolar coupling between the electron spins can contribute to the ZFS, but this contribution is believed to be minor for transition metal complexes.¹² The ZFS tensor is traceless and can be characterized, in its principal axis system, by two constants:

$$D = D_{zz} - \frac{1}{2}(D_{xx} + D_{yy}) \quad (9a)$$

$$E = \frac{1}{2}(D_{xx} - D_{yy}) \quad (9b)$$

The ZFS interaction has a form similar to the quadrupolar interaction in NMR.

The modulation of various terms in equation (8) by random processes in liquids leads to electron spin relaxation. The rotational modulation of the anisotropies of the g and hyperfine tensors are important sources of electron relaxation for $S = \frac{1}{2}$ systems. Still another relaxation mechanism for $S = \frac{1}{2}$ systems, in analogy with the case of nuclear relaxation, is the spin–rotation coupling. The electron relaxation in $S = \frac{1}{2}$ systems is discussed at length in the book by Muus and Atkins¹³ and is summarized in the book by Banci et al.²

For systems with $S \geq 1$, the electron spin relaxation is usually so fast (often on the picosecond timescale) that it competes effectively with complex reorientation as the main modulation mechanism for the dipole–dipole part of the modified Solomon–Bloembergen equations, even in small complexes. Bloembergen and Morgan¹⁴ presented, as early as the early 1960s, a Redfield-type theory (see **Relaxation Theory: Density Matrix Formulation**) where they related this efficient electronic relaxation in hexaaquo complexes of transition metal ions to the modulation of the ZFS by the distortion of the hydration shell. The Bloembergen–Morgan equations for T_{1e} and T_{2e} are often written as

$$T_{1e}^{-1} = \frac{\Delta^2}{25} [4S(S+1) - 3] \left(\frac{\tau_v}{1 + \tau_v^2 \omega_S^2} + \frac{4\tau_v}{1 + 4\tau_v^2 \omega_S^2} \right) \quad (10)$$

$$T_{2e}^{-1} = \frac{\Delta^2}{50} [4S(S+1) - 3] \times \left(3\tau_v + \frac{5\tau_v}{1 + \tau_v^2 \omega_S^2} + \frac{2\tau_v}{1 + 4\tau_v^2 \omega_S^2} \right) \quad (11)$$

where τ_v is the correlation time for the collision-related modulation of the ZFS, and Δ^2 is the trace of the square of the transient ZFS tensor:

$$\Delta^2 = D_{xx}^2 + D_{yy}^2 + D_{zz}^2 = \frac{2}{3}D^2 + 2E^2 \quad (12)$$

The combination of the modified Solomon–Bloembergen equations with the Bloembergen and Morgan theory for electron spin relaxation rates provides a complete theory for the magnetic field dependence of the PRE, known in the literature as the Solomon–Bloembergen–Morgan (SBM) theory.

The Bloembergen–Morgan theory has rather severe validity conditions, very clearly stated in the original paper. The most important limitation is the validity requirement for the Redfield-type or perturbative approach, which can generally be formulated as $\tau_v^2 \Delta^2 \ll 1$. It is unfortunately rather common in the literature to use equations (10) and (11) uncritically, also beyond the limits of their validity. Analogous equations have also been derived for the case of rotational modulation of a static ZFS.¹⁵ This case should be handled with care in the context of PRE, because it violates the requirement of no correlation between rotation and electron relaxation. An improvement of the SBM theory, within the same general framework and with the same validity limits, has been proposed by Rubinstein et al.¹⁶ They noted that for systems with $S \geq \frac{3}{2}$ one may have more than one electronic T_1 or T_2 , and they elegantly described the collision modulation of the ZFS as a pseudorotation process.

The issue of the electron spin relaxation for $S \geq 1$ in solution is not really settled, on the fundamental level of the applicability of the spin Hamiltonian formalism. An interesting line of thought, which still awaits a quantitative formulation, is that the electronic relaxation in liquids might in fact be similar to that in solids, where one talks about mechanisms involving interactions between the electron spin and phonons, mediated by the spin–orbit coupling.²

2.4 Beyond the Solomon–Bloembergen–Morgan Theory

During the last decade, significant effort has been invested into moving the paramagnetic relaxation theory beyond the limitations of the SBM theory. Two main approaches can be discerned. One of them can be referred to as ‘low-field theories’. These are designed to handle cases when the electron Zeeman interaction does not dominate the energy level structure, either because the slow reorientation does not average out the anisotropic term in equation (8) or because another interaction (in the first place the ZFS interaction) simply is stronger and determines the quantization direction of the electron spin. This approach was originally proposed by Lindner¹⁷ and was subsequently developed by Bertini and co-workers^{1,2} and by Sharp.¹⁸ The form of the resulting equation for T_{1M}^{-1} is similar to equation (4), in the sense that it consists of a sum of terms containing spectral density functions at the transition frequencies in the combined nuclear spin–electron spin system. The coefficients of the various spectral densities depend on the angle between the two molecule–fixed axis systems: the dipole–dipole axis and the principal axis of the anisotropic interaction. The electron spin relaxation enters the theories of this type in the simple form of ‘electron relaxation

time', $\tau_S = T_{1e} = T_{2e}$, i.e. the electron spin is assumed to be in the Redfield limit. In addition, a frequency dependence of τ_S , similar to that given by the Bloembergen–Morgan theory, is sometimes used.

The other approach tries to solve the problem using more general, and more cumbersome, methods^{3,8,19,20} based on the stochastic Liouville equation (see *Liouville Equation of Motion*).¹³ This formulation is often referred to as the 'slow-motion approach'. The nuclear spin is considered to be weakly coupled (in the sense that the Redfield formalism is valid) to a composite lattice, containing the electron spin degree of freedom as well as rotations and possibly other classical degrees of freedom. The electron spin and the classical degrees of freedom are coupled through the ZFS interaction of arbitrary strength. The dynamics in the composite lattice can be described in terms of a spectral density function, and the nuclear T_1 is determined by the value of the spectral density at the nuclear Larmor frequency, while the nuclear T_2 depends on the spectral density at the nuclear Larmor frequency and at zero frequency. There is no need to invoke the concept of electronic relaxation time, even though the result of numerical calculations becomes identical to the SBM theory under appropriate limiting conditions. The disadvantage of the approach is its complexity: the composite lattice spectral density is obtained by the inversion of a complex matrix, in principle of infinite dimensions.

The magnetic field dependences of the nuclear spin–lattice relaxation rate, calculated using the methods of Bertini et al.² and of Benetis et al.,⁸ have been compared with each other, imposing on the latter model the additional assumption of exponential electron spin relaxation.² For the case of large ZFS, the results of the two methods are identical and very different from the predictions of the SBM theory (Figure 1).

2.5 The Curie Spin Relaxation

Gueron, Fiat, and Vega²¹ have proposed an additional mechanism for the PRE, due to dipolar coupling of the nuclear spin with the thermally averaged electron magnetic moment. This average 'Curie spin' is aligned along the external magnetic field and is proportional to its magnitude. The interaction between the nuclear spin and the Curie spin is modulated by reorientation and exchange, but not by the electron spin relaxation. If the electron relaxation is much faster than the reorientation and exchange, and if the magnetic field is high, the Curie spin relaxation can become important (in particular for T_{2M}) in spite of the fact that the average electronic magnetic moment is of course much smaller than the real, rapidly oscillating one.

2.6 Intermolecular Relaxation

The above-mentioned theories of intramolecular nuclear spin relaxation due to dipole–dipole interaction assume that the distance R between the I and S spins is constant. The chemical exchange can be thought of as an extremely crude way of incorporating possible intermolecular effects or modulation of the dipole–dipole interaction by the variation of the interspin distance; it is allowed to be given a value of either R or infinity. For many transition metal complexes, this essentially intramolecular approach is sufficient. For other systems, where the paramagnetic centers in solution are either transition metal complexes with a nonlabile coordination sphere, or stable organic radicals, the relaxation of the solvent nuclei is predominantly intermolecular in nature (the concept of outer sphere relaxation is also used), and a more refined approach to the modulation of the spin–spin distance by translational diffusion is required. The problem can be solved at different levels of sophistication. The earlier development has been reviewed by Kowalewski et al.³ Among more recent contributions, one should mention the work of Bayburt and Sharp²² dealing with the limiting case of ZFS dominating over the electron Zeeman interaction.

3 EXPERIMENTAL METHODS

Most experimental work on PRE is technically very simple. Basically, one measures the nuclear spin–lattice or spin–spin relaxation rate (the latter is commonly estimated from the linewidth) for ligand nuclei in the presence and in the absence of the paramagnetic reagent, and one obtains the PRE by subtraction. The experiments are often performed to yield the result as a function of concentration of the paramagnetic species, temperature, pressure, or magnetic field. Variable concentration work can provide information on complexation equilibria. Variable temperature measurements can be used to clarify the relationships between the relaxation and exchange processes. Variable pressure experiments provide mechanistic information on the exchange processes (see *Kinetics at High Pressure*). Variable field measurements are PRE experiments *par excellence*, if one is interested in verifying theoretical models. The variable temperature and variable field measurements are discussed in the following two sections, and the experimental section is concluded by a brief presentation of

the paramagnetic relaxation effects in certain two-dimensional experiments.

3.1 Variable Temperature: Fast and Slow Exchange

As can be seen from equations (1)–(3), the relationship between relaxation and exchange is simplest for the spin–lattice relaxation, where one can easily define two limiting conditions: fast exchange, $\tau_M \ll T_{1M}$; and slow exchange, $\tau_M \gg T_{1M}$. Assume a simple case of a small complex in low viscosity solution, with T_{1M} dominated by the dipole–dipole interaction and with the reorientation of the complex determining τ_{c1} and τ_{c2} . For such a case, we are likely to have $(\tau_{c1} \omega_I)^2 \ll 1$ and $[\tau_{c2} (\omega_S \pm \omega_I)]^2 \ll 1$ and, as the rate of reorientation increases with increasing temperature, the nuclear relaxation rate decreases. The opposite is true for the ligand exchange—the rate is going to increase with increasing temperature. The measurements of the PRE in the slow exchange regime give directly the exchange lifetime and its temperature dependence/activation parameters. Measurements in the fast exchange limit provide the relaxation rate in the paramagnetic complex which, given a suitable theoretical model, can yield information on structural as well as dynamic parameters. The slow and fast exchange conditions can also be formulated for paramagnetic line broadening, a quantity commonly measured in variable temperature studies. An example of variable temperature ^{17}O line-broadening data, taken from the work of Hugi et al.,²³ is shown in Figure 2.

3.2 Variable Field: Physics of Relaxation

When one wishes to reach a deeper understanding of the details of the relaxation mechanism, a variable field [nuclear magnetic relaxation dispersion (NMRD)] study is a very powerful tool. Changing the magnetic field provides a direct

Figure 2 Oxygen-17 T_{2r}^{-1} in aqueous solution of a Ti(III) salt as a function of reciprocal temperature. Measurements were made at: (Δ , $\blacktriangle$) 8.4 T, ($\square$, $\blacksquare$) 4.7 T, and ($\circ$, $\bullet$) 1.4 T. Open and filled symbols refer to different pH values. way of measuring the frequency dependence of the relevant spectral densities.

Figure 2 gives an example of a variable field T_2 study. More commonly, the variable field studies are concentrated on T_1 measurements. Besides performing the regular inversion–recovery experiments at as many high-field spectrometers as possible, it is useful to apply field cycling experiments (see *Field Cycling Experiments*) to obtain the PRE also at very low magnetic fields. An illustrative example of the use of NMRD over a very wide range of magnetic fields is provided by the water proton relaxation in an aqueous solution of Mn(II) ions. The first field cycling experiments for this system were reported as early as the 1960s.²⁴ More recent data, as a function of solution viscosity varied by means of adding glycerol, are shown in Figure 3, taken from Bertini et al.²⁵ The Mn(II) ion is characterized by very small ZFS and slow electron spin relaxation; the data in Figure 3 can be interpreted successfully using the SBM theory. The scalar relaxation is observed at low field, because the electron relaxation is slow. In pure water, the scalar contribution disperses at ω_I of about 0.1 MHz, where $(T_{2e}\omega_S)^2$ becomes larger than unity. At higher fields, the dipolar relaxation dominates, and the second dispersion at ω_I of about 10 MHz corresponds to the condition $\omega_S\tau_R = 1$. Upon increasing the glycerol content, the viscosity increases, and both τ_R and τ_v increase with it, which changes the NMRD profiles.

A different case is presented by the PRE of water protons in an aqueous solution of another divalent first-row transition metal ion, Ni(II). An NMRD curve for this system, taken from work by Kowalewski et al.,²⁶ is shown in Figure 4. Here, the field dependence of the PRE is much weaker. The origin of this different behavior is to be sought in the electron relaxation in Ni(II), much faster than in the case of Mn(II). In fact, the nuclear and electron relaxation in aqueous Ni(II) is beyond the validity region of the SBM theory, and the details of the analysis of the data in Figure 4 are still not

Figure 3 Water ^1H NMRD profiles of Mn(II) solutions in pure water ($\circ$) and with increasing amounts of deuterated glycerol [($\bullet$) 10%, (∇) 20%, ($\blacktriangledown$) 35%, ($\square$) 55%, ($\blacksquare$) 65%]. completely settled.^{18,20,26} The flatness of the NMRD curve is caused by the rapid electron relaxation, which makes the scalar contribution negligible and reduces the efficiency of the dipole–dipole contribution. The weak increase of PRE at high field can be related to the onset of the dispersion of the electron relaxation.

The NMRD measurements are by no means limited to low-molecular-weight paramagnetic systems. A large number of data for metalloproteins in solutions can be found in the book by Banci et al.² and in a review by Koenig and Brown.²⁷

3.3 Novel Experiments

The last few decades have seen a tremendous growth in the number of available NMR experiments. In many of these experiments the paramagnetic relaxation effects are a nuisance, and are carefully avoided by removing oxygen and paramagnetic impurities from the samples. In some cases, however, paramagnetic systems can be studied, and special features introduced into common two-dimensional techniques (NOESY and COSY) by the paramagnetic relaxation are worth mentioning.

The NOESY experiment suffers from the PRE in the sense that the cross-relaxation rates involving nuclei close to paramagnetic centers become much smaller than the leakage rates, which reduces the intensity of the cross peaks. As demonstrated, by Emerson and La Mar²⁸ among others, it is nevertheless possible to perform NOESY studies of the active site regions of fairly large paramagnetic proteins. The COSY experiments suffer from the PRE because of rapid relaxation and excessive signal cancellation when the linewidth is much larger than the J coupling. COSY cross peaks have nevertheless been reported in paramagnetic proteins. The results may, however, require a reevaluation in the light of the recent work by Bertini et al.,²⁹ who have demonstrated that the cross peaks may actually arise through relaxation-allowed coherence transfer, originating from cross correlation of the dipole–dipole and Curie relaxation mechanisms, rather than through J couplings.

1 INTRODUCTION

Two recent important developments of metallic alloys are the discoveries of quasicrystalline (QC) alloys and bulk metallic glasses (BMGs). In both cases, NMR studies have obtained crucial information that is important for the understanding of the novel properties of these systems. Discovered in 1984, QC alloys possess long-range translational and orientational orders, which lead to sharp Bragg diffraction peaks.¹ However, the diffraction patterns display point-group symmetry, such as icosahedral (i) symmetry, incompatible with periodicity.¹ Thus, QC alloys belong to a new class of solids unlike crystalline and glassy materials. In addition to their fascinating structure, QC alloys also possess novel physical properties such as the extremely low electric conductivity.² In this article we will focus on how NMR provides crucial information on the electronic structures of these QC alloys. Unlike crystalline and QC solids, glasses lack both long-range translational and orientational orders. Conventional metallic glasses are produced by rapid quenching of melts at cooling rates larger than 10^5 K s^{-1} . In contrast, the newly discovered BMGs can be produced at a typical cooling rate of 1 K s^{-1} such that large pieces of glassy materials can be obtained. Examples of such BMGs are the Zr-based and Pd-based quaternary and quinary alloys.^{3,4} Such BMGs exhibit excellent thermal stability making it experimentally possible to access the metallic supercooled liquid state down to the glass transition temperature (T_g). Clearly, BMGs possess unique thermodynamic and kinetic properties that hinder nucleation and growth in the supercooled liquid state. We will show how NMR can be used to obtain crucial information on the nature of atomic motions in the glassy and the supercooled liquid state of BMGs. Despite their different long-range orders,

metallic glasses and QC alloys could share some similarities in local structures. For instance, icosahedral clusters were proposed to be the local structure in some metallic glasses and supercooled liquids. Experimentally, upon thermal annealing BMGs were observed to form QC phases prior to crystallization.⁵

2 BASIC NMR CHARACTERISTICS IN QUASICRYSTALLINE ALLOYS

NMR studies of QC alloys were carried out immediately after the initial discovery.⁶ Structure, atomic motion, and electronic structures are the three main themes of most NMR studies of QC alloys. Lacking periodicity, the local environments in QC alloys are highly diversified despite the long-range translational and orientational orders. There exist a large number of nonequivalent atomic sites in QC alloys. As a result, the ^{27}Al NMR and NQR spectra measured in icosahedral Al-based QC alloys are broad and featureless. Based on ^{27}Al NQR spectra of i- $\text{Al}_{65}\text{Cu}_{23}\text{Fe}_{12}$ and i- $\text{Al}_{70}\text{Cu}_{15}\text{Ru}_{15}$ it was inferred that there exists a broad distribution of the magnitude of the EFG tensors associated with chemically nonequivalent Al sites.^{7,8} On single-grain i-AlPdMn samples, the angular dependence of ^{27}Al NMR spectra was investigated.^{8,9} In i- $\text{Al}_{70}\text{Pd}_{21.5}\text{Mn}_{8.5}$, the ^{27}Al NMR spectrum was found to be independent of the relative orientation between the static magnetic field (B_0) and the twofold rotation axis of the sample indicating a quasi-continuous distribution of structural environments.⁸ In i- $\text{Al}_{72.4}\text{Pd}_{20.5}\text{Mn}_{7.1}$, the ^{27}Al NMR spectrum was found to be slightly different at parallel and perpendicular orientations between B_0 and the five-fold rotation axis suggesting a large but finite number of physically nonequivalent atomic sites.⁹ A typical ^{27}Al NMR spectrum of Al-based QC alloys measured by the Hahn echo pulse sequence is shown in Figure 1. Powder pattern simulation of the $1/2 \leftrightarrow -1/2$ central transition at $B_0 = 9.4 \text{ T}$ shows that the quadrupole frequency $\nu_Q = 3\chi/2I(2I - 1)$ is on the order of 1.7 MHz in i- $\text{Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$ (Figure 1),¹⁰ consistent with the NQR measurements.⁸ The isotropic shift is on the order of 150 ppm. Since the estimated second-order isotropic quadrupole shift $\delta_{\text{iso}}^{(2)}$ is around -70 ppm and the typical ^{27}Al chemical shift is between 0 and 200 ppm, the Knight shift K is on the order of 200 ppm or less which is much smaller than $K^{27\text{Al}}$ of 1600 ppm observed in Al metal.

NMR was used to study atomic motion in QC alloys. In i- $\text{Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$, a sharp increase of $1/T_1^{27\text{Al}}$ was measured above 673 K due to motion-induced quadrupole relaxation.¹⁰ The Arrhenius plot indicated a thermally activated process with activation energy of 0.48 eV. It is about three times smaller than that in corresponding crystalline alloys where vacancy-assisted diffusion dominates. This suggests that a different atomic transport process is at work in QC alloys at high temperature. ^{27}Al two-dimensional exchange NMR has been employed to measure atomic motion in i- $\text{Al}_{70}\text{Pd}_{21.4}\text{Re}_{8.6}$ below 130 K.¹¹ The mixing time dependence of the two-dimensional exchange spectrum suggests that the detected atomic motion is spatially confined in this temperature range, extending over only several inter-atomic distances and is attributed to a mode of local motion specifically related to quasicrystallinity.¹¹

Figure 1 (a), (b), and (c) are the ^{27}Al spectra of $i\text{-Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$ at various temperatures. The circles are the simulated spectrum of a powder-pattern of the anisotropic second-order quadrupole interaction convoluted with linewidth broadening. The dashed line is the quadrupole powder pattern ($\nu_Q = 1.7\text{ MHz}$, $\eta = 0$). (d) ^{27}Al spectrum of crystalline $\text{Al}_7\text{Cu}_2\text{Fe}$ at 973 K

3 PROBING ELECTRONIC STRUCTURES OF QUASICRYSTALLINE ALLOYS BY NMR

High-quality QC alloys exhibit remarkably different physical properties than typical metals, with poor electric and thermal conductivity and very small electric heat capacity.² The electric resistivity of a QC alloy increases as structural order increases in contrast to typical metals.² Furthermore, the electric resistivity increases with decreasing temperature.² In fact, some of the high-quality QC alloys were found to be in the proximity of metal-insulator transition.¹² These unusual physical properties are related to novel structures of the electronic density-of-states (DOS). It is well-established both theoretically and experimentally that a broad DOS pseudogap at E_F of about 0.5–1 eV in width exists in QC alloys caused by electron scattering at the almost spherical pseudo-Brillouin zone at the Fermi surface. The pseudogap was predicted to be enhanced¹³ by sp-d hybridization in Al-based QC alloys containing intermediate transition metals and plays a crucial role in the thermodynamic stability of QC phases. In addition, it was also predicted theoretically that a set of spiky DOS peaks of about 10 meV in width exist within the pseudogap as a result of strong hybridization between atomic orbitals in the presence of high local symmetry¹⁴ and hierarchical packing of icosahedral clusters.¹ The presence of such sharp feature at E_F will have a strong influence on the electric and thermal

properties of QC alloys. We will show how NMR can be used to detect and characterize such sharp DOS features at E_F .

3.1 Unusual Temperature Dependence of Nuclear Spin-Lattice Relaxation

Unlike in typical metallic alloys, the measured K and $1/T_1$ in QC alloys are very small. It indicates that the DOS at E_F , $g(E_F)$, of QC alloys is small compared to the calculated value based on free-electron model. However, some earlier NMR studies did not find evidence of sharp DOS features.^{15,16} Sharp features become noticeable as the quality of QC alloys improves. The NMR evidence of sharp DOS features is the unusual temperature dependence of $1/T_1$ that deviates substantially from the relation $1/T_1 \propto T$ observed in typical metallic systems. Figure 2 shows the nuclear spin-lattice relaxation (NSLR) curves of ^{27}Al measured in $i\text{-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$.¹⁷ Here, $M^*(t) = [M_0 - M(t)]/[M_0 - M(0)]$ is plotted¹⁷ as a function of the recovery time t scaled by T^2 . The NSLR curves measured between 100 and 600 K collapse into a single curve indicating that $1/T_1 \propto T^2$ (Figure 2). As discussed later, this novel temperature dependence is the signature of the sharp DOS valley at E_F . Similar temperature dependence of $1/T_1$ was also observed in other QC alloys including $i\text{-Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$ and $i\text{-Al}_{62.5}\text{Cu}_{24.5}\text{Fe}_{13}$,¹⁷ $i\text{-Al}_{70}\text{Pd}_{8.6}\text{Re}_{21.4}$,¹⁸ $i\text{-Al}_{70.5}\text{Pd}_{21}\text{Re}_{8.5}$, $i\text{-Al}_{62}\text{Cu}_{25.5}\text{Fe}_{12.5}$ and $i\text{-Al}_{72.4}\text{Pd}_{20.5}\text{Mn}_{7.1}$.¹⁹ At higher temperature above 600 K, $1/T_1$ is dominated by atomic motion-induced quadrupole relaxation.¹⁰ At low temperature below 20 K, $1/T_1^{27\text{Al}}T \propto T^{-0.69}$ was observed in $i\text{-Al}_{70}\text{Pd}_{8.6}\text{Re}_{21.4}$.¹⁸ This power law was described as a result of gradual real-space localization of the itinerant charge carriers. Similar low-temperature $1/T_1$ behaviors were also observed in $i\text{-Al}_{70.5}\text{Pd}_{21}\text{Re}_{8.5}$, $i\text{-Al}_{62}\text{Cu}_{25.5}\text{Fe}_{12.5}$, and $i\text{-Al}_{72.4}\text{Pd}_{20.5}\text{Mn}_{7.1}$.¹⁹ The low-temperature NMR results, consistent with the low-temperature electric conductivity, magnetoresistivity,¹² and magnetic susceptibility²⁰ measurements, indicate a strong effect of the weak localization and electron-electron interaction in high-quality QC alloys at low temperature.

Figure 2 The inversion recovery curves of the ^{27}Al nuclear magnetization M versus τ which is scaled by T^2 in $i\text{-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$. It shows that $1/T_1 \propto T^2$

3.2 The Mechanism of the Nuclear Spin-lattice Relaxation

In NMR studies of QC alloys, ^{27}Al , ^{63}Cu , and ^{65}Cu are the most frequently used isotopes. Two mechanisms can induce NSLR for these quadrupolar nuclei. One mechanism is the coupling between the nuclear spin and the unpaired conduction electron spins (magnetic relaxation). The second mechanism is the coupling of the nuclear electric quadrupole moment with the fluctuating EFG induced by atomic motions (quadrupolar relaxation). For magnetic relaxation, $1/T_1 \propto \gamma_n^2$; for quadrupolar relaxation, $1/T_1 \propto Q^2$. The relative contributions of the two mechanisms can be determined by measuring $1/T_1$ of a pair of proper isotopes. For i-AlCuRu and i-AlCuFe, ^{63}Cu and ^{65}Cu is such an excellent pair.¹⁷ $T_1^{65\text{Cu}}/T_1^{63\text{Cu}} = (\gamma_{63\text{Cu}}/\gamma_{65\text{Cu}})^2 = 0.87$ for magnetic relaxation and $T_1^{65\text{Cu}}/T_1^{63\text{Cu}} = (Q_{63\text{Cu}}/Q_{65\text{Cu}})^2 = 1.14$ for quadrupole relaxation. Figure 3 shows the ^{63}Cu and ^{65}Cu NSLR curves measured in i-Al₆₅Cu₂₀Ru₁₅ at 300 K and 9.4 T where $T_1^{65\text{Cu}}/T_1^{63\text{Cu}}$ was measured to be 0.83–0.90. In i-Al_{62.5}Cu_{24.5}Fe₁₃ $T_1^{65\text{Cu}}/T_1^{63\text{Cu}}$ was also measured to be 0.80–0.87.¹⁷ Thus, $1/T_1^{63\text{Cu}}$ and $1/T_1^{65\text{Cu}}$ in i-Al₆₅Cu₂₀Ru₁₅ and i-Al_{62.5}Cu_{24.5}Fe₁₃ are dominated by magnetic relaxation.¹⁷ In i-Al₆₅Cu₂₀Ru₁₅ $1/T_1^{27\text{Al}}$ was found¹⁷ to follow almost the same temperature dependence as $1/T_1^{63\text{Cu}}$. It suggests that the observed unusual temperature dependences of $1/T_1^{27\text{Al}}$, $1/T_1^{63\text{Cu}}$, and $1/T_1^{65\text{Cu}}$ are originated from the same mechanism through the coupling between the nuclear spins and unpaired conduction electron spins.

A strong field dependence of $1/T_1^{27\text{Al}}$ was observed in i-Al_{72.4}Pd_{20.5}Mn_{7.1}.²¹ The measured $1/T_1^{27\text{Al}}$ was ascribed to two components; one is independent of B_0 dominating at low temperature while the other is inversely proportional to B_0 dominating at high temperature.²¹ The origin of the second component remains unexplained.²¹ The nature of $1/T_1^{27\text{Al}}$ in other QCs were shown to be different. In i-Al₇₀Pd₂₀Re₁₀ and i-Al₆₅Cu₂₀Ru₁₅, $1/T_1^{27\text{Al}}$ was measured to be

field independent;²⁰ in i-Al₇₀Pd_{21.4}Re_{8.6} $1/T_1^{27\text{Al}}$ was measured to be field independent as well.¹⁸ Thus, the observed field dependence of $1/T_1^{27\text{Al}}$ in i-Al_{72.4}Pd_{20.5}Mn_{7.1} is not intrinsic to QC alloys. In Al-based QC alloys with intermediate transition metals, NMR results could be complicated by possible localized magnetic moments at the atomic sites of the transition metals. Thus, the field dependence of $1/T_1^{27\text{Al}}$ in i-AlPdMn might be related to localized magnetic moments since the magnetic moment concentration in i-AlPdMn is several orders of magnitude larger than in i-AlPdRe and i-AlCuRu according to magnetic susceptibility measurement.²⁰ In view of this, i-AlPdRe and i-AlCuRu are more appropriate systems for NMR study of the intrinsic electronic properties of QC alloys.

3.3 The Sharp DOS Feature

As discussed in Section 3.1, below 20 K the measured T_1 in i-Al₇₀Pd_{8.6}Re_{21.4} are found to be associated with the electron-electron interaction and weak localization. Above 600 K, T_1 is dominated by the contribution of atomic motion. Therefore, only T_1 measured in the intermediate temperature range, which is governed by the coupling between the nuclear spins and the unpaired independent conduction electron spins, will be used to extract the sharp DOS feature at E_F . In this section, we discuss the derivation of the sharp DOS feature by analyzing the NMR results measured in this temperature range.

In Al-based QCs with intermediate transition metals such as i-AlPdRe and i-AlCuRu, the Al 3s and 3p-bands are strongly hybridized with the Re 5d-band and the Ru 4d-band, respectively. The K and $1/T_1$ of ^{27}Al , ^{63}Cu and ^{65}Cu are dominated by the Fermi-contact interaction with the conduction 3s-electron spins and the core-polarization induced by the conduction d electron spins. Denoting the partial DOS of the 3s and d-bands as $g_s(E)$ and $g_d(E)$, respectively, K is described by

$$K = \frac{1}{k_B T} \int [\alpha_s g_s(E) + \alpha_d g_d(E)] f(E) [1 - f(E)] dE, \quad (1)$$

where $f(E)$ is the Fermi-Dirac distribution function, $\alpha_s = \frac{4\pi}{3} \hbar^2 \gamma_e^2 \langle |u_k^2(0)| \rangle_{E_F}$ where γ_e is the electronic gyromagnetic ratio and $\langle |u_k^2(0)| \rangle_{E_F}$ is the density of the 3s-band wave function at the Al nucleus averaged over the Fermi surface, α_d is associated with the core-polarization by the d-bands and is negative. $1/T_1$ is described by

$$\frac{1}{T_1} = \int [\beta_s g_s^2(E) + \beta_d g_d^2(E)] f(E) [1 - f(E)] dE, \quad (2)$$

where $\beta_s = 4\pi \hbar \gamma_n^2 \alpha_s^2$ and $\beta_d = 4\pi p \hbar \gamma_n^2 \alpha_d^2$ (p is a factor related to the local symmetry and degeneration of the d-bands).²²

Since $f(E)[1 - f(E)]$ vanishes quickly as E deviates from E_F by a few $k_B T$, the temperature dependence of K and $1/T_1$ are determined by DOS near E_F . In typical metallic systems, since the DOS variation over several $k_B T$ is small near E_F , K is temperature independent and $1/T_1 \propto T$. In high quality QC alloys, however, novel temperature dependences of K and $1/T_1$ were observed inferring a sharp DOS feature near E_F . For Al-based QC alloys containing intermediate transition metals,

Figure 3 The ^{63}Cu and ^{65}Cu NSLR curves in i-Al₆₅Cu₂₀Ru₁₅ at 300 K and 9.4 T. The curve for ^{63}Cu is plotted as $M^*(0.87t)$. It shows that $T_1^{65\text{Cu}}/T_1^{63\text{Cu}}$ is 0.83–0.90

Figure 4 $1/T_1^{27\text{Al}}$ versus T in $\text{i-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$. The solid line is a fit with equation (5)

the theoretical calculations indicated¹³ an enhanced pseudogap at E_F by sp-d hybridization leading to a sharp DOS valley. The structures of the partial DOS $g_s(E)$ and $g_d(E)$ within the sharp DOS valley near E_F can be assumed as

$$\begin{aligned} g_s(E) &= g_{0s} + g_{1s}|E - E_F|^\varepsilon, \\ g_d(E) &= g_{0d} + g_{1d}|E - E_F|^\varepsilon \end{aligned} \quad (3)$$

with g_{0s} and g_{0d} as the residual DOS at E_F for 3s-band and d-bands, respectively.

K is obtained from equations (1) and (3) as

$$K = (\alpha_s g_{0s} + \alpha_d g_{0d}) + 2C(\varepsilon)(\alpha_s g_{1s} + \alpha_d g_{1d})(k_B T)^\varepsilon, \quad (4)$$

where $C(\varepsilon) = \int_0^\infty x^\varepsilon e^x / (1 + e^x)^2 dx$. Using equations (2) and (3), $1/T_1$ is obtained as

$$\begin{aligned} \frac{1}{T_1} &= k_B T [(\beta_s g_{0s}^2 + \beta_{ds} g_{0d}^2) + 4C(\varepsilon)(\beta_s g_{0s} g_{1s} + \beta_{ds} g_{0d} g_{1d})(k_B T)^\varepsilon \\ &\quad + 2C(2\varepsilon)(\beta_s g_{1s}^2 + \beta_{ds} g_{1d}^2)(k_B T)^{2\varepsilon}]. \end{aligned} \quad (5)$$

At low temperature, equations (4) and (5) lead to the conventional temperature dependences where K is temperature independent and $1/T_1 \propto T$. As discussed above, however, equations (4) and (5) are not suitable for analyzing the low temperature K and $1/T_1$ data in QC alloys since the electron-electron interaction and weak localization are not included. At higher temperatures, equations (4) and (5) lead to $K \propto T^\varepsilon$ and $1/T_1 \propto T^{1+2\varepsilon}$. The power law $1/T_1 \propto T^2$ was observed in $\text{i-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$ and $\text{i-Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$ above 100 K suggesting that $\varepsilon = 1/2$.¹⁷ Indeed, the fit of $1/T_1^{27\text{Al}}$ by equation (5) shows that $\varepsilon \approx 1/2$ (Figure 4). Since $1/T_1 \propto T^2$ is induced by the sharp DOS valley and is clearly obeyed up to 400 K, the width of the $\varepsilon = 1/2$ region in the sharp DOS valley should be at least as large as 25 meV.¹⁷ The measured small residual $g(E)$ at E_F in $\text{i-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$ and $\text{i-Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$ agrees with the heat capacity measurements.¹⁷ Since the NMR results at much higher temperature are complicated by atomic motion,¹⁰ the DOS shape further away from E_F cannot be determined by NMR.

For $\varepsilon = 1/2$, equation (4) leads to a weak temperature dependence of K at high temperature. Indeed, $K^{27\text{Al}}$ was measured to follow such a weak temperature dependence in $\text{i-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$ and $\text{i-Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$.^{10,17} Moreover, the measured temperature dependence of $K^{27\text{Al}}$ was found¹⁷ to be correlated with that of $1/T_1^{27\text{Al}}$ as described by equations (4) and (5). The analysis of the temperature dependences of $K^{27\text{Al}}$ and $1/T_1^{27\text{Al}}$ indicate a strong effect of the core-polarization at Al sites that is consistent with the theoretical prediction of the strong sp-d hybridization in Al-based QC alloys containing intermediate transition metals.¹²

3.4 Comments on the Approximation Method Based on Taylor Expansion

An approximation method was used to describe the DOS variation near E_F for narrow d-bands and analyze the non-linear temperature dependence of $1/T_1$ and the temperature dependence of K such as in Pt metal.²² A similar approximation was used to analyze the nonlinear temperature dependence of $1/T_1$ in QC alloys.^{10,19,21} Here we show that such approximation can often be insufficient and misleading in analyzing the effect of the DOS variation near E_F .

The approximation is based on the Taylor expansion of $g(E)$ at E_F (E_F at $T = 0$) as

$$\begin{aligned} g(E) &= g(E_F^0) + (E - E_F^0)g'(E_F^0) \\ &\quad + \frac{1}{2}(E - E_F^0)^2 g''(E_F^0), \end{aligned} \quad (6)$$

with $g'(E_F^0)$ and $g''(E_F^0)$ as the first and second derivatives of $g(E)$ to E at E_F^0 , respectively. Because of the second term in equation (6), E_F could be temperature dependent if $g(E)$ is not symmetric about E_F^0 . Define $\Delta E_F = E_F - E_F^0$, equation (6) can be rewritten as

$$\begin{aligned} g(E) &= [g(E_F^0) + \Delta E_F g'(E_F^0) + \frac{1}{2}(\Delta E_F)^2 g''(E_F^0)] \\ &\quad + (E - E_F)[g'(E_F^0) + \Delta E_F g''(E_F^0)] \\ &\quad + \frac{1}{2}(E - E_F)^2 g''(E_F^0). \end{aligned} \quad (7)$$

Using equation (7) and the conservation of electron density described by $\frac{d}{dT} [\int g(E) f(E) dE] = 0$, it is straightforward to obtain

$$\begin{aligned} \frac{d(\Delta E_F)}{dT} &\left[g(E_F^0) + \Delta E_F g'(E_F^0) + \frac{1}{2}(\Delta E_F)^2 g''(E_F^0) \right. \\ &\quad \left. + \frac{\pi^2}{6} g''(E_F^0)(k_B T)^2 \right] \\ &= -\frac{\pi^2}{3} [g'(E_F^0) + \Delta E_F g''(E_F^0)] k_B^2 T. \end{aligned} \quad (8)$$

The derivatives of ΔE_F with T can be derived from equation (8) and the Taylor expansion of E_F can be calculated at $T = 0$ as

$$\begin{aligned} E_F &= E_F^0 - \frac{\pi^2}{6} (k_B T)^2 \frac{g'(E_F^0)}{g(E_F^0)} + \frac{\pi^4}{72} (k_B T)^4 \frac{g'(E_F^0)}{g(E_F^0)} \\ &\quad \times \left[2 \frac{g''(E_F^0)}{g(E_F^0)} - \left(\frac{g'(E_F^0)}{g(E_F^0)} \right)^2 \right] + O(T^6). \end{aligned} \quad (9)$$

For a symmetric $g(E)$ about $E = E_F^0$, $g'(E_F^0) = 0$ and E_F is temperature independent.

Using equations (1), (7), and (9), K can be calculated to the order of T^5 as

$$K \propto g(E_F^0) \left\{ 1 + \frac{\pi^2}{6} (k_B T)^2 \left[\frac{g''(E_F^0)}{g(E_F^0)} - \left(\frac{g'(E_F^0)}{g(E_F^0)} \right)^2 \right] + \frac{\pi^6}{60} (k_B T)^4 \left(\frac{g'(E_F^0)}{g(E_F^0)} \right)^2 \left[3 \frac{g''(E_F^0)}{g(E_F^0)} - \left(\frac{g'(E_F^0)}{g(E_F^0)} \right)^2 \right] \right\} + 0(T^6). \quad (10)$$

Using equations (2), (7), and (9), the calculated $1/T_1$ is given by

$$\frac{1}{T_1} \propto g^2(E_F^0) \left\{ k_B T + \frac{\pi^2}{3} (k_B T)^3 \frac{g''(E_F^0)}{g(E_F^0)} + \frac{\pi^6}{60} (k_B T)^5 \frac{g''(E_F^0)}{g(E_F^0)} \left[7 \frac{g''(E_F^0)}{g(E_F^0)} - 5 \left(\frac{g'(E_F^0)}{g(E_F^0)} \right)^2 \right] \right\} + 0(T^7). \quad (11)$$

As an approximation, equations (9), (10), and (11) are valid only if the second terms on the right hand side of these equations are much smaller than the corresponding first terms. This is exactly what was assumed in Refs.^{10,19,21,22} in which only the first and second terms of these equations were included in the approximation. There, the measured $1/T_1$ in QC alloys were fitted with only the T and T^3 terms.^{10,19,21} However, the fits of the $1/T_1$ data indicated that the contribution of the T^3 term is comparable or even larger than that of the T term within the investigated temperature range. In this case, equation (11) shows that the contribution of the T^5 term cannot be neglected and the expansion itself may not converge. Moreover, K should be dominated by the contribution of the T^2 and T^4 terms. Thus, the approximation implies a strong temperature dependence of K , in contrast to the observation of a weak temperature dependence of K .^{10,17} Thus, the approximation is not valid for analyzing the measured $1/T_1$ in QC alloys. In general, it is not valid to use this approximation method to analyze $1/T_1$ that deviates significantly from $1/T_1 \propto T$.

4 THE ALIGNMENT ECHO TECHNIQUE FOR $I \geq 1$

NMR has made important contributions to the study of atomic and molecular motion in amorphous systems. However, NMR was rarely used to measure atomic motion in metallic glasses and metallic supercooled liquids, especially slow atomic motion. The reasons are twofold. First, the fast rate of crystallization upon heating in conventional metallic glasses and supercooled liquids does not allow sufficient time for most experimental approaches including NMR. Secondly, the longest timescale of atomic motion detectable by NMR is intrinsically limited by T_1 that is very short in typical metallic systems. Since BMGs exhibit excellent glass formability and remarkable thermal stability, a large temperature range becomes accessible for NMR up to temperatures significantly above T_g . This allows the experimental studies of the nature of

glass transition and the nature of atomic motion in the supercooled liquid state near T_g . It was fortunate for NMR studies that the representative BMGs, $\text{Zr}_{41.5}\text{Ti}_{22.5}\text{Cu}_{22.5}\text{Ni}_{10}\text{Be}_{22.5}$ (vit1) and $\text{Zr}_{41.5}\text{Ti}_{22.5}\text{Cu}_{22.5}\text{Ni}_{10}\text{Be}_{27.5}$ (vit4), contain Be where T_1^{Be} is very long. This makes NMR detection of slow atomic motion feasible in both the glassy and deeply supercooled liquid states.^{23–25}

The nuclear spin alignment echo technique (SAE) of ^2H ($I = 1$) has been used extensively for studying motion in polymers.²⁶ This technique was extended to the case of $I = 3/2$ in the study of translational atomic motion in BMGs using ^9Be NMR.^{23–25} Later, ^7Li SAE was used in measuring ionic motion in electrolyte materials.²⁷ The ^2H SAE technique was described extensively in the literature.²⁶ A general treatment was given recently for $I = 1$ to $9/2$.²³ Following the latter, assume that the truncated Hamiltonian of a nuclear spin system in the rotating frame consists of the Zeeman interaction (due to resonance off-set) and first-order electric quadrupole interaction given by

$$\hat{H} = \beta \hat{I}_z + \alpha (3\hat{I}_z^2 - \hat{I}^2) \quad (12)$$

where β is the shift relative to the rf frequency, α is proportional to the quadrupole resonance frequency.

The pulse sequence of SAE, $90^\circ - \tau_1 - \theta_\phi - t - \theta_{\phi'} - \tau_2 -$, is applied with nonselective RF pulses with the time parameters chosen such that $\tau_1 < T_2 < t$. θ and θ' are the flipping angles of the second and third pulses, respectively, with ϕ and ϕ' as the corresponding phases with respect to the first pulse. Since atomic motion could occur during the diffusion time t , the values of α and β associated with a given nuclear spin during the time interval τ_1 are denoted as α_1 and β_1 , respectively, and as α_2 and β_2 , respectively, during the time interval τ_2 . Since $t > T_2$, the spin density operator during t evolves into a diagonal density operator ($\hat{\rho}(t)$) represented by a linear combination of various nuclear spin orders (from the Zeeman order to $2I$ -th-rank spin order). The k th-rank spin order is proportional to the k th-rank zeroth-order irreducible tensor $A^{(k,0)}$ (see Table 1 in Ref.²³ for the explicit expressions of $A^{(k,0)}$ for $I = 1/2$ to $9/2$). The signal appearing after the third pulse is given by²³

$$S(\tau) = -\cos \phi_{\text{eff1}} e^{i\phi_{\text{eff2}}} \sum_{\text{odd } k} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2) + i \sin \phi_{\text{eff1}} e^{i\phi_{\text{eff2}}} \sum_{\text{even } k} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2), \quad (13)$$

where $\phi_{\text{eff1}} = \phi + \beta_1 \tau_1$, $\phi_{\text{eff2}} = \phi' + \beta_2 \tau_2$, and $f_k(\theta, \alpha \tau)$ is the coefficient given by

$$f_k(\theta, \alpha \tau) = \text{Trace}(e^{-i\theta I_y} e^{-3i\alpha I_z^2 \tau} \hat{I}_x e^{3i\alpha I_z^2 \tau} e^{i\theta I_y} A^{(k,0)}) \quad (\text{odd } k) \\ f_k(\theta, \alpha \tau) = \text{Trace}(e^{-i\theta I_y} e^{-3i\alpha I_z^2 \tau} \hat{I}_y e^{3i\alpha I_z^2 \tau} e^{i\theta I_y} A^{(k,0)}) \quad (\text{even } k). \quad (14)$$

Thus, $f_k(\theta, \alpha_1 \tau_1)$ is the coefficient of the k th-rank nuclear spin order during t . For example, $f_1(\theta, \alpha_1 \tau_1)$ and $f_2(\theta, \alpha_1 \tau_1)$ correspond to the Zeeman and quadrupole order, respectively. It is of note that $\cos \phi_{\text{eff1}} e^{i\phi_{\text{eff2}}} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2)$ (odd k) and $\sin \phi_{\text{eff1}} e^{i\phi_{\text{eff2}}} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2)$ (even k) are single-particle correlation functions connecting the local environments experienced by a nuclear spin during τ_1 and τ_2 .

For an ensemble of nuclear spins, an alignment echo forms at $\tau_2 = \tau_1$ if no motion occurs during t . On the other hand, atomic motion may induce the change of the local environments and destroy the single-particle correlation leading to the alignment echo decay. The k th-rank nuclear spin order created during t could decay as well during t with a decay rate of W_k induced by the NSLR mechanisms. Thus, following equation (13) the SAE echo height is described by

$$S_{\text{echo}}(t) = - \sum_{\text{oddk}} e^{-W_k t} \langle \cos \phi_{\text{eff}1} e^{i\phi_{\text{eff}2}} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2) \rangle \\ + i \sum_{\text{evenk}} e^{-W_k t} \langle \sin \phi_{\text{eff}1} e^{i\phi_{\text{eff}2}} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2) \rangle \quad (15)$$

with $\langle \rangle$ denoting the ensemble average. In metallic glasses, NSLR is usually dominated by the coupling between the nuclear spins and unpaired conduction electron spins. In this case, the evolution of $\hat{\rho}(t)$ can be described by:

$$\frac{d\hat{\rho}(t)}{dt} = J_1 [[\hat{\rho}(t) - \hat{\rho}_0, \hat{I}_+], \hat{I}_-], \quad (16)$$

with J_1 as a constant related to the magnetic properties of the spin system and $\hat{\rho}_0$ as the density operator at thermal equilibrium. Using the following identity

$$[[A^{(k,0)}, \hat{I}_+], \hat{I}_-] = k(k+1)A^{(k,0)}, \quad (17)$$

it is straightforward to obtain $\hat{\rho}(t)$ as

$$\hat{\rho}(t) = \hat{\rho}_0 + \sum_{k=0}^{2I} C_k e^{-k(k+1)t/2T_1} A^{(k,0)} \quad (18)$$

with C_k as the coefficients. Thus, $W_k = k(k+1)/2T_1$ which is true for other magnetic relaxation mechanisms as well. Since W_k varies with k , it is easier to extract the information about motion when only singular rank of nuclear spin order is created during t . In this case the $e^{-W_k t}$ factor of the chosen rank can be easily separated from the motion-related single-particle correlation functions by measuring T_1 .

In the presence of both a α distribution $\delta\alpha$ and a β distribution $\delta\beta$, it is in general difficult to produce a singular rank of spin order. If $\delta\beta \ll \delta\alpha$, τ_1 can be chosen such that $\delta\beta\tau_1 \ll \pi/2 \ll \delta\alpha\tau_1$. Then, odd-ranked spin orders can be created separately from even-ranked spin orders by choosing $\phi = 0^\circ$ (180°) for creating odd-ranked spin orders and $\phi = 90^\circ$ (270°) for creating even-ranked spin orders. Therefore, by selecting proper ϕ it is possible to produce pure Zeeman order or quadrupole order for $I = 1$. For $I = 3/2$, pure quadrupole order can be produced by choosing $\phi = 90^\circ$ (270°). On the other hand, the Zeeman order and octupole order cannot be separated. Equation (15) shows that the contribution of certain undesired nuclear spin orders can be suppressed also by the choice of the θ or θ' values based on the value of $f_k(\theta, \alpha\tau)$.

In Ref.²³ $f_k(\theta, \alpha\tau)$ ($k = 1, 2, \dots, 2I$) were derived explicitly based on the equation

$$e^{-i\alpha\hat{I}_z^n} \hat{I}_\pm e^{i\alpha\hat{I}_z^n} = \hat{I}_\pm [1 \quad \cos 2\alpha \quad \dots \quad \cos(2I-1)\alpha] \\ \times \begin{bmatrix} 1 & 1 & \dots & 1 \\ 0 & 2^2 & \dots & (2I-1)^2 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 2^{2I-1} & \dots & (2I-1)^{2I-1} \end{bmatrix} \begin{bmatrix} 1 \\ (1 \pm 2\hat{I}_z)^2 \\ \vdots \\ (1 \pm 2\hat{I}_z)^{2I-1} \end{bmatrix} \\ - i\hat{I}_\pm [\sin 2\alpha \quad \sin 4\alpha \quad \dots \quad \sin(2I-1)\alpha] \\ \times \begin{bmatrix} 2 & 4 & \dots & (2I-1) \\ 2^3 & 4^3 & \dots & (2I-1)^3 \\ \vdots & \vdots & \ddots & \vdots \\ 2^{2I-2} & 4^{2I-2} & \dots & (2I-1)^{2I-2} \end{bmatrix} \begin{bmatrix} (1 \pm 2\hat{I}_z) \\ (1 \pm 2\hat{I}_z)^3 \\ \vdots \\ (1 \pm 2\hat{I}_z)^{2I-2} \end{bmatrix} \quad (19)$$

for half-integer I ($I = 3/2, 5/2, 7/2, 9/2$) and on the equation

$$e^{-i\alpha\hat{I}_z^n} \hat{I}_\pm e^{i\alpha\hat{I}_z^n} = \hat{I}_\pm [\cos \alpha \quad \cos 3\alpha \quad \dots \quad \cos(2I-1)\alpha] \\ \times \begin{bmatrix} 1 & 1 & \dots & 1 \\ 1 & 3^2 & \dots & (2I-1)^2 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 3^{2I-2} & \dots & (2I-1)^{2I-2} \end{bmatrix} \\ \times \begin{bmatrix} 1 \\ (1 \pm 2\hat{I}_z)^2 \\ \vdots \\ (1 \pm 2\hat{I}_z)^{2I-2} \end{bmatrix} \\ - i\hat{I}_\pm [\sin \alpha \quad \sin 3\alpha \quad \dots \quad \sin(2I-1)\alpha] \\ \times \begin{bmatrix} 1 & 3 & \dots & (2I-1) \\ 1 & 3^3 & \dots & (2I-1)^3 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 3^{2I-1} & \dots & (2I-1)^{2I-1} \end{bmatrix} \begin{bmatrix} (1 \pm 2\hat{I}_z) \\ (1 \pm 2\hat{I}_z)^3 \\ \vdots \\ (1 \pm 2\hat{I}_z)^{2I-1} \end{bmatrix} \quad (20)$$

for integer I ($I = 1, 3$). It is interesting to note that by using

$$e^{-i\alpha\hat{I}_z^n} \hat{I}_\pm^n e^{i\alpha\hat{I}_z^n} = e^{-in(n-1)\alpha} \hat{I}_\pm^{n-1} (e^{-i\alpha\hat{I}_z^n} \hat{I}_\pm e^{i\alpha\hat{I}_z^n}) \quad (21)$$

and equations (19) and (20), a general formula for $e^{-i\alpha\hat{I}_z^n} \hat{I}_\pm^n e^{i\alpha\hat{I}_z^n}$ can be easily obtained.

For $I = 1$, $f_k(\theta, \alpha\tau)$ are given by

$$f_1(\theta, \alpha\tau) = -\sqrt{2} \sin \theta \cos 3\alpha\tau; \\ f_2(\theta, \alpha\tau) = \sqrt{\frac{3}{2}} \sin 2\theta \sin 3\alpha\tau. \quad (22)$$

Both $f_1(\theta, \alpha\tau)$ and $f_2(\theta, \alpha\tau)$ are suitable for detecting motion, although the maximized signal from $f_1(\theta, \alpha\tau)$ (Zeeman order) is larger. For $I = 3/2$,

$$f_1(\theta, \alpha\tau) = -\frac{1}{\sqrt{5}} \sin \theta (2 + 3 \cos 6\alpha\tau); \\ f_2(\theta, \alpha\tau) = -\frac{3}{2} \sin 2\theta \sin 6\alpha\tau; \\ f_3(\theta, \alpha\tau) = -\frac{3}{2\sqrt{5}} \sin \theta (5 \cos^2 \theta - 1)(1 - \cos 6\alpha\tau). \quad (23)$$

It is possible to create a pure Zeeman order by choosing $\phi = 0^\circ$ (180°) and $5 \cos^2 \theta = 1$ or $5 \cos^2 \theta' = 1$. In this case

$$S_{\text{echo}}(t) \propto e^{-t/T_1} \langle f_1(\theta, \alpha_1 \tau_1) f_1(\theta', -\alpha_2 \tau_2) \rangle \propto 4e^{-t/T_1} + \frac{9}{2} e^{-t/T_1} \langle \cos 6(\alpha_1 - \alpha_2) \tau_1 \rangle \quad (24)$$

Since motion affects the second term but not the first, almost half the resonance signal does not change after motion. Thus, the existence of two terms with different decay rates complicates the analysis. On the other hand, a pure quadrupole order can be created by choosing $\phi = 90^\circ$ (270°). Then, the SAE echo height is given by

$$S_{\text{echo}}(t) \propto \frac{9}{8} e^{i\phi'} e^{-W_2 t} \sin 2\theta \sin 2\theta' \langle \cos 6(\alpha_1 - \alpha_2) \tau_1 \rangle. \quad (25)$$

The signal is maximized at $\theta = \theta' = 45^\circ$. For $I = 5/2$,

$$\begin{aligned} f_1(\theta, \alpha\tau) &= -\frac{1}{\sqrt{70}}(9 + 16 \cos 6\alpha\tau + 10 \cos 12\alpha\tau) \sin \theta; \\ f_2(\theta, \alpha\tau) &= \frac{\sqrt{3}}{2\sqrt{7}}(4 \sin 6\alpha\tau + 5 \sin 12\alpha\tau) \sin 2\theta; \\ f_3(\theta, \alpha\tau) &= -\frac{1}{2\sqrt{5}}(-3 - 2 \cos 6\alpha\tau + 5 \cos 12\alpha\tau) \\ &\quad \times \sin \theta (5 \cos^2 \theta - 1); \\ f_4(\theta, \alpha\tau) &= \frac{5}{8\sqrt{7}}(-2 \sin 6\alpha\tau + \sin 12\alpha\tau) \sin 2\theta (1 + 7 \cos 2\theta); \\ f_5(\theta, \alpha\tau) &= -\frac{5}{64\sqrt{7}}(3 - 4 \cos 6\alpha\tau + 12 \cos 12\alpha\tau) \\ &\quad \times \sin \theta (15 + 28 \cos \theta + 21 \cos 4\theta). \end{aligned} \quad (26)$$

All $f_k(\theta, \alpha\tau)$ associated with odd-ranked nuclear spin orders contain a constant term as well as motion-related terms. As discussed above, this complicates the analysis when measuring the single-particle correlation functions of these spin orders. On the other hand, by choosing $\phi = 90^\circ$ (270°) and $1 + 7 \cos 2\theta = 0$ or $1 + 7 \cos 2\theta' = 0$, a pure quadrupole order can be created. The SAE echo height is then given by

$$S_{\text{echo}}(t) \propto \frac{6}{7} e^{i\phi'} e^{-W_2 t} \sin 2\theta' \sin 2\theta' \times \left\langle \cos 6(\alpha_1 - \alpha_2) \tau_1 + \frac{25}{16} \cos 12(\alpha_1 - \alpha_2) \tau_1 \right\rangle \quad (27)$$

5 DETECTION OF SLOW ATOMIC MOTION IN BULK METALLIC GLASSES BY NMR OF ^9Be

The ^9Be spectra of vit1 and vit4 consist of a narrow central line and a broad line (Figure 5). The broad line, with a field-independent $\Delta\nu_{1/2}$ of (100 ± 10) kHz, is associated with the satellite transitions ($3/2 \leftrightarrow 1/2$ and $-1/2 \leftrightarrow -3/2$) broadened by the first order quadrupole interaction. The central line, with $\Delta\nu_{1/2}$ as (6.1 ± 0.2) kHz at 9.4 T and (3.6 ± 0.1) kHz at 4.7 T, is associated with the central transition ($1/2 \leftrightarrow -1/2$) broadened by the Zeeman interaction distribution. The $K^{9\text{Be}}$ is negligible and $T_2^{9\text{Be}}$ about 1.5 ms.²⁴ Dominated by Korringa relaxation, $1/T_1^{9\text{Be}}$ is²⁴ proportional to T with

Figure 5 The ^9Be spectra of vit1 at 9.4 T. The broad line is shown more clearly by expanding the vertical scale by a factor of 3

$(TT_1)^{-1} = 0.00105 \text{ K}^{-1} \text{ s}^{-1}$. According to equation (18), the decay rate of the ^9Be quadrupole order is $3/T_1$ as demonstrated experimentally.²³

The ^9Be SAE pulse sequence is: $90_x^0 - \tau_1 - 45_{\pm y}^0 - t - 45_{\phi'}^0 - \tau_2 -$ with a short τ_1 ($6 - 15 \mu\text{s}$) to create a pure quadrupole order. Following equation (26), the SAE echo height is proportional to $f(t) = \langle \cos(\omega_1 - \omega_2) \tau_1 \rangle e^{-3t/T_1}$. $\omega_1 = 6\alpha_1$ and $\omega_2 = 6\alpha_2$, varying over a range of $2\pi \times 100$ kHz in vit1 and vit4, are determined by the truncated quadrupole interactions experienced by the spin during τ_1 and τ_2 , respectively. The featureless broad line shown in Figure 5 indicates that the characteristic powder pattern of the observed ^9Be spectrum in Be metal is smeared out in vit1 and vit4. It suggests a random distribution of quadrupole interaction, which is crucial for SAE to be effective in detecting motion. In glasses and supercooled liquids, the quadrupole interaction with respect to B_0 differs from site to site because of the disordered structure. Thus, single-atom jumps are expected to change ω randomly within its range which induces a reduction of $f(t)$. On the other hand, SAE is not sensitive to collective motion since the quadrupole interactions at Be sites change very little under collective translational motion involving Be atoms and most of their nearest neighbors. Also, SAE is not sensitive to restricted collective rotational motion with small rotation angle because $|(\omega_1 - \omega_2)|\tau_1 \ll 1$.

Fast data acquisition is crucial for studying thermal dynamics in metastable materials such as metallic supercooled liquids. In Refs.^{24,25} the pulse-spin locking technique was used to improve S/N. Following the ^9Be SAE pulse sequence, a train of 90° pulses are applied; the full sequence is $90_x^0 - \tau_1 - 45_{\pm y}^0 - t - 45_{\phi'}^0 - 2\tau_1 - 90_{\phi'}^0 - 2\tau_1 - 90_{\phi'}^0 - \dots - 90_{\phi'}^0 -$. Here, a train of echoes with the same origin and feature as the first alignment echo are detected and all echoes are accordingly summed up. The full sequence for measuring $1/T_1$, using the saturation recovery method with a comb and quadrupole echo detection sequence, is 'comb' - $t - 90_x^0 - \tau - 90_{\pm y}^0 - 2\tau - 90_{\pm y}^0 - 2\tau - 90_{\pm y}^0 \dots - 90_{\pm y}^0 -$. Using pulse-spin locking,

Figure 6 The temperature dependence of the atomic jump rate Ω and the diffusivity D in vit1 and vit4. D (scale on the right) and Ω (scale on the left) are plotted versus $1000/T$. A kink at 620 K, which is around T_g , is observed in the $D(T)$ curves in both vit1 and vit4. This kink is absent in the $\Omega(T)$ curves that follow the same Arrhenius behavior in both the supercooled liquid and glassy state

each ^9Be SAE decay curve and $1/T_1$ can be measured in several minutes. This enables the isothermal annealing study and the first NMR study in supercooled metallic liquids.

The ^9Be SAE echo decay curve measured at 620 K is shown in Figure 6 that is fitted by a single-exponential function $f(t) = e^{-t/T_{QE}}$. Such behavior is expected for atomic motion causing random changes of ω , where $1/T_{QE} = 3/T_1 + \Omega$ with Ω as the atomic jump rate. The observed single-exponential decay is inconsistent with constrained jumps between neighboring sites such as double-well potentials. It is consistent with unconstrained Be hopping assisted by thermal fluctuation of spread-out free volume.²⁴ In vit1 and vit4, the measured Ω follows Arrhenius behavior $\Omega(T) = \Omega_0 e^{-E_a/k_B T}$ with the fitted activation energy $E_a = (1.2 \pm 0.15) \text{ eV}$. Below 620 K, no annealing-time dependence of Ω is observed by SAE indicating that the measured Ω is intrinsic for the glassy state. The SAE measurements inferred that the Be diffusion process is via single-atom hopping.²⁴ In deeply supercooled liquids, the combine SAE and diffusion measurements indicated that two diffusion processes contribute to the long-range Be transport.²⁵ One is single-atom hopping. The other process is collective motion involving most of the nearest neighbors of Be atoms.

1 INTRODUCTION

Recourse to the NMR periodic table of spin isotopes reveals that about 75% of these nuclei possess a spin $I > \frac{1}{2}$, i.e., the spin isotopes known as the quadrupolar nuclei. Most quadrupolar nuclei (approximately 90%) have half-integer spin ($I = \frac{3}{2}, \frac{5}{2}, \frac{7}{2}, \dots$), and it is therefore not surprising that by far the largest number of solid state NMR studies of quadrupolar nuclei have involved half-integer spins, maybe with the exception of ^2H ($I = 1$). Magic angle spinning (MAS) NMR of quadrupolar nuclei made its breakthrough in the early 1980s, first of all thanks to the exploratory ^{27}Al and ^{23}Na MAS investigations by Müller et al.,¹ Oldfield et al.,² and Samoson and Lippmaa.³ Perhaps the best known MAS NMR spectrum for a half-integer quadrupolar nucleus is that of ^{79}Br in a KBr sample, which is used by almost every MAS NMR spectroscopist for adjustment of the magic angle.⁴ Since that time, MAS NMR studies of $I = \frac{3}{2}, \frac{5}{2}, \frac{7}{2}, \dots$ quadrupolar nuclei have constituted an increasingly important tool in solid state chemistry and materials research. In particular, ^{23}Na ($I = \frac{3}{2}$) and ^{27}Al ($I = \frac{5}{2}$) MAS NMR have played a significant role in studies of minerals, zeolites, catalysts, cements, and ceramics as evidenced by the numerous investigations in these fields.

For most half-integer quadrupolar nuclei (e.g., ^{23}Na and ^{27}Al), the quadrupolar coupling interaction is the predominant mechanism leading to strong line broadening in the solid state NMR spectra of powders. For a few other less commonly studied nuclei (e.g., ^{51}V , ^{59}Co , ^{85}Rb , ^{87}Rb , and ^{133}Cs), additional line broadening from chemical shielding anisotropy (CSA) becomes important, and may influence the appearance of their spectra.⁵ The line broadening of the individual transitions ($I \leftrightarrow I - 1, \dots, +\frac{1}{2} \leftrightarrow -\frac{1}{2}, \dots, -I + 1 \leftrightarrow -I$) from the quadrupolar interaction can be quantified in terms of the quadrupolar coupling constant $\chi = e^2qQ/h$ (i.e., the magnitude of the interaction) and the asymmetry parameter η ($0 \leq \eta \leq 1$), which characterizes the symmetry of the electric field gradients around the nucleus. For example, for an axially symmetric electric field gradient tensor ($\eta = 0$), the *satellite*

transitions (i.e., transitions other than $m = \frac{1}{2} \leftrightarrow m = -\frac{1}{2}$) give rise to characteristic quadrupolar splittings

$$\nu_Q = \frac{\chi}{4I(2I - 1)}(6|m| - 3) \quad (1)$$

between the ‘horns’ for the different symmetric $\pm m \leftrightarrow \pm(m - 1)$ transitions. From equation (1), it also follows that the maximum width of the spectrum for a spin- I quadrupolar nucleus, given approximately by $2\nu_Q$ for $|m| = I$, equals $3\chi/2I$.⁶ Therefore, for the complete spectrum of all transitions not to extend beyond a spectral width of, for example, 2 MHz it is required that $\chi \leq 2 \text{ MHz}$ for $I = \frac{3}{2}$ and $\chi \leq 3.3 \text{ MHz}$ for $I = \frac{5}{2}$, i.e. rather small quadrupolar couplings. On the other hand, the *central* ($+\frac{1}{2}, -\frac{1}{2}$) transition, which is not affected by the first-order quadrupolar splitting, has a much smaller linewidth than any satellite transition. Thus, this has been the most commonly observed transition in static and MAS NMR studies of half-integer quadrupolar nuclei.

The line-narrowing effect of MAS will split the satellite transitions into numerous spinning sidebands (ssbs; cf. the ^{79}Br MAS spectrum of KBr⁴) and *reduce* the width for the central transition by a factor of about 2.5–3 as compared with the static spectrum. Provided the spinning speed ($\nu_r = \omega_r/2\pi$) is larger than the CSA and dipolar interactions, MAS will greatly improve both resolution and sensitivity (S/N ratio) for the observed spectrum. In high-field NMR, the quadrupolar interaction is much smaller than the Zeeman splitting, and can be described by average Hamiltonian theory in the secular approximation.^{6,7} In this approximation, the central transition is perturbed only to second order by the quadrupolar interaction (see below).^{6,7} For polycrystalline powders, this leads to a characteristic lineshape, which is unaffected (or cannot be further narrowed) by increasing ν_r beyond the width of the lineshape.⁸ Provided ν_r is larger than this width, χ , η , and δ (the isotropic chemical shift) can easily be determined with good accuracy by computer fitting of the observed lineshape.⁶ As an example of the characteristic lineshapes that may be observed for the central transition at sufficiently high spinning speeds, Figure 1 shows a series of computer simulations for a spin $I = \frac{5}{2}$ nucleus (e.g., ^{27}Al) using $\chi = 5.0 \text{ MHz}$, $\nu_L = 104.2 \text{ MHz}$, and various η values ($0 \leq \eta \leq 1$). For comparison, the corresponding lineshapes for the static case are also shown. It should be noted that the total width of the MAS lineshape between the outermost shoulders/edges increases only slightly on increasing η , whereas the positions of the singularities, shoulders, and edges depend strongly on η . Furthermore, the widths of the lineshapes are proportional to χ^2 and inversely proportional to the Larmor frequency $\nu_L = \omega_L/2\pi$, i.e. to the magnetic field strength for a particular nucleus (see below).

From the above considerations one may draw the following qualitative conclusions.

1. For small quadrupolar couplings, the second-order contribution may be too small for the lineshape of the central transition to be resolved in the MAS spectrum. This would prevent determination of χ and η from this transition, which is usually the case for $\chi/[4I(2I - 1)] \lesssim 75 \text{ kHz}$ at $\nu_L = 100 \text{ MHz}$, i.e., $\chi \lesssim 0.9 \text{ MHz}$ for ^{23}Na and $\chi \lesssim 3.0 \text{ MHz}$ for ^{27}Al at 9.4 T. In such cases, the manifold of ssbs for the satellite transitions may be taken into full advantage, since it has been shown that accurate χ and η values may

Figure 1 Simulated static (left) and MAS (right) lineshapes for the central transition of a spin $I = \frac{5}{2}$ nucleus for various values of η and assuming $\nu_r = \infty$. All simulated spectra employed $\chi = 5.0$ MHz, $\nu_L = 104.2$ MHz (i.e., ^{27}Al at 9.4 T), and a Lorentzian line broadening of 100 Hz

be determined from computer fitting of the ssb intensity pattern observed on modern spectrometers equipped with fast receivers.^{6,9}

2. For much larger χ values than discussed in (1), the manifold of ssbs for the satellite transition may extend far beyond the maximum spectral width of the spectrometer and appear with heavily reduced intensities as compared with (1). In such cases, χ and η are most conveniently determined by computer fitting of the second-order quadrupolar lineshape observed for the central transition. Obviously, the availability of the maximum magnetic field strength and spinning speed will set the limit for the maximum χ value that can readily be determined for each nuclei by MAS NMR. This will be discussed further below.
3. For cases of intermediate χ values between (1) and (2), it may be possible to determine χ and η from computer analysis of both the manifold ssbs (1) and the lineshape for the central transition (2). In such cases, it turns out that the more accurate values are obtained from analysis of the ssb pattern (2).

Since the methods (1)–(3) outlined above for determination of χ and η all involve computer fitting of lineshapes and/or intensities from experimental MAS spectra, this puts high demands on the quality of the MAS probes, especially on the spinning performance. Thus, for the sample spinner systems the following requirements are important:

- (a) the highest possible spinning frequency ν_r for the largest possible sample volume of the rotor; ν_r values up to about 24 kHz have been achieved for small cylindrical (3.5 mm

outer diameter) rotors during recent years (see *Jakobsen, Hans J.: A Retrospect on the Development of High-Speed Sample Spinners for Solids since 1980* and *Doty, F. David: A Random Walk Toward High-Speed Sample Spinning*);

- (b) long term stability in ν_r ($\Delta\nu_r$ within a few hertz) at any spinning speed for a particular rotor size; this can be achieved by stabilizing the air-drive pressure mechanically (however, computer controlled rotor-speed stabilizers with $\Delta\nu_r \lesssim 1$ Hz are also available);
- (c) adjustability and long term stability of the magic angle (54.736°) to within about 0.001° ; this is of special importance when second-order lineshapes for the ssbs of the satellite transitions are subjected to computer simulations.

During the past decade, our laboratory has been intensively engaged in design/construction of spinner assemblies and CP MAS probes with special emphasis on fulfilling the requirements for studies of quadrupolar nuclei.^{10–12} In particular, the recent progress and positive development around real supersonic spinning systems (see *Jakobsen, Hans J.: A Retrospect on the Development of High-Speed Sample Spinners for Solids since 1980*) will have further impact on quadrupolar nuclei.

2 HAMILTONIAN FOR QUADROPOLAR NUCLEI IN MAS NMR

The underlying theory and development of a software package for simulation/fitting of MAS NMR spectra to different approximations under different experimental conditions have been described in detail in recent papers from our laboratory.^{5,6,9} In this description, the general Hamiltonian for a quadrupolar nucleus in a strong magnetic field $\mathbf{B}_0$ and subjected to an rf field $\mathbf{B}_1$,

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_Q + \hat{\mathcal{H}}_{\text{CSA}} + \hat{\mathcal{H}}_{\text{DD}} + \hat{\mathcal{H}}_{\text{rf}} \quad (2)$$

is approximated by the second-order average Hamiltonian for a Larmor period,

$$\hat{\mathcal{H}}(t) = \hat{\mathcal{H}}_Q^{(1)}(t) + \hat{\mathcal{H}}_Q^{(2)}(t) + \hat{\mathcal{H}}_{\text{rf}}(t) \quad (3)$$

where the Zeeman interaction representation (high-field NMR, $\hat{\mathcal{H}}_Z \gg \hat{\mathcal{H}}_Q$) is employed and $\hat{\mathcal{H}}_{\text{CSA}} + \hat{\mathcal{H}}_{\text{DD}}$ have been neglected (this is acceptable for most quadrupolar nuclei under MAS conditions).

Under MAS and in the second-order approximation, the first- and second-order terms of the quadrupolar interaction take the forms

$$\hat{\mathcal{H}}_Q^{(1)}(t) = \omega_Q^{(1)}(t)[3\hat{I}_z^2 - I(I+1)] \quad (4)$$

$$\begin{aligned} \hat{\mathcal{H}}_Q^{(2)}(t) = & \omega_Q^{(21)}(t)[-8\hat{I}_z^2 + 4I(I+1) - 1]\hat{I}_z \\ & + \omega_Q^{(22)}(t)[-2\hat{I}_z^2 + 2I(I+1) - 1]\hat{I}_z \end{aligned} \quad (5)$$

where the factors $\omega_Q^{(1)}(t)$ and $\omega_Q^{(2q)}(t)$ are time-dependent because of MAS, and are given by

$$\omega_Q^{(1)}(t) = \frac{2\pi\chi}{4I(2I-1)} \times \sum_{n=1}^2 [P_n^{(0)} \cos(n\gamma + n\omega_r t) + R_n^{(0)} \sin(n\gamma + n\omega_r t)] \quad (6)$$

$$\omega_Q^{(2q)}(t) = \frac{1}{2\omega_L} \left(\frac{2\pi\chi}{4I(2I-1)} \right)^2 \times \left\{ C^{(q)} + \sum_{n=1}^4 [P_n^{(q)} \cos(n\gamma + n\omega_r t) + R_n^{(q)} \sin(n\gamma + n\omega_r t)] \right\} \quad (7)$$

The time-independent coefficients $C^{(q)}$, $P_n^{(q)}$, and $R_n^{(q)}$ are functions of the asymmetry parameter η ($0 \leq \eta \leq 1$) and the Euler angles α and β ; expressions for these coefficients are given in Table 1 of Skibsted et al.⁶ The Euler angles (α, β, γ) relate the principal axis frame of the quadrupolar coupling tensor to the rotor fixed frame, and are defined according to the conventions of Spiess.¹³ Finally, for on-resonance excitation (X phase), the rf term is given by

$$\hat{\mathcal{H}}_{\text{rf}} = \gamma B_1 \hat{I}_x \quad (8)$$

and for an infinitely short (ideal) rf pulse, the expression for the total FID for a quadrupolar nucleus in a powder undergoing MAS has been derived:⁶

$$s(t) = \sum_{\alpha\beta\gamma} \sum_m p_m \exp[i\Phi_m(\alpha, \beta, \gamma; t)] \quad (9)$$

From equations (4)–(7), we note that the first- and second-order terms for the quadrupolar interaction can be written as

$$\begin{aligned} \hat{\mathcal{H}}_Q^{(1)}(t) + \hat{\mathcal{H}}_Q^{(2)}(t) = & [\hat{\mathcal{H}}_Q^{(1)}(t)]_{\text{time-dependent}} \\ & + [\hat{\mathcal{H}}_Q^{(2)}(t)]_{\text{time-dependent}} \\ & + [\hat{\mathcal{H}}_Q^{(2)}(t)]_{\text{time-independent}} \end{aligned} \quad (10)$$

since the two coefficients $C^{(1)}$ and $C^{(2)}$ in equation (7) are time-independent, i.e., independent of the spinning frequency. These time-independent second-order terms describe small frequency shifts depending on the Euler angles α and β , whereas the time-dependent second-order terms describe the distribution of intensity from the individual crystallites over the ssbs. It is the combination of these two second-order effects that introduces a unique lineshape not only for the central transition (and any possible ssbs) but also a unique and different lineshape for each ssb of the satellite transitions.

As mentioned above, we see from equations (6) and (7) that the first-order contribution $\hat{\mathcal{H}}_Q^{(1)}(t)$, which determines the width of the satellite transitions, is proportional to χ , while the second-order contributions are proportional to χ^2 and inversely proportional to ν_L .

2.1 Central Transition

The central $(+\frac{1}{2}, -\frac{1}{2})$ transition for half-integer quadrupolar nuclei has the largest transition probability,^{6,14} and is independent of the quadrupolar interaction to first order $[\hat{\mathcal{H}}_Q^{(1)}(t)]$. Therefore, it has the largest intensity and exhibits the most narrow spectral width of all transitions for a powder. However, provided χ is large enough, the linewidth will broaden and eventually give rise to the unique lineshape discussed above, because of the contribution from $\hat{\mathcal{H}}_Q^{(2)}(t)$. In addition to the ratio χ^2/ν_L for a particular I spin, the experimental observation of a well-defined second-order lineshape is very much dependent on the presence of other line-broadening mechanisms such as relaxation, crystallinity, a distribution of χ and η values within the powder, or paramagnetic impurities. Provided ν_r is greater than the width of the central transition, the ssbs from this transition are usually small. In such cases, there are only negligible differences between the lineshape of the observed centerband and the simulated (optimized) lineshape employing only the time-independent terms $C^{(1)}$ and $C^{(2)}$ of equation (7), i.e., simulations assuming infinite ν_r and displayed in Figure 1. Calculations in this approximation reduce to an expression that is equivalent to that originally derived by Samoson et al.⁸ These authors also produced graphs for the positions of the singularities (relative to the isotropic chemical shift)⁸ for the lineshapes (Figure 1). Good estimates of χ , η , and δ may be derived from these graphs for an observed spectrum (e.g., for starting parameters in a computer fitting of the experimental lineshape). When ν_r becomes similar to or smaller than the width of the central transition, decent simulations for comparison with the experimental spectra can only be performed by including all terms of equation (7) (both time-independent and time-dependent). This makes the simulations/fitting more difficult and time-consuming. Obviously, a straightforward determination of large χ values from MAS NMR of the central transition becomes very much dependent on the maximum spinning speed for the MAS probe employed, combined with the available magnetic field strength¹⁵ (see below).

2.2 Satellite Transitions

As opposed to the central transition, the appearance of the satellite transitions in MAS NMR first of all reflects the first-order $[\hat{\mathcal{H}}_Q^{(1)}(t)]$ quadrupolar interaction. The MAS NMR spectrum of these transitions consists of a manifold of ssbs with a maximum width approximately equal to $3\chi/2I$. The shape of the envelope for this symmetrical ssb pattern reflects the value of η .^{6,9} On modern spectrometers with maximum spectral widths of 2–4 MHz, the observation of this ssb pattern constitutes a very accurate method for the determination of small χ values ($\lesssim 4$ MHz). The effect of the second-order $[\hat{\mathcal{H}}_Q^{(2)}(t)]$ interaction is to introduce a unique

lineshape or (if unresolved) line broadening for each ssb. This lineshape (or broadening) differs for each ssb throughout the spectrum, and the shape of the n th sideband from the centerband also varies, depending upon ν_L . However, since the ratio of the second-order to first-order coefficients is proportional to $\chi/[4I(2I - 1)\nu_L]$ [equations (6) and (7)], and usually small (of order 10^{-3} for $\chi < 4$ MHz and $\nu_L \approx 100$ MHz, i.e., ^{23}Na and ^{27}Al at 9.4 T), the effect of the second-order terms on the integrated intensities for each ssb can be neglected. This is illustrated in Figure 2, which shows simulations of the ssb manifold for the satellite transitions of a spin $I = \frac{3}{2}$ nucleus with $\chi = 2.0$ MHz, $\eta = 0.0$, and $\nu_L = 105.8$ MHz (^{23}Na and 9.4 T) based on equation (9) with an infinite short (ideal) rf pulse. The simulation in Figure 2(a), which includes $\omega_Q^{(1)}(t)$ and all terms of $\omega_Q^{(2q)}(t)$, shows different peak heights for the symmetrical ($\pm n$ th) ssbs because of the lineshape for the individual ssbs induced by the time-dependent terms of $\omega_Q^{(2q)}(t)$. Examples of the lineshapes are apparent from the expansions in Figure 2(a). The simulation in Figure 2(b) uses $\omega_Q^{(1)}(t)$ and only the time-dependent terms of $\omega_Q^{(2q)}(t)$ (i.e., no lineshape but ‘true’ intensities for the ssbs), while the calculated spectrum in Figure 2(c) is based on the first-order terms [$\omega_Q^{(1)}(t)$] only. Comparison of the spectra in Figures 2(b) and 2(c) demonstrates that the first-order terms alone yield an excellent approximation for the ssb intensities. Thus, employing integrated intensities for each ssb in the experimental spectrum, it is unnecessary to include any second-order terms for determination of even quite large χ values by fitting of simulated to experimentally integrated ssb intensities. This not only greatly reduces computing time, but is also quite fortunate, since often the lineshapes of the ssbs are unresolved or distorted compared with the real MAS lineshape because of different line-broadening mechanism, small variations in spinning speed, or slight misadjustment of the magic angle. In particular, it should be noted that an incorrect setting of the magic angle (off by 0.01° or less) can have a dramatic effect on the lineshape of the ssbs¹⁶ as opposed to the effect on the lineshape for the central transition. Finally, it should be mentioned that in certain cases it may be of interest to perform the full simulations as in Figure 2(a) for comparison of experimental and simulated second-order lineshapes for the ssbs. Examples of the different types of simulated ssb patterns for comparison with experimental spectra may be found in Skibsted et al.^{6,9,17}

In view of the large spectral widths (megahertz range) generally required for the observation of all ssbs for the satellite transitions, it is expected that the assumption of ideal rf excitation and detection used in the simulations above (e.g., Figure 2) does not hold for the experimental ssb intensities. The reason is that maximum achievable rf field strengths are usually in the range $\gamma B_1/2\pi \approx 50$ – 100 kHz and that MAS probes are usually high- Q probes ($Q \approx 200$). However, as is apparent from our first simulations employing ideal rf excitation of experimental MAS satellite spectra,⁹ the effects of nonideal rf pulse excitation are not as serious as would have been expected based on earlier experiences of nonuniform rf excitation in static solid state NMR. The reason is that pulse imperfections (i.e., both phase and intensity errors) experienced by a particular crystallite and pulse imperfections for another crystallite are transmitted to a large part of ssbs across the spectrum because of the time dependence of the

quadrupolar interaction due to the sample rotation during acquisition. Our later work⁶ has evaluated the impact of nonuniform rf excitation on the first-order ssb intensities in MAS NMR of satellite transitions and also the effect of the Q factor of the probe during detection. Both effects tend to reduce the ssb intensities in the outer wings of the spectrum, and have been incorporated into the simulation software. For simulations including these effects and their excellent agreement with experimental ssb intensities, the reader is referred to the figures in Skibsted et al.⁶ (in particular Figures 2 and 6). From these results, it may be summarized that the main experimental implications to reduce phase and intensity errors are

1. on-resonance rf conditions for the center of the spectrum;
2. $\gamma B_1/2\pi \geq 40$ kHz;
3. a small pulse length ($\tau_p \lesssim 1 \mu\text{s}$), ensuring that $\tau_p \ll (1/\nu_L)$ and that the spectrum can be phased to positive absorption across the full spectral width ($1/\Delta t$) using a linear phase correction of $-360^\circ \times \tau_p/(2 \Delta t)$.

It should be noted that the discrepancy between the ideal and finite pulse spectra increases markedly on increasing τ_p , which is partly ascribed to transfer of magnetization into multiple quantum coherences.¹⁸ On the other hand, at least simulations indicate that the spectra are less sensitive to increases in the rf field strength in the normal range of $40 \text{ kHz} \leq \gamma B_1/2\pi \leq 100 \text{ kHz}$. Finally, it is our experience that the observation of a perfect symmetry of the ssb intensities for the satellite transitions around the center of the spectrum can be quite sensitive to the complete probe tuning circuitry (including filters, cable lengths, and the MAS probe itself). For example, changing lengths of the coaxial cables may slightly influence and can be used to improve the symmetry of the ssb intensities for the satellite transitions at different nuclear resonance frequencies.

3 APPLICATIONS OF HIGH-SPEED MAS NMR TO QUADROPOLAR NUCLEI

From the theoretical considerations and aspects discussed above, it is obvious that stable and high speed spinning performance for the MAS probe constitute a most important entity of the complete spectrometer system in determinations of quadrupolar coupling parameters employing MAS NMR. In addition these probe properties also play a decisive role in many applications of MAS NMR to quadrupolar nuclei in inorganic chemistry, geology, and materials research. In this section, we shall consider selected examples of the applications of high-speed MAS NMR; those of a straightforward, routine nature will be presented first, and will be followed by some examples of determination of large χ values.

3.1 Clay Minerals

The mixed-layer illite/smectite clay minerals constitute an important class of minerals that have been studied intensively by ^{27}Al MAS NMR since the early days of this technique. These minerals exhibit two central transitions in their ^{27}Al MAS NMR spectra: one each for octahedrally and tetrahedrally coordinated aluminum, Al(VI) and Al(IV); respectively. Generally, these studies aimed at a determination

Figure 2 Simulated MAS NMR spectra of the satellite transitions for a spin $I = \frac{3}{2}$ nucleus using $\chi = 2.0$ MHz, $\eta = 0.0$, $\nu_r = 10$ kHz, and $\nu_L = 105.8$ MHz (^{23}Na at 9.4 T). The calculations include (a) $\omega_Q^{(1)}(t)$ and all terms for $\omega_Q^{(2q)}(t)$, (b) $\omega_Q^{(1)}(t)$ and the time-dependent terms of $\omega_Q^{(2q)}(t)$, and (c) $\omega_Q^{(1)}(t)$ only. The second-order lineshape of the individual ssbs in (a), caused by the time-independent terms of $\omega_Q^{(2q)}(t)$, is clarified in the expansions

of the Al(IV)/Al(VI) ratios of the samples. However, the early determinations were severely hampered by the large number of ssbs for the central transitions (and therefore overlapping resonances) in the region of interest (0–70 ppm) because of the maximum $\nu_r \approx 4$ kHz employed prior to 1987. Furthermore, the intensities of these ssbs increase markedly with increasing content of paramagnetic impurities (especially Fe) of the samples.^{19,20} The advent of high-speed spinning ($\nu_r \approx 10$ kHz) caused a dramatic improvement in the simplicity for the spectra since the ssbs could now be significantly suppressed,²¹ and most importantly can be placed outside the region for the two centerband signals, even at the highest magnetic field strengths employed today. Provided the sample is excited by proper rf field strength and pulse length (i.e., a short and ‘hard’ pulse with flip angle $<15^\circ$),³ the resulting spectra allow quantitative assessment of the Al(IV)/Al(VI) ratios in a simple and accurate manner. Such determinations have been of particular interest in examining clays sampled from a depth of about 4000 m in the oilfields of the North Sea.²¹

3.2 Ultrastable Y Zeolites

Ultrastable Y (USY) zeolites represent an important class of catalytic materials, which are usually prepared by hydrothermal dealumination of Y zeolites with a framework Si/Al ratio of about 2.5. The structural changes accompanying this treatment have been intensively studied by ²⁹Si and ²⁷Al MAS NMR. ²⁹Si MAS NMR shows that the framework Si/Al ratio, $F(\text{Si/Al})$, a quantity strongly related to the degree of stabilization and catalytic properties, increases as a function of steaming temperature and time. On the other hand, the total bulk Si/Al ratio, as measured by X-ray fluorescence (XRF), remains virtually constant, even for highly dealuminated samples. Therefore, large quantities of nonframework aluminum (NFA) must be present in USY zeolites, and numerous studies have employed ²⁷Al MAS NMR in attempts to characterize and quantify the Al species in these materials.²² ²⁷Al MAS NMR spectra of USY zeolites are generally described as consisting of three signals: one at approximately 60 ppm, assigned to framework aluminum (FA), and one each at about 30 and 0 ppm attributed to NFA. In addition, the spectra exhibit a very broad hump below the three more distinct resonances—a feature that is especially pronounced in spectra of highly dealuminated samples. Quantification of the three ²⁷Al resonances in terms of the NFA% of the total Al content has consistently given too low values for the $\text{Al}^{\text{NFA}}/\text{Al}^{\text{total}}$ % in all attempts of such determinations. This led to the concept of ‘NMR-invisible Al’, which flourished in the literature for some time and has been associated in particular with NFA sites having large quadrupolar interactions.

It was not until recently, when we applied high-speed spinning, $\nu_r \approx 18$ kHz, to USY zeolites in a study at 9.4 T,²² that good consistency between the quantitative results ($\text{Al}^{\text{NFA}}/\text{Al}^{\text{total}}$ %) obtained by ²⁷Al MAS NMR and a combination of other methods (XRF and ²⁹Si MAS NMR) could be achieved. The effect of high-speed spinning on the ²⁷Al MAS NMR spectra of strongly dealuminated USY zeolites is to increase the intensities of all three resonances (0, 30, and 60 ppm) by different percentages. This intensity increase occurs at the expense of the broad hump, which is

completely eliminated (‘spun out’) only for $\nu_r \approx 18$ kHz at 9.4 T (see Figure 3 of Kellberg et al.²²). Thus, the results of high-speed spinning show that the NFA residing within the hump contributes to all three narrow resonances. This is consistent with a ²⁷Al–{¹H} cross polarization MAS study of the same zeolites, which shows that the NFA in USY zeolites consists of Al species possessing all three types of Al coordination: Al(IV), Al(V), and Al(VI). Further details on the nature of the NFA can be found in Kellberg et al.²² Thus, this technique appears a prerequisite and the most straightforward method for obtaining quantitative results of the different Al species in these catalysts.

3.3 Determination of ‘Large’ χ Values from the Central Transition at High Spinning Speeds

Perhaps the most important implication of high-speed spinning involves the determination of ‘large’ quadrupolar coupling constants χ from simulations of ‘undistorted’ second-order lineshapes for the central transition of half-integer quadrupolar nuclei. In this sense of the word, ‘undistorted’ means that ν_r is sufficiently large to place the first-order ssbs for the central transition just outside the region for the centerband. In such cases, the analysis/simulation of the experimental spectrum in terms of χ , η , and δ is usually straightforward. At lower spinning speeds, the central transition splits into complicated lineshapes, which are generally unamenable to spectral simulation and quantification—at least if χ and η are unknown. Obviously, a high-performance, high-speed spinning probe can be an economical alternative to a high-field spectrometer in such studies.¹⁵ In general, the condition for the observation of a distortionless centerband for a spin- I half-integer quadrupolar nucleus can be expressed as¹⁵

$$\chi^2(1 + \frac{1}{6}\eta)^2 \lesssim \frac{112\nu_L\nu_r I^2(2I-1)}{9(I + \frac{3}{2})} \quad (11)$$

Thus, employing $\nu_r = 20$ kHz and the highest magnetic field strength presently available (17.6 T), undistorted lineshapes for the central transition may be observed in ²³Na ($I = \frac{3}{2}$, $\nu_L = 198.4$ MHz) and ²⁷Al ($I = \frac{5}{2}$, $\nu_L = 195.4$ MHz) MAS NMR for χ values up to 7.8 and 15.8 MHz, respectively (assuming an intermediate value of $\eta = 0.60$).

As an illustrative example of the advantages of high-speed spinning in MAS NMR of quadrupolar nuclei at intermediate magnetic field strengths, we reinvestigated the ²⁷Al MAS NMR spectrum of 3CaO·Al₂O₃ (C₃A) at 7.1 and 9.4 T for ν_r up to 19 kHz.¹⁵ An earlier reported ²⁷Al MAS spectrum of C₃A, recorded at 11.7 T and $\nu_r \approx 7$ kHz, showed a poorly resolved and distorted spectrum for the central transition.²³ However, this spectrum was analyzed in terms of just one set of quadrupolar coupling parameters,²³ despite the fact that the unit cell of C₃A contains two nonequivalent AlO₄ groups according to XRD. In the early days (1987), with a maximum spinning speed $\nu_r \approx 10$ kHz for our MAS probes, we recorded the ²⁷Al MAS spectrum of C₃A [Figure 3(a)] at 7.1 T, using $\nu_r = 8.0$ kHz. At that time, this spectrum was far too distorted and complex for us to analyze. Following our development of a high-speed 4 mm rotor system,¹² we later recorded the 18–19 kHz ²⁷Al spectra shown in Figures 3(c) and 3(e) (on-

Figure 3 Experimental (a), (c), (e) and simulated (b), (d), (f) 78.2 MHz (7.1 T) ^{27}Al MAS NMR spectra of the central transition (including spinning sidebands) for C_3A obtained at different spinning speeds. For (a) and (b), $\nu_r = 8.0$ kHz, with the spectrum in (a) recorded in 1987 using a 7 mm rotor. For (c) and (d), $\nu_r = 18.7$ kHz (4 mm rotor), where resonances from the $(\pm\frac{3}{2}, \pm\frac{1}{2})$ satellite transitions have been included in the simulated spectrum (d). For (e) and (f), $\nu_r = 18.2$ kHz, obtained under a slightly off-MAS (about 0.2°) condition to suppress resonances from the $(\pm\frac{3}{2}, \pm\frac{1}{2})$ satellite transitions; these transitions are not included in the simulation (f). The parameters used for the simulated spectra are given in Skibsted et al.¹⁵ Positions of spinning sidebands and centerbands for the satellite transitions in the experimental spectra are indicated by asterisks (*)

and slightly off-angle, respectively). These spectra are easily analyzed in terms of two sets of χ , η , and δ values, as shown by the simulated spectra in Figures 3(d) and (f), which result from addition of two second-order lineshapes in a 1:1 ratio.¹⁵ With these parameters at hand, the simulated spectrum for $\nu_r = 8.0$ kHz in Figure 3(b) shows an excellent agreement with the originally recorded 'low-speed' spectrum in Figure 3(a).

Other research groups have similarly taken advantage of the combination of especially high magnetic field strengths with high-speed spinning for determination of 'large' χ values from observed second-order lineshapes of the central transition in ^{27}Al MAS NMR.^{24–26} Examples include the extensively studied mineral andalusite, which has been investigated at 11.7 T employing $\nu_r = 15$ kHz²⁴ and 18.4 kHz,²⁵ respectively, and at 14.1 T for $\nu_r = 14.8$ –19.5 kHz.²⁶

Another aspect of high-speed spinning in MAS NMR for the central transition(s) may be found in the important area of quantitative analysis. Examples include accurate determinations of (i) the relative number of multiple sites within the asymmetric unit of synthetic or natural minerals^{16,27} and (ii) the composition/identification of individual phases in phase mixtures.¹⁷ Such analysis may be greatly assisted by the information that can be gained from the observation of the ssb pattern for the satellite transitions.^{16,17,27}

3.4 Exactly On- and Slightly Off-MAS NMR of the Satellite Transitions

As pointed out and demonstrated for our first probe design with $\nu_r \approx 15$ kHz,¹¹ the possibility of high-speed spinning is important not only for the observation of the central transition but especially also in MAS NMR of the satellite transitions. The obvious reason is the increased sensitivity with which the individual ssbs for these transitions can be observed by increasing ν_r . Maybe just as important is the ability to adjust the magic angle accurately, because the correct second-order MAS lineshape (if observable) for each ssb is extremely dependent on an exact setting of the magic angle (see above). Thus, we have designed an adjustment device that allows very fine increments and stability in the angle adjustment.²⁸ Furthermore, ^{23}Na MAS NMR of the satellite transitions for NaNO_3 was proposed as a much more sensitive sample, as compared with ^{79}Br MAS NMR of KBr ,⁴ for accurately setting the magic angle.²⁸ In the ^{23}Na MAS NMR spectrum of NaNO_3 , no second-order lineshapes are observed for the ssbs^{6,9} and the linewidth of the individual ssbs can be narrowed down to between 0.7 and 0.8 ppm at the magic angle. Actually, the linewidth varies slightly throughout the ssbs of the manifold; the narrowest ssbs (approx. 0.7 ppm) are observed for

Figure 4 Expansion of part of the complex spinning sideband lineshapes observed for the ^{23}Na satellite transitions in NaNO_3 using slightly off MAS ($\Delta\theta = -0.44^\circ$) at 105.8 MHz (9.4 T): (a) experimental spectrum; (b) simulated spectrum calculated using $\nu_r = 6730$ Hz, $\Delta\theta = -0.44^\circ$, $\chi = 337$ kHz, and $\eta = 0.0$. Distortions from the central transition and its first few ssbs are observed near 0 kHz

the two ‘horns’ about ± 80 kHz from the center of the spectrum, whereas the broader ssbs (approx. 0.8 ppm) and the most sensitive to angle adjustment are found close to the central transition. Using these linewidths as a probe, it is our experience that the magic angle can be adjusted to better than 0.001° . Slightly off-MAS (i.e., with variable angle spinning VAS), the individual ssbs start splitting into complex lineshapes. For example, for an offset $\Delta\theta = -0.44^\circ$ in the angle adjustment, the very broad and complex lineshapes observed for the ssbs are shown for some of these as the expansion in Figure 4(a). These lineshapes depend on χ , η ($\chi = 337$ kHz, $\eta = 0.00$ for NaNO_3 ^{6,9}), ν_r , and the offset $\Delta\theta$, and can be simulated based on the first-order Hamiltonian alone, employing the correct angle for the spinning axis ($54.736^\circ + \Delta\theta$), as shown in Figure 4(b). Note that the width of the ssb lineshapes mainly reflects the degree of offset $\Delta\theta$, while the lineshapes themselves are determined by χ and η for the sample.

The observation and simulation of the slightly off MAS ^{23}Na NMR spectrum of NaNO_3 in Figure 4 suggest an alternative

method for the determination of χ and η that can be useful in certain situations. For ‘small’ χ values that do not give rise to an observable second-order lineshape for the central transition, χ and η are usually determined from analysis of the manifold of ssbs observed on large spectral widths (1–4 MHz), as discussed earlier. However, if a spectrometer with a fast receiver is not available, the observation of a limited number of ssbs (e.g., employing a 100 kHz spectral width) slightly off-MAS may allow determination of χ and η from lineshape analysis as illustrated in Figure 4.

4 OTHER SAMPLE ROTATION TECHNIQUES

In addition to the development and straightforward applications of high speed MAS for half-integer quadrupolar nuclei, the past decade has also witnessed the appearance and applications of several other sample rotation techniques for studies of such nuclei. These methods include double rotation (DOR)

(see *Double Rotation*) dynamic angle spinning (DAS) (see *Dynamic Angle Spinning*) (MAS) nutation NMR (see *Nutation Spectroscopy of Quadrupolar Nuclei*) and variable angle spinning (VAS) (see *Variable Angle Sample Spinning*). DOR NMR (see *Double Rotation*) especially appears a very promising method, particularly when combined with high speed MAS, in studies of multiple sites leading to overlapping MAS lineshapes for the central transitions.

1 INTRODUCTION

The introduction of the Hartmann–Hahn¹ technique of cross polarization into solid state nuclear magnetic resonance spectroscopy, particularly when combined with multiple pulse methods² to remove homo- and heteronuclear, dipolar broadening, was a significant addition to the methods available for the study of solid compounds by NMR. When cross polarization and proton decoupling were incorporated into the magic angle spinning technique,³ there was produced a significant enlargement of the repertoire of sensitive NMR spectrometric procedures available for obtaining high-resolution spectra of solid state compounds and materials.⁴ This important new spectroscopic method became known as cross polarization magic angle spinning (CP MAS) NMR. When the ¹³C spectra of compounds containing nitrogen were studied by CP MAS some lines appeared as broadened asymmetric doublets. It was soon realized that this characteristic lineshape resulted from the ¹⁴N nuclear quadrupole moment interfering with the ability of the magic angle spinning to average out the ¹³C–¹⁴N dipolar interactions. This interpretation was based on earlier observations of the ¹³C lineshapes of carbon nuclei bonded to nitrogen in the NMR of single crystals. We shall now briefly describe the main features of such high-resolution NMR spectra of single crystals to provide a suitable background for understanding the theoretical interpretation of the asymmetrical ¹³C–¹⁴N lineshapes in CP MAS spectra.

1.1 Single Crystal NMR Spectra

Within a short time after their introduction, the new NMR spectroscopic techniques were applied to obtain ¹³C chemical shielding data on a wide range of organic compounds. It was soon found in compounds containing a nitrogen nucleus adjacent to the carbon nucleus being studied that splittings

from ¹³C–¹⁴N dipolar couplings were observed. Griffin et al.⁵ found that the NMR spectrum of a single crystal of glycine at a certain orientation with respect to the magnetic field exhibited three lines from the methylene carbons split by adjacent ¹⁴N nuclei. In measurements of the ¹³C chemical shielding tensor in the metal complex K₂Pt(CN)₄Br_{0.3}·3H₂O, Stoll et al.⁶ observed large effects clearly shown to be caused by ¹⁴N quadrupolar interactions. In that compound, the electric quadrupolar interactions are of comparable size to the ¹³C–¹⁴N dipolar interaction; consequently, mixing with the pure Zeeman eigenfunctions occurs. These required eigenfunctions were obtained by the application of first-order perturbation theory and subsequent diagonalization of the combined Zeeman-quadrupole Hamiltonian. Stoll et al. assumed an axially symmetric electric field gradient tensor with its symmetry axis along the C–N bond. Good quantitative agreement was found between the theoretical and experimental spectral lineshapes for all the angular variations studied.

Because amino acids are of great biological importance, the observations of ¹³C–¹⁴N dipolar–quadrupolar interactions clearly meant that single crystal NMR spectra of amino acids would soon be investigated. Thus simultaneously there were reported such detailed studies of alanine⁷ and glycine.⁸ Though these two detailed single crystal studies cover similar ground, we shall give details about the more complete studies of alanine and use some of the theoretical ideas later in our discussion of the effects of ¹⁴N quadrupolar interactions causing asymmetry in certain magic angle spectral lineshapes of compounds with C–N bonds.

The proton-enhanced proton-decoupled ¹³C NMR spectra of a single crystal of L-alanine were studied by Naito et al.⁷ The C-α line showed a triplet pattern arising from dipolar coupling with the ¹⁴N (*S* = 1) nuclei (Figure 1). These splittings were asymmetric, especially in the *a*-axis orientation. The dipolar interactions in the presence of the ¹⁴N quadrupolar interaction were calculated by applying ideas first employed by VanderHart et al.⁹ to provide a theoretical analysis of the static proton resonance spectra of polycrystalline HMn(CO)₅ and HCo(CO)₄. The appropriate Hamiltonian for the case where the quadrupole asymmetry parameter *η* is zero is written in the following form for later convenience:

$$\mathcal{H} = -\gamma_N \hbar B_0 S_z + \frac{\chi \hbar}{4S(2S-1)} [3S_z^2 \cos^2 \theta + 3S_x^2 \sin^2 \theta + 3(S_z S_x + S_x S_z) \sin \theta \cos \theta - S^2] \quad (1)$$

where the quadrupolar coupling constant is $\chi = e^2 q Q / h$. This Hamiltonian was used to determine the required eigenfunctions of the ¹⁴N nucleus, and these in turn employed to calculate the eigenfunctions of the ¹³C–¹⁴N dipolar interaction as a function of *θ*, the angle between the direction of the external magnetic field and the symmetry axis of the electric field gradient tensor, i.e., the C_θ–N bond direction. It was thus possible to calculate the three ¹³C resonances predicted (and observed experimentally for the C-α nucleus) which correspond to the nitrogen Zeeman states | + 1⟩, | 0⟩, and | − 1⟩, respectively. When the sign of the quadrupole coupling constant was assumed to be positive, good agreement was found between the calculated and experimental data for all the angles studied. The experimental results thus give the sign of the quadrupole coupling constant.

Figure 1 Lineshape of the C- α nucleus in the ^{13}C CP MAS spectrum of polycrystalline L-alanine taken at a field of 4.6 T. 2 MAGIC ANGLE SPINNING

As is well known, MAS tends to average out anisotropic interactions to their corresponding isotropic values when they are very weak as compared with their Zeeman interactions. Theoretical consideration of the effect of the ^{14}N quadrupolar interaction on the ^{13}C MAS spectra based on the above ideas, show that for ^{13}C nuclei bonded to ^{14}N an asymmetric doublet pattern is expected. Lippmaa et al.¹⁰ reported that a high-resolution rotational-synchronized proton-enhanced magic angle spinning ^{13}C NMR spectrum of the polycrystalline solid of the one-dimensional compound tetrathiofulvalene-tetracyanoquinodimethane (TTF-TCNQ) exhibited a three-line spectrum, one line of which consisted of an asymmetric doublet which they attributed to the C-N group. The splitting was found to be field-dependent and identified as arising from dipole-dipole interaction with the ^{14}N nuclei having a quadrupole interaction of comparable magnitude to their Zeeman interaction. This was the first observation of an asymmetric lineshape in a ^{13}C magic angle spinning NMR spectrum of a compound containing a ^{13}C - ^{14}N bond.

3 EFFECTS OF AN AXIALLY SYMMETRIC ELECTRIC FIELD GRADIENT

The influence of spinning on the solid state NMR spectrum of a molecular system consisting of spin pairs in which one of the two spins has a quadrupole moment was first treated theoretically by Kundla and Alla.¹¹ The quadrupolar interaction fixes the spin moment at a definite orientation in the principal axis system (PAS) of the molecule. Rotation of the sample causes a rotational synchronized movement of the spin moment which does not permit the complete averaging of the dipole-dipole interaction between the spin- $\frac{1}{2}$ nucleus I and the quadrupole nucleus $S = 1$. The degree of the averaging depends on the ratio of the quadrupolar and Zeeman energies of the S nucleus.

The Hamiltonian may be written as

$$\mathcal{H} = \mathcal{H}_Z^I + \mathcal{H}^S + \mathcal{H}_D^{IS} \quad (2)$$

Here $\hat{\mathcal{H}}_Z^I$ is the Zeeman term of the I nucleus, $\mathcal{H}^S$ is the quadrupolar Hamiltonian, and $\mathcal{H}_D^{IS}$ the dipolar interaction

Hamiltonian between the I and S spins. It is assumed that $\mathcal{H}_D^{IS}$ is small so that first-order perturbation theory may be applied to calculate the resonance frequencies of the I -spin spectral lines. Because of the rotation of the sample at frequency ω_r , the eigenfunctions and eigenvalues of the unperturbed system become time-dependent. These were calculated for the case where the quadrupole coupling is symmetric. The energy levels were expressed in terms of parameters such as $k = \omega_Q/\omega_Z^S$; θ , the angle between the rotation axis and the magnetic field; the Euler angles α , β , and γ of the sample-fixed coordinate system, in which the α axis coincided with the rotational axis; and the PAS. When $\theta = 0$, the eigenvalue equations became the same as those giving the dependences of the spectral lines on the orientation of the nonrotating single crystal as described by Stoll et al.⁶ To obtain the lineshapes and resonances of the polycrystalline sample at high spinning speeds, the average positions, $\overline{\Delta_n^D}$, were obtained by averaging over all orientations represented by the angle β . Numerical calculations for the magic angle case showed that the line splittings and total widths depend strongly on the relative strengths of the Zeeman and quadrupolar interactions. Moreover, it was shown that in a strong magnetic field, the I -spin spectrum is an asymmetric doublet, one of the lines being the sum of two components, the full width of the single line being twice as large as that of the composite line. The splitting increased with increasing k leading to a regular triplet. The isotropic spin-spin interaction between the I and S nuclei was predicted to shift the I -spin spectral lines, the effect decreasing with increasing values of k .

Apparently unaware of the above work of the Estonian scientists, several groups reported CP MAS spectra of polycrystalline organic compounds containing C-N bonds such as amino acids, peptides, and proteins in which significant differences were observed between the solid state spectra and those in solution.^{12,13} Most of the resonances from carbons bonded to nitrogens were split into broadened doublets, and some of the resonances from more distant carbons were also affected.

A classical and much studied example is the CP MAS spectrum of polycrystalline alanine.¹⁴ The observed splittings of the asymmetric doublet of the C- α resonance was 45 Hz with a 200 MHz magnet and ~ 100 Hz when measured at 90 MHz. The spectra can be fully interpreted and quantitatively explained by the following theoretical treatment.¹⁴ First, the ^{14}N quadrupolar interaction is of comparable magnitude to the Zeeman interaction, so the ^{14}N spin eigenfunctions must be determined by diagonalizing the nitrogen Zeeman quadrupole Hamiltonian, and those eigenfunctions used in the calculation of the ^{13}C - ^{14}N dipolar interactions. At the outset it should be understood that in this problem it is important to be mindful of the timescale of the magic angle spinning. In the experiments described by Naito et al.¹⁴ the spinning frequency was 4.5 kHz, which is small compared with the ^{14}N quadrupolar interaction in L-alanine for which $\chi = 1.205$ MHz; the adiabatic approximation can therefore be employed to determine the nitrogen spin functions at time t from the following equation

$$\mathcal{H}_{ZQ}\psi_N(t) = E(t)\psi_N(t) \quad (3)$$

Here, $\mathcal{H}_{ZQ}(t)$ is the Zeeman quadrupole Hamiltonian of the nitrogen nuclei at time t . For the amino nitrogen in amino

acids and the cyano nitrogen in nitriles, one may assume with a high degree of accuracy that the electric field gradient tensor is axially symmetric, i.e., $\eta = 0$. Thus for the MAS spectrum of L-alanine we can write the Zeeman quadrupole Hamiltonian as

$$\begin{aligned} \mathcal{H}_{ZQ}(t) = & -\gamma_N \hbar S_z B_0 + \frac{\chi \hbar}{4S(2S-1)} [3S_z^2 \cos^2 \theta(t) \\ & + 3S_x^2 \sin^2 \theta(t) + 3(S_z S_x + S_x S_z) \sin \theta(t) \\ & \times \cos \theta(t) - S^2] \end{aligned} \quad (4)$$

Here, $\theta(t)$ is the periodic value of the angle between the field direction $\mathbf{B}_0$ and the internuclear vector $\mathbf{r}_{CN}$. Under MAS, when a rigid array of nuclei is rotated with an angular velocity ω_r about an axis inclined at an angle β to the direction of the external magnetic field $\mathbf{B}_0$, and at an angle β' to $\mathbf{r}_{CN}$, we may write that $\theta(t)$ can vary as follows:

$$\cos \theta(t) = \cos \beta \cos \beta' + \sin \beta \sin \beta' \cos(\omega t + \psi) \quad (5)$$

where ψ is the azimuthal angle of $\mathbf{r}_{CN}$ at time $t = 0$.

In this case the ^{13}C - ^{14}N dipolar interaction is very small compared with the Zeeman interaction, so first-order perturbation theory can be used to calculate the ^{13}C - ^{14}N dipolar interaction at time t . The dipolar splitting of the ^{13}C resonance resulting from that calculation using the Hamiltonian $\mathcal{H}_{ZQ}$ represented by equation (3) yields

$$\begin{aligned} \Delta E_i(t) = & -\gamma_C \gamma_N \hbar^2 / r_{CN}^3 \{ [a_i(t)^2 - c_i(t)^2] [1 - 3 \cos^2 \theta(t)] \\ & - (9/2)^{1/2} [a_i(t) + c_i(t)] b_i(t) \sin 2\theta(t) \} \end{aligned} \quad (6)$$

Here, $a_i(t)$, $b_i(t)$, and $c_i(t)$ ($i = 1, 2$, and 3) are the coefficients at time t of the Zeeman quantized spin functions of the nitrogen nuclei, namely, $|1\rangle$, $|0\rangle$, and $|-1\rangle$, respectively. In L-alanine the ^{13}C - ^{14}N dipolar interaction, 0.6636 kHz, is small compared with the spinning frequency 4.5 kHz, so in such cases the $\Delta E_i(t)$ have to be averaged from $t = 0$ to $t = \infty$ to obtain the ^{13}C - ^{14}N dipolar energy of the spinning sample. The values of $\Delta E_i(t)$ were calculated for each 5° of $\omega t + \psi$ in the range 0° to 360° with constant β' , and these values were then averaged to yield $\overline{\Delta E_{i\beta'}(t)}$. The theoretical lineshapes for polycrystalline samples rotating at the magic angle $\beta = 54.7^\circ$ are obtained by calculating the numerical values of $\overline{\Delta E_{i\beta'}(t)}$ when β' is varied in steps of 2° in the interval 0° to 90° , each $\overline{\Delta E_{i\beta'}(t)}$ being weighted by its probability $\sin \beta'$. Finally, convoluting the theoretical lineshapes with a Gaussian function gave the actual lineshape. The linewidth of the Gaussian function is an adjustable parameter which takes into account any instrumental line broadening, such as effects arising from improper decoupling setting, any slight misalignment of the magic angle, and any magnetic field inhomogeneities, etc.

As shown in Figure 1, the calculated and experimental spectra agreed well. Clearly the calculated lineshape is an asymmetric doublet with a splitting of 48 Hz for a ^{13}C resonance frequency of 50.3 MHz and 108 Hz for a resonance frequency of 22.6 MHz, both values in good agreement with experimental observations.^{12,14} This field-dependence of the asymmetric doublet splitting arises because a weak field causes a relative increase in the contributions from the off-diagonal elements of the matrix representation of the Hamiltonian

$\hat{\mathcal{H}}_{ZQ}(t)$. Noteworthy also was the finding that when the sign of the term $\chi \hbar$ in the lineshape calculation was chosen as negative, the shape was reversed, i.e., the intensity of the high-frequency (low-field) peak was now stronger than the other one. This observation thus presents a means of determining the sign of the quadrupole coupling constant of ^{14}N bonded to ^{13}C by lineshape analysis of the CP MAS ^{13}C NMR spectra.

When the spectrum of cyanoacetamide was studied the same theoretical treatment was applicable because here also the ^{13}C - ^{14}N dipolar interaction, 1.46 kHz, was smaller than the rotor spinning frequency. The lineshape exhibited a reversal of the intensities of the doublet components. When the value of $\chi \hbar$ was taken to be negative, the simulated lineshape was in good agreement with that observed experimentally. The splitting of the asymmetric doublet for the nitrile was 338 Hz in the simulated spectrum, in good agreement with the experimentally measured splittings of 305 Hz to 356 Hz for different cyano compounds.

The above theoretical treatment and the simulated MAS lineshapes were based on the important assumption that the rotor spinning speed was very small in comparison with the size of the quadrupole interaction of the ^{14}N nucleus in the molecule. It was, however, shown that if the spinning speeds were as large as the ^{14}N quadrupolar interaction (i.e., in the MHz range), which seems highly unlikely, the lineshape predicted is quite different from those obtained at low spinning frequencies. For the extremely high spinning frequency case, a truncated Zeeman quadrupole Hamiltonian $\hat{\mathcal{H}}_{ZQ}(t)$ (the time-dependent part is truncated) can be used for the MAS lineshape calculation. Using the same parameters as employed in the simulation of the spectra of nitrile compounds with a value of $\chi = 3.87$ MHz and 24 Hz for the halfwidth of the Gaussian broadening function, it was found that the predicted splitting is less than one-third of the slow-spinning case, giving a broad powder pattern as the expected lineshape.

Contemporaneously with the above work, Zumbulyadis et al.¹⁵ presented an extensive analysis of the influence of quadrupole nuclei on the magic angle spinning spectra of spin- $\frac{1}{2}$ nuclei. Here also, as above, the treatment was restricted to the case with an axially symmetric quadrupolar tensor. The formal theory described was similar to that described above; it also made use of the adiabatic approximation, in which a time-dependent wavefunction is approximated by an eigenfunction of the instantaneous Hamiltonian multiplied by a time-dependent phase factor. Theoretical powder patterns were calculated for a range of values of parameters typical of ^{13}C coupled to ^{14}N , the results being given as a function of ratio of the spin-1 Zeeman frequency Z to the quadrupole coupling constant χ . Each spectrum consisted of double-peaked bands with an intensity ratio of 1:2; the ratio of the S -spin Zeeman to the quadrupolar interaction (Z/χ) determined the widths of the bands and the splittings between them. This was also implicit in the theories of Naito et al.^{14,16} as was the finding that both the widths and splittings of the bands decrease at higher magnetic fields where the quadrupolar interaction induces less mixing of the S -spin Zeeman eigenstates. It was also shown that the appearance of the bands depended critically on the mutual orientations of the unique principal axes of the dipolar and quadrupolar interaction tensors, the doublet splitting going through a minimum when the two principal axes were oriented at the magic angle *with respect to each other*.

4 ¹⁴N EFFECTS OF AN ASYMMETRIC ELECTRIC FIELD GRADIENT

Though the above theoretical treatments^{14,15} were successful in providing an interpretation of the CP MAS ¹³C spectra of a number of nitrogen-containing compounds and, in particular, explaining the asymmetric lineshapes associated with C–N bonds, the restriction to cases with symmetric ¹⁴N quadrupolar tensors was limiting. When the quadrupole coupling parameter $\eta \neq 0$, the C–N bond direction may not be parallel to the principal axis of the quadrupolar tensor. In this situation the off-diagonal elements in the matrix representation of the Hamiltonian $\mathcal{H}_{ZQ}$ will contain η , and hence a large value of the quadrupolar asymmetry parameter will be quite effective in determining the resulting MAS lineshape.

To extend the theory to include the ¹³C CP MAS spectra of important organic molecules such as nitroanilines, and biomolecules like imidazoles, polypeptides, and proteins in which the influence of asymmetry of the ¹⁴N quadrupole coupling tensor may play an important role in determining the lineshapes of the spectra, it was necessary to extend the theoretical formulation though the basic ideas were still sufficient to permit the required extension to encompass a wider range of molecular environments.¹⁶

The adiabatic approximation represented by equation (2) is still used but the Zeeman quadrupole Hamiltonian for ¹⁴N must be modified to reflect the asymmetry of η , the nitrogen asymmetry parameter. The Hamiltonian is now written as

$$\mathcal{H}_{ZQ}(t) = -\gamma_N \hbar B_0 S_z' + \frac{eQq_{zz}}{4S(2S-1)} \times \{(3S_z'^2(t) - S^2) + \eta[S_x'^2(t) - S_y'^2(t)]\} \quad (7)$$

where $\eta = (q_{xx} - q_{yy})/q_{zz}$; eq_{ii} are the principal values of the electric field gradient tensor at the ¹⁴N nucleus in the compound. They obey the convention that $|q_{zz}| \geq |q_{yy}| \geq |q_{xx}|$. The quantity e^2Qq_{ii} ($i = x, y, z$) is one of the principal values of the quadrupole coupling tensor and e^2Qq_{zz} is the quadrupole coupling constant. In this case there are two different coordinate systems to be considered. The Zeeman coordinate system is specified by (x', y', z') , and the principal axis system coordinates of the ¹⁴N electric field gradient tensor of the compound by (x, y, z) . The Euler angles of the spinner rotation axes (x^R, y^R, z^R) are written as β' , θ , and ψ . The magic angle spinning axis, z^R , is inclined at an angle β' with the z axis, and at the magic angle β to the static magnetic field (Z'). The angle ψ is time-dependent and given by $\psi = \omega_r t + \psi_0$, where ψ_0 is the initial angle when $t = 0$ and ω_r is the angular velocity of spinning. Transformations of the coordinate systems (see Figure 2) give the ¹⁴N Zeeman quadrupole Hamiltonian in the Zeeman coordinate system, and the resulting eigenstates are used to calculate the ¹³C–¹⁴N dipolar energy. Since, in general, the internuclear vector r_{CN} is not collinear with the z axis of the electric field gradient tensor, its direction is defined by the polar angles (θ, ψ) in the principal axis system of the electric field gradient tensor. First order perturbation theory can again be used to calculate the ¹³C–¹⁴N dipolar energy of the ¹³C resonance of a certain

Figure 2 Diagrammatic representation of the coordinate transformations required to calculate the ¹³C lineshapes when the quadrupolar parameter η is asymmetric. They can be summarized as follows:

$$\begin{array}{ccccc} x, y, z & & x^R, y^R, z^R & & x', y', z' \\ \text{Principal} & \xrightarrow{(\beta', \phi, \psi)} & \text{Rotating} & \xrightarrow{(\beta, 0, 0)} & \text{Zeeman} \\ \text{axis system} & & \text{axis system} & & \text{axis system} \end{array}$$

molecular orientation at time t and is given by

$$\Delta E_{i\beta'\Phi}(t) = \langle \beta | \psi_N(t) | \mathcal{H}_D(t) | \beta \rangle \psi_N(t) - \langle \alpha | \psi_N(t) | \mathcal{H}_D(t) | \alpha \rangle \psi_N(t) \quad (8)$$

Here, $|\alpha\rangle$ and $|\beta\rangle$ are the ¹³C Zeeman spin functions. As before, the ¹³C–¹⁴N dipolar interaction is smaller than the spinning frequency, so $\Delta E_{i\beta'\Phi}(t)$ must be averaged over one rotor cycle, i.e., from $t = 0$ to $t = \infty$, to give the ¹³C–¹⁴N dipolar energy in the spinning sample, namely

$$\overline{\Delta E_{i\beta'\Phi}(t)} = (1/2\pi) \int_0^{2\pi} \Delta E_{i\beta'\Phi}(\psi) d\psi \quad (9)$$

The values of $\overline{\Delta E_{i\beta'\Phi}(t)}$ were calculated numerically for small increments of the appropriate angles and the resulting values averaged. The resulting theoretical averaged line positions for the spinning sample were weighted by their probability, $\sin \beta'$, and then convoluted with a suitable lineshape function to yield the actual lineshape.

One of the first compounds chosen to test the above theory for calculating the MAS lineshapes of molecules containing ¹⁴N nuclei with nonasymmetric quadrupolar tensors, i.e., with $\eta \neq 0$, was polycrystalline 2,6-dimethyl-3-nitroaniline. This molecule has two different types of ¹⁴N nuclei. The ¹³C MAS NMR spectrum showed that the resonances for both the nitro and amino carbon nuclei exhibited asymmetric doublet patterns (Figure 3). The high-frequency line in the nitro doublet was more intense than the other component, whereas the reverse was the case for the amino peak. Clearly the differences in the lineshapes arose from the different signs, orientations, and magnitudes of the respective electric field gradient tensors for the two ¹⁴N nuclei. Calculations of the theoretical lineshapes by the method outlined above using the appropriate molecular parameters and a reasonable assignment for the orientation of the ¹⁴N electric field gradient tensor based on that of *p*-nitrotoluene yielded lineshapes similar to those observed

Figure 3 Lineshape of the resonance of the carbon nucleus adjacent to the NO₂ group in the ¹³C CP MAS spectrum of 2,6-dimethyl-3-nitroaniline. Computer-simulated spectrum calculated with a quadrupolar asymmetry parameter $\eta = 0.408$ and (a) the ¹⁴N quadrupolar coupling constant $e^2Qq_{zz}/h = -1.340$ MHz; (b) the quadrupolar coupling assumed to be positive. (Reproduced by permission of Academic Press from Naito et al.¹⁶)

experimentally. With the value of χ being 1.340 MHz and $\eta = 0.408$ for ¹⁴N of the -NO₂ group, good agreement was found with the experimental lineshape only when the sign of the quadrupole coupling constant was taken as negative. The simulation of the lineshape of the amino peak required more insight. Values for χ , η , and $\gamma_C\gamma_N\hbar/(2\pi r_{CN}^3)$, based on literature information, were chosen to be 3.977 MHz, 0.263, and 0.8466 kHz, respectively. In the case where the z axis of the quadrupole coupling constant was chosen to lie normal to the plane of the NH₂ group and the y axis assumed to be tilted 40° from the C-N bond direction, with the sign of the quadrupole coupling constant negative the resulting simulated lineshape was in excellent agreement with that observed experimentally. Also, the calculated value for the doublet splitting was 110 Hz, in good agreement with the observed value of 102 Hz.

It proved more difficult to provide an unambiguous interpretation of the lineshapes of the ¹³C CP MAS NMR spectrum of polycrystalline glycylglycine and glycyl-L-alanine. Here again the orientation of the principal axes of the ¹⁴N quadrupole coupling tensor was unknown. Proceeding as before, the calculated lineshapes for the case where the z axis was assumed to lie along the direction of the N-H bond led to a narrow singlet pattern not in agreement with the experimental spectrum. When the z axis was chosen to be normal to the C-N-C plane and the y axis along the N-H bond, the simulated lineshapes again did not agree with the observed lineshape. Several possible orientations of the axes were tried, but only when the z axis of the quadrupole tensor of the amino nitrogen was assumed to lie along the C-N bond direction and the sign of the quadrupole coupling constant taken as positive, together with acceptable values of the other constants, was a satisfactory lineshape simulation obtained. Moreover, the calculated doublet splitting for the C- α carbon in glycylglycine was 49 Hz, which was in good agreement with the experimental value of 41 Hz.

Given the satisfactory simulations of the observed lineshapes from the theory for amino acids and polypeptides, attention was then turned to a more sophisticated molecule of biological interest, namely, trimethylimidazole. This molecule

has two different types of nitrogen nuclei. The quadrupole coupling constants and asymmetry constants of the two nitrogen nuclei are for N-1, $\chi = 1.424$ MHz and $\eta = 0.980$, and for N-2 $\chi = 3.267$ MHz and $\eta = 0.129$. The large difference in the two quadrupolar tensors for the two nitrogen nuclei is obviously mainly the cause of the notable difference between the lineshapes observed for the C-4 and C-5 carbon atoms in the CP MAS spectrum of ¹³C in this compound. Nevertheless, it was only possibly to simulate the experimental lineshapes successfully after a judicious choice of the orientations with respect to the molecular axes of the respective quadrupolar tensor axes.

Furthermore, this work clearly showed that in nitrogen-containing organic compounds, if the correct quadrupole coupling tensor and the relative orientations of the principal axes with respect to the molecular axes are known for a particular nitrogen nucleus, it is possible to calculate the theoretical lineshape for the carbon nucleus bonded to the nitrogen. That the sign of the quadrupole coupling constant for the nitro and amino nitrogen atom in organic compounds differed was new. Since each group containing a nitrogen atom has a characteristic quadrupole coupling tensor, it follows that the ¹³C resonances in the CP MAS NMR spectra of the carbon atoms in such groups, e.g., -NO₂, -NH₂, $\equiv$ N, -NH₃⁺, and -CN, all exhibit characteristic lineshapes. This information is obviously of considerable practical importance for the assignment of the solid state ¹³C CP NMR spectra of organic compounds, particularly those of biological importance and heterocyclic compounds, pharmaceuticals, dyestuffs, etc.

Another approach to calculating the lineshapes of the ¹³C MAS spectra of nitrogen-containing organic compounds was put forward by Hexem et al.¹⁷ This was based on writing the Hamiltonian of the spin system in terms of irreducible spherical tensor operators, namely

$$\mathcal{H} = \sum_{\lambda} \sum_l \sum_{m=-l}^l (-1)^m R_{l-m}^{\lambda} T_{lm}^{\lambda} \quad (10)$$

In this equation, λ represents the type of interaction, including the Zeeman interactions for the carbon, Z_C , and nitrogen spins, Z_N ; the quadrupole interaction of the nitrogen spin, Q ; D , the ¹³C-¹⁴N dipolar interaction; and CS , the chemical shielding of the carbon spins. The quantity J , the indirect spin-spin interaction, is ignored because it was assumed to be negligible. The rotational properties of the irreducible spherical tensors were used to obtain the Hamiltonian in a more convenient form. The time-dependence of the resulting Hamiltonian was removed by applying average Hamiltonian theory. The part of the average Hamiltonian representing the dominant interactions of the carbon atoms and which commutes with the appropriate Zeeman Hamiltonian can be written as

$$\begin{aligned} \mathcal{H}^C(\phi) = & C^Z \rho_{00}^Z T_{00}^Z + C^{CS} \rho_{00}^{CS} T_{00}^{CS} \\ & + \sum_{m=-2}^2 C^D (-1)^m R_2^D - (\phi) T^D 3_{2m} \end{aligned} \quad (11)$$

where $C^Z = \gamma_C \hbar$, $C^{CS} = \gamma_C$, $\rho_{00}^{CS} = \sigma_{iso}$, $T_{00}^Z = B_{00} I_z$, $C^D = -2\gamma_C\gamma_N\hbar^2$, and σ_{iso} is the isotropic chemical shift. Making use of Wigner rotation matrices, one set of Euler angles transforms the principal axis system of the dipolar interaction

to the principal axis system of the electric field tensor, while the angles $(0, \theta_M, \psi)$ transforms further the spatial components to the axis system of the spinning rotor. In this last transformation, θ_M is the magic angle (54.7°) and ψ is the azimuthal angle of rotation about the rotor axis.

The shifts in the energy levels of ^{13}C were calculated using zero-order average Hamiltonian theory, which is equivalent to first-order perturbation theory, this procedure being possible because the small size of the dipolar coupling means that it can be treated as a perturbation. Because of the relative orders of magnitude of the ^{14}N quadrupole coupling constant and the lower achievable spinning rates, one cannot use zero-order average Hamiltonian theory to average $\hat{\mathcal{H}}_{\text{CN}}^{\text{D}}$, the heteronuclear Hamiltonian over one rotational period. The ^{14}N matrix was diagonalized and the induced carbon shifts calculated. The carbon shifts were calculated for a sufficient number of points as described in the earlier theoretical treatments. These dipolar shifts were averaged over one rotation period $\overline{\omega_n^{\text{C}}}$ by numerical integration over the azimuthal angle of rotation, ϕ . This is equivalent to assuming the adiabatic approximation for calculating the change of the nitrogen states over the rotational period described in detail earlier by Naito et al.^{14,16} and by Zumbulyadis et al.¹⁵

As a preliminary test of theory, and to compare the results from diagonalizing the nitrogen Hamiltonian matrix with those obtained by using first-order perturbation theory to obtain the coefficients in the eigenfunction $\Phi_n^{\text{N}}(\phi)$ representing a linear combination of the Zeeman spin states, Hexem et al.¹⁷ calculated the expected powder ^{13}C spectrum for a C–N bond. Typical values of the parameters were used and the quadrupole coupling tensor was assumed to be axially symmetric with $\eta = 0$. When these theoretical predictions for the lineshapes were compared with the experimental observations for polycrystalline alanine, it was clear that the spectra lacked the resolution to show the fine structure predicted by the powder pattern. The calculated spectrum obtained using a value of 0.26 for the quadrupole asymmetry parameter, η , and taking its sign as positive was in good agreement with the experimental spectrum, in general accord with the findings of Naito et al.¹⁶

Explaining the ^{13}C lineshape of the α -carbon in *N*-acetylvaline was more challenging. In this case $\eta = 0.31$ and in the case of the polypeptide bond study of Naito et al.¹⁶ it was necessary to consider carefully the relative orientations of the principal axes of the electric field gradient tensor with respect to the molecular axes. Consideration of several orientations soon yielded a set of parameters which produced good agreement between the computer simulated lineshape and that observed experimentally.

The extensive studies of Hexem et al.¹⁷ and Naito et al.¹⁶ showed clearly that comparing the experimental and computer-calculated spectra provides a ready method for obtaining information concerning the relative orientations of the dipolar and electric field gradient tensors from the manifestations of the influences of those parameters on the ^{13}C NMR lineshapes. Moreover, such studies also enable the sign of the asymmetry parameter of the ^{14}N nucleus bonded to the carbon to be established. Also, as is clearly apparent from the theoretical treatments outlined earlier in this article, the extent of the splitting between the doublet peaks characteristic of the ^{13}C resonance of a C–N bond depends on the magnitude and the asymmetry parameter of the ^{14}N quadrupole tensor, the

internuclear distance, the strength of the applied magnetic field, and the orientation of the internuclear vector r_{CN} in the principal axis system of the electric field gradient tensor.¹⁸

Kundla and Alla¹¹ had earlier shown that the line splittings and total widths depended on the relative strengths of the Zeeman and quadrupolar interactions. The magnitude of the splitting is directly dependent on the dipolar interaction and the asymmetry parameter, which is different for differing values of the Euler angles defining its spatial orientation, with the Zeeman frequency of the ^{14}N nucleus being Z_{N} , the dipolar coupling $D = \gamma_{\text{C}}\gamma_{\text{N}}\hbar/4\pi^2 r_{\text{CN}}^3$, and the polar and azimuthal angles as β^{D} and α^{D} , the doublet splitting S is given by:

$$S = \frac{9}{20}(D\chi/Z_{\text{N}})(3\cos^2\beta^{\text{D}} - 1 + \eta\sin^2\beta^{\text{D}}\cos 2\alpha^{\text{D}}) \quad (12)$$

which is in terms of all the geometric ($r, \alpha^{\text{D}}, \beta^{\text{D}}$) and energy variables (χ, Z_{N}, η) up to first order in (χ/Z_{N}) . As a test of equation (13) the values of the splitting S predicted by that equation were plotted against the experimentally observed splittings for more than 20 compounds containing different types of C–N bonds.¹⁹ An excellent linear relationship was found which may, at first sight, seem surprising because of the wide range of different molecular species involved.

5 INFLUENCE OF J COUPLING

In the Hamiltonians used in all the theoretical treatments described, the term $\mathcal{H}_J$ representing the indirect J coupling was ignored. This was because the value of J_{iso} was expected to be so small that it would have little, or no effect, on the CP MAS lineshapes of ^{13}C – ^{14}N -containing compounds. The excellent agreements found between the experimental and theoretical lineshapes shows that this was usually an easily justifiable assumption. The inclusion of J coupling leads to the introduction of the term:²⁰

$$[-(\Delta J/3)(3\cos^2\beta^J - 1 + \eta\sin^2\beta^J\cos 2\alpha^J)] \quad (13)$$

where β^J and α^J give the orientation of the unique z axis of the $\mathbf{J}$ tensor in the PAS of the quadrupole tensor. To illustrate the effect of the J coupling, Figure 4 shows how the normal two-peak powder spectrum becomes a three-peak spectrum for the case of ^{14}N . The theoretical spectra were calculated from the computer program of Naito et al.,^{14,16} modified to include the term $\mathcal{H}_J$ in the Hamiltonian. The introduction of the indirect spin–spin coupling results in a splitting of the $m_{14\text{N}} = -1$ and $+1$ levels, while the $m_{14\text{N}} = 0$ peak is unaffected. In the calculations, the ^{14}N electric field gradient tensor was assumed to be axially symmetric with the largest principal component parallel to the ^{13}C – ^{14}N dipolar vector. A similar procedure was employed by Eichele and Wasylishen,²¹ though they used a different computer program based on the perturbation method to interpret and simulate the spectrum demonstrating the first observation of the indirect spin–spin coupling $^1J(^{14}\text{N}, ^{13}\text{C})$ effect which they discovered in the ^{13}C CP MAS NMR spectrum of $[(n\text{-C}_3\text{H}_7)_4\text{N}][\text{Cd}(\text{SCN})_3]$. Because of the excellent agreement found between the simulated and the experimental spectra they estimated the value of $^1J(^{14}\text{N}, ^{13}\text{C}) = 11 \pm 3$ Hz.

Figure 4 Diagrammatic representation of the effect of including the term $\mathcal{H}_J$ in the Hamiltonian before calculating the lineshape

6 OTHER SPIN- $\frac{1}{2}$ NUCLEI BONDED TO ^{14}N : ^1H CRAMPS

Protons are ubiquitous in nature and bond to many different types of nuclei. Of these the bonding to ^{14}N is important because N–H bonds are fundamental in the molecular composition of amino acids, polypeptides, and proteins. Unfortunately, the ^1H CP MAS spectra of such compounds were generally found to be lacking in structure because of the dipolar broadening caused by homonuclear interactions and magnetic shielding anisotropies. The introduction of the technique of combining sample rotation and multiple pulse NMR spectroscopy, the so-called CRAMPS procedure pioneered by Gerstein et al.,²² was a major innovative addition to the CP MAS methodology which considerably enlarged its range of applications, making it possible to obtain high-resolution proton spectra of hydrogen-containing solids many of which are of great industrial importance. When applied to solid amino acids the CRAMPS technique yielded proton CP MAS spectra in which there were identified²³ asymmetric peaks clearly arising from the ^1H – ^{14}N dipolar interaction and the ^{14}N quadrupole interaction not being averaged out, as earlier described for the analogous ^{13}C – ^{14}N case. The resolution of the characteristic asymmetric lineshapes varied with the type of multiple pulse sequence used. This was presumably because a faster spinning frequency was required to reduce the N–H dipolar interactions. In all cases, characteristic asymmetric doublets were observed for the ^1H – ^{14}N bonds, with the exception of the N-2 and N-3 nuclei in the imidazole ring of L-histidine hydrochloride monohydrate. Those two bonds exhibited broad asymmetric peaks, possibly being the result of strong hydrogen bonding.

The asymmetric peaks in the CRAMPS MAS spectra of amino acids were simulated by Naito et al.²³ using the computer programs based on the theoretical treatments

Figure 5 Lineshape of the CP MAS spectrum of a proton bonded to the peptide nitrogen nucleus in *N*-acetyl glycine. (a) Experimental spectrum obtained by using CRAMPS with the MREV-8 pulse sequence. (b) Computer-simulated spectrum obtained using a quadrupolar asymmetry parameter $\eta = 0.32$ and $e^2Qq_{zz}/h = -3.21$ MHz. (Reproduced by permission of the American Chemical Society from Naito et al.²³)

described earlier.^{14,16} In addition, it was necessary to multiply the quadrupole and Zeeman terms in the Hamiltonian by the scaling factors $S_m S_r$. The term S_m is the scaling factor for the multiple pulse scheme used, and $S_r = \frac{1}{2}(3 \cos^2 \theta - 1)$ is the scaling factor caused by a group rotation where θ is the angle between the rotation axis and the N–H direction. The lineshapes were simulated successfully. That of the peptide proton was well simulated (see Figure 5) using the ^{14}N coupling constant of -3.2 MHz and $\eta = 0.31$, the parameters having been determined in a single crystal ^{14}N NMR study on *N*-acetylvaline though the sign of the quadrupole coupling constant had been established previously from a comparison of the experimental and computer-simulated peptide carbon nuclei.¹⁶ In addition, it was necessary to interchange the assigned axes of the electric field gradient tensor so that the x axis was parallel to the N–H bond direction. The spectral peaks for the proton bonded to the imidazole nitrogen N nuclei were simulated using the ^{14}N coupling constants earlier determined from ^{14}N NMR single crystal studies. The simulated spectra showed that broad lines were to be expected and that a clear asymmetric doublet was not to be anticipated in this case. It was also to be expected that the proton bonded to the N-2 nucleus should have a broader lineshape than that for the N-3 nucleus. These predicted lineshapes were in good agreement with those observed experimentally.

The interesting ^{14}N -containing spin-pairs $^{14}\text{N} \equiv ^{15}\text{N}^+$ – and $^{15}\text{N} \equiv ^{14}\text{N}^+$ –yield unusual lineshapes.²⁴ It should also be mentioned that the ^{13}C MAS lineshapes of the parent compounds 5-methyl-2-[α - ^{15}N]diazobenzenesulfonic acid and its isotopomer with [β - ^{15}N] exhibit characteristic novel lineshapes. It was, however, possible to obtain approximate lineshape simulations for the ^{13}C – ^{14}N residual dipolar couplings even though the resulting ragged appearances of the simulations were clearly caused by the use of insufficient increments of the orientations of the angles β^Q and γ^Q in the calculations. Convolution of the two simulated spectra yielded a lineshape which was a good reproduction of the spectrum resulting from convoluting the observed ^{13}C MAS spectra of the two isotopomers. An apparent triplet lineshape was observed for the carbon nucleus bonded to the α - and β - ^{14}N nuclei of the diazo group, which arises from two different residual ^{13}C – ^{14}N dipolar couplings acting on the same carbon nucleus. It proved possible to simulate that feature.

Mention should be made of related studies of the lineshapes found for off-magic angle, or variable-angle, ^{13}C NMR spectra of compounds which exhibit ^{13}C – ^{14}N dipolar–quadrupolar interaction effects.²⁵ Though to some extent peripheral to the main thrust of this article, the phenomena described in those studies are of considerable interest.

1 INTRODUCTION

As explained in detail in *Magic Angle Spinning Carbon-13 Lineshapes: Effect of Nitrogen-14*, magic angle spinning does not always eliminate from spin- $\frac{1}{2}$ spectra the influence of dipolar coupling to quadrupolar nuclei. In particular, when quadrupolar energies are not negligible compared with Zeeman energies, spin- $\frac{1}{2}$ spectra may show splittings and/or lineshapes which arise from residual dipolar coupling to quadrupolar nuclei. This phenomenon was first discovered and thoroughly investigated for the (^{13}C , ^{14}N) nuclear pair, but it soon became apparent that the effect was more widespread, indeed ubiquitous. The present article will discuss a wide range of examples and will place particular emphasis on the perturbation approach, which is adequate to explain many cases. The discussion will be limited to the centers of gravity of what are, strictly speaking, powder bandshapes. The reader is referred to *Magic Angle Spinning Carbon-13 Lineshapes: Effect of Nitrogen-14* for details of more exact theory, for questions of powder bandshapes, and for all examples involving ^{14}N . The whole subject has received attention in a review article¹ which summarizes the theoretical approaches and also lists cases for many different nuclear spin pairs.

2 THEORETICAL BACKGROUND

Consider a pair of nuclei I and S , where the former has the spin quantum number $\frac{1}{2}$ and the latter is quadrupolar. For simplicity in this discussion, it will be assumed that the electric field gradient at S is axially symmetric, but the reader must be careful not to infer that the results below apply to the general case of $\mu \neq 0$. The phenomenon mentioned above can be traced to the influence of terms in the quadrupolar Hamiltonian involving nuclear spin operators other than $\hat{S}_z$. When Zeeman terms dominate, the energy levels of quadrupolar nuclei are properly characterised by the spin component quantum number m_S , associated with $\hat{S}_z$. Since the relevant Hamiltonian terms

have angular dependences $\frac{1}{2}(3 \cos^2 \theta_Q - 1)$, where θ_Q is the angle between the major principal axis of the quadrupolar tensor and the applied magnetic field ($\mathbf{B}_0$), their effects are averaged to zero by magic angle spinning at a fast enough rate. Moreover, in such circumstances, the only terms in the dipolar Hamiltonian connecting the quadrupolar nucleus with the spin- $\frac{1}{2}$ nucleus which are secular involve similar angular dependence $\frac{1}{2}(3 \cos^2 \theta_D - 1)$ where θ_D is the angle between $\mathbf{B}_0$ and the internuclear distance between the spin $\frac{1}{2}$ and the quadrupolar nuclei. Thus, magic angle spinning at a sufficiently high rate is enough to eliminate these dipolar interactions. Therefore, resonance frequencies in spin- $\frac{1}{2}$ MAS spectra are unaffected by dipolar interactions to quadrupolar nuclei in such circumstances. Similar considerations apply to anisotropy and asymmetry in the indirect ('scalar') coupling between a spin- $\frac{1}{2}$ nucleus and a quadrupolar nucleus: MAS suffices to remove the influence of such coupling components on the frequencies in the spin- $\frac{1}{2}$ spectrum, though the isotropic part of the coupling is retained.

However, when quadrupolar and Zeeman terms in the Hamiltonian become comparable, the situation is drastically changed. The detailed theoretical treatment using the full Hamiltonian is discussed in *Magic Angle Spinning Carbon-13 Lineshapes: Effect of Nitrogen-14*. Here, the perturbation treatment, which is frequently applicable, will be presented. The use of perturbation theory was pioneered by Olivieri and co-workers² for the (^{13}C , ^{14}N) case (though it was implicit in earlier treatments), and rapidly extended³ to situations involving higher-spin quadrupolar nuclei.

The spin- $\frac{3}{2}$ case is chosen here for illustration purposes. Consider the so-called 'alphabet expansion' of the dipolar and axially-symmetric quadrupolar interactions (Table 1). In the high-field approximation the Zeeman levels may be designated as $|m_S\rangle$, where $m_S = \frac{3}{2}, \frac{1}{2}, -\frac{1}{2}$ or $-\frac{3}{2}$. Under the influence of terms C , D , E , and F of the 'quadrupolar alphabet', these wavefunctions are mixed to become

$$|(-\frac{3}{2})'\rangle = |-\frac{3}{2}\rangle + a_1^* |-\frac{1}{2}\rangle - a_2^* |\frac{1}{2}\rangle \quad (1a)$$

$$|(-\frac{1}{2})'\rangle = -a_1 |-\frac{3}{2}\rangle + |-\frac{1}{2}\rangle + a_3^* |\frac{1}{2}\rangle - a_2^* |\frac{3}{2}\rangle \quad (1b)$$

$$|(\frac{1}{2})'\rangle = a_2 |-\frac{3}{2}\rangle - a_3 |-\frac{1}{2}\rangle + |\frac{1}{2}\rangle - a_1^* |\frac{3}{2}\rangle \quad (1c)$$

$$|(\frac{3}{2})'\rangle = +a_2 |-\frac{1}{2}\rangle + a_1 |\frac{1}{2}\rangle + |\frac{3}{2}\rangle \quad (1d)$$

where, in the perturbation approach, $a_1 = \langle \frac{1}{2} | \hat{\mathcal{H}}_Q | \frac{3}{2} \rangle / \gamma_s \hbar B_0$, $a_2 = \langle -\frac{1}{2} | \hat{\mathcal{H}}_Q | -\frac{3}{2} \rangle / 2\gamma_s \hbar B_0$ and $a_3 = \langle -\frac{1}{2} | \hat{\mathcal{H}}_Q | \frac{1}{2} \rangle / \gamma_s \hbar B_0$, etc.

The alphabet terms C and D are relevant for a_1 and a_3 whereas terms E and F are effective for a_2 . However, it can be shown that $a_3 = 0$ and that a_2 cannot affect the I spectrum. Now, because of the mixed nature of the Zeeman levels, terms C and D of the (I , S) 'dipolar alphabet' become secular, the additional energy contributions being

$$\begin{aligned} \langle (-\frac{3}{2})' m_I | \hat{\mathcal{H}}_D | (-\frac{3}{2})' m_I \rangle &= \langle (\frac{3}{2})' m_I | \hat{\mathcal{H}}_D | (\frac{3}{2})' m_I \rangle \\ &\quad - a_1 D m_I \end{aligned} \quad (2a)$$

$$\begin{aligned} \langle (-\frac{1}{2})' m_I | \hat{\mathcal{H}}_D | (-\frac{1}{2})' m_I \rangle &= \langle (\frac{1}{2})' m_I | \hat{\mathcal{H}}_D | (\frac{1}{2})' m_I \rangle \\ &\quad + a_1 D m_I \end{aligned} \quad (2b)$$

Table 1 The NMR Internal Hamiltonian: The Alphabet Expansion

Term	Geometric factor ^c	Spin factors ^c		
		Dipolar	Quadrupolar ^b	Connectivity
A	$1 - 3 \cos^2 \theta$	$\hat{I}_x \hat{S}_z$	$(\hat{I}_z)^2$	Secular
B	$-\frac{1}{4}(1 - 3 \cos^2 \theta)$	$\hat{I}_+ \hat{S}_- + \hat{I}_- \hat{S}_+$	$\hat{I}_+ \hat{I}_- + \hat{I}_- \hat{I}_+$	Flip-flop ^a
C	$-\frac{3}{2} \sin \theta \cos \theta \exp(-i\phi)$	$\hat{I}_x \hat{S}_+ + \hat{I}_+ \hat{S}_z$	$\hat{I}_z \hat{I}_+ + \hat{I}_+ \hat{I}_z$	Single quantum
D	$-\frac{3}{2} \sin \theta \cos \theta \exp(i\phi)$	$\hat{I}_x \hat{S}_- + \hat{I}_- \hat{S}_z$	$\hat{I}_z \hat{I}_- + \hat{I}_- \hat{I}_z$	
E	$-\frac{3}{4} \sin^2 \theta \exp(-2i\phi)$	$\hat{I}_+ \hat{S}_+$	$(\hat{I}_+)^2$	Double quantum
F	$-\frac{3}{4} \sin^2 \theta \exp(2i\phi)$	$\hat{I}_- \hat{S}_-$	$(\hat{I}_-)^2$	

^aSecular for the quadrupolar and homonuclear dipolar interactions, but nonsecular for heteronuclear dipolar interactions.

^bFor the axially symmetric case ($\eta = 0$).

^cThere are also constant numerical factors ($\hbar D$ for the dipolar case and $\hbar \chi / 2S(2S - 1)$ for the quadrupolar case).

where D is the dipolar coupling constant, $\gamma_I \gamma_S (\mu_0 / 4\pi) (\hbar / 2\pi) r_{IS}^{-3}$ (to be distinguished from the alphabet term D !). Therefore the energy levels are modified as shown in Figure 1, and the outer lines of the I multiplet will be shifted in one direction, while the inner lines will shift to the same extent but in the opposite direction. Of course the terms in the Hamiltonian also involve geometric factors which depend on the Euler angles connecting the dipolar and quadrupolar tensors with the magnetic field $\mathbf{B}_0$. Since these are *not* of the form $(3 \cos^2 \theta - 1)$, they are not eliminated by MAS although they are reduced. Thus each of the multiplet components in the I spectrum will be powder patterns under MAS. However, the structure of these powder patterns is not usually observed, and consequently the useful information normally comes from consideration of the centers of gravity of the bands. Of course the indirect coupling tensor $\mathbf{J}$ has some common features with $\mathbf{D}$, and therefore it will in principle also need to be considered.

Full evaluation for the general case results¹ in the following perturbation expression for the shift induced in the center of gravity of the spin- $\frac{1}{2}$ transition frequency associated with quadrupolar basis state m_S

$${}^2\Delta v(m_S) = \frac{3\chi}{20\nu_S} \left[\frac{S(S+1) - 3m_S^2}{S(2S-1)} \right] \times \left[Df(\alpha^D, \beta^D, \eta) - \frac{\Delta J}{3} f(\alpha^J, \beta^J, \eta) \right] \quad (3)$$

where $f(\alpha, \beta, \eta) = 3 \cos^2 \beta - 1 + \eta \sin^2 \beta \cos 2\alpha$, α and β are the relevant Euler angles (see Harris and Olivieri¹), η is the asymmetry in the electric field gradient, χ is the quadrupole coupling constant, ν_S is the Larmor frequency of the quadrupolar nucleus and ΔJ is the anisotropy in $\mathbf{J}$. The above equation assumes that $\mathbf{J}$ is an axially symmetric tensor. Simplifications result if there are further assumptions. In particular, if $\mathbf{J}$ and $\mathbf{D}$ are co-axial, and if η is ignored, the complete equation for the spin- $\frac{1}{2}$ transition frequency is

$$\nu(m_S) = \nu_I - m_S J_{\text{iso}} + \frac{3D'\chi}{20\nu_S} \left[\frac{S(S+1) - 3m_S^2}{S(2S-1)} \right] \quad (4)$$

where ν_I is the Larmor frequency of the spin- $\frac{1}{2}$ nucleus, J_{iso} is the isotropic part of $\mathbf{J}$, and D' is an effective dipolar coupling constant, incorporating the anisotropy in $\mathbf{J}$

$$D' = D - \frac{\Delta J}{3} \quad (5)$$

The second-order shift itself, $\nu(m_S) - \nu_I + m_S J_{\text{iso}}$, depends only on the square of m_S , and for $m_S = \pm S$ it is independent of S . It is therefore convenient to normalize effects to the shift of the 'outermost' lines, defined as

$$\Delta = -\frac{3}{10} \frac{\chi D'}{\nu_S} \quad (6)$$

This enables the second-order shifts of all lines to be written as

$${}^2\Delta v(m_S) = -\left[\frac{S(S+1) - 3m_S^2}{S(2S-1)} \right] \Delta \quad (7)$$

Table 2 lists the shifts of all lines, for various half-integral values of S , in terms of Δ .

Figure 1 Energy-level diagram for an IS nuclear spin pair with $I = \frac{1}{2}$, $S = \frac{3}{2}$ to show the perturbations induced by quadrupolar and dipolar interactions. The extent of the perturbations is greatly exaggerated. It is assumed that γ_I , γ_S , and J_{iso} are all positive

Table 2 Second-Order Shifts in the Spectra of Spin- $\frac{1}{2}$ Nuclei Arising from Coupling to a Half-Integral Quadrupolar Nucleus S^a

S	m_S				
	$\pm\frac{1}{2}$	$\pm\frac{3}{2}$	$\pm\frac{5}{2}$	$\pm\frac{7}{2}$	$\pm\frac{9}{2}$
$\frac{3}{2}$	-1	1			
$\frac{5}{2}$	$-\frac{4}{3}$	$-\frac{1}{3}$			
$\frac{7}{2}$	$-\frac{5}{2}$	$-\frac{1}{2}$	1		
$\frac{9}{2}$	$-\frac{7}{3}$	$-\frac{1}{3}$	$\frac{1}{3}$	1	
$\frac{11}{2}$	$-\frac{8}{3}$	$-\frac{1}{3}$	$-\frac{1}{6}$	$\frac{1}{3}$	1

^aNote: The values are normalized to the shift of the outermost lines as expressed in equation (6).

3 CONSEQUENCES OF PERTURBATION THEORY

A number of significant features can be understood from equations (3)–(7).

1. While perturbation theory holds, second-order shifts are inversely proportional to B_0 , so that no new information is obtained by using several spectrometers. However, such experiments can be used to check that the origin of splittings in the spectra does indeed involve second-order effects, since the behavior with B_0 differs from that of splittings caused by either J_{iso} or differences in chemical shifts.
2. Since second-order shifts depend on m_S^2 , their values occur in pairs, with the outermost multiplet lines moving most. Figure 2 illustrates the situation as a function of $\chi D/\nu_S$ when $\Delta J = 0$.
3. The average second-order shift is zero, so the isotropic chemical shift is simply obtained by averaging the frequencies of all the lines.
4. The isotropic coupling constant, $|J_{\text{iso}}|$, is also readily obtained as the average spacing between lines, though care must be taken if there is any crossover of frequencies. The value of $|J_{\text{iso}}|$ is also available from the central spacing $|\nu(m_S = \frac{1}{2}) - \nu(m_S = -\frac{1}{2})|$.
5. Since the innermost lines shift in the opposite direction to the effect on the outermost lines, there is a ‘bunching’ of lines at one end of the spectrum. The extent of coalescence is more apparent for lower values of S for a given $\chi D/\nu_S$. The sense depends on the sign of Δ , and in favorable cases it gives important information on relative signs.
6. In particular, if $\mathbf{J}$ and $\mathbf{D}$ are co-axial the following general rule results: ‘bunching’ occurs to low frequency (i.e. Δ is positive) if *either* χ is negative (with D and D' of the same sign) *or* χ is positive (with D and D' of opposite signs). An analogous statement can be made if Δ is negative. This rule takes into account the effects of signs of magnetogyric ratios. Thus, if the magnitude and sign of χ is known, together with r_{IS} , and if η is ignored, then ΔJ can be derived unambiguously. However, if only r_{IS} and $|\chi|$ are available, two possible values of ΔJ can be calculated but they cannot be distinguished.
7. When perturbation theory holds, neither the magnitude nor the sign of J_{iso} influences Δ .
8. If the value of $|J_{\text{iso}}|$ is negligible compared to linewidths, then there will be $S + \frac{1}{2}$ lines. The relative frequencies at which ‘bunching’ takes place will give the sign of χ . The magnitude of Δ will enable r_{IS} to be determined if $|\chi|$ is known, and vice versa. However, $S = \frac{3}{2}$ is a special

Figure 2 Second-order shifts in spin- $\frac{1}{2}$ MAS spectra arising from coupling to a quadrupolar nucleus S , as a function of the parameter $\chi D'/\nu_S$ under a perturbation approach according to equation (7): (a) $S = \frac{3}{2}$; (b) $S = \frac{5}{2}$. A positive value of Δ is assumed

Figure 3 Second-order shifts in spin- $\frac{1}{2}$ MAS spectra arising from coupling to a quadrupolar nucleus $S = \frac{3}{2}$ as a function of the parameter $\chi D'/\nu_S$ under a perturbation approach according to equation (7): (a) $J_{\text{iso}} = 0$; (b) $-J_{\text{iso}} > 0$. A positive value of Δ is assumed

case, since a 1:1 doublet will be seen [Figure 3(a)], of spacing $\frac{3}{10}(\chi D/\nu_S)(3 \cos^2 \beta^D - 1 + \eta \sin^2 \beta^D \cos 2\alpha^D)$ in the general case, and information on the sign of χ is lost.

9. The same denominator in equation (7) reflects the fact that the validity of the perturbation approach depends on $\chi/2S(2S - 1)\nu_S$, higher spins are more accurately treated than lower spins for equivalent values of χ .

4 RESULTS AND DISCUSSION

Many examples are now known where perturbation theory is reasonably applicable. In particular, the (^{119}Sn , $^{35/37}\text{Cl}$) situation is appropriate^{3,4} since in such cases $|\chi|$ is generally modest (~ 35 MHz). Thus even for a 4.7 T spectrometer, the perturbation parameter $\chi/2S(2S - 1)\nu_S$ is only in the region of 0.30. The splitting arising from $|J_{\text{iso}}|$ cannot be ignored. However, since chlorine is monovalent, coaxiality of $\mathbf{J}$ and $\mathbf{D}$ is a reasonable approximation for directly-bonded Sn–Cl groups except when chlorine is in a bridging situation. In fact,

Figure 4 Tin-119 CP MAS NMR spectra at 74.63 MHz for (a) $(\text{PhCH}_2)_3\text{SnCl}$ and (b) Et_2SnCl_2 , showing the second-order effects of coupling to the chlorine nuclei.⁴ The markers are at 1 kHz and 0.5 kHz intervals for (a) and (b), respectively

a typical spectral pattern is a 1:1:2 triplet with relative spacings 2:1 [Figure 4(a)], which is strictly the case only when $|J_{\text{iso}}| = 2\Delta$. Values of $|J(\text{Sn}, \text{Cl})|$ have therefore been derived, as have approximate data for ΔJ . When more than one chlorine is coupled to the same Sn, simple convolution suffices to predict the spectral appearance. If the chlorines are equivalent, then $|J_{\text{iso}}| = 2\Delta$ leads to a 1:2:4:1:4:4 multiplet (with the first spacing twice the others), such as has been observed [Figure 4(b)] for Et_2SnCl_2 .⁴

Cases involving ^{31}P coupled to metal nuclei are also common, and have been shown^{5,6} to occur for a range of S -spin metals, e.g. $^{63/65}\text{Cu}$ ($S = \frac{3}{2}$), ^{55}Mn ($S = \frac{5}{2}$), ^{59}Co ($S = \frac{7}{2}$), and ^{93}Nb ($S = \frac{9}{2}$). Figure 5 shows an example where the second-order effects are relatively small. In a number of such cases perturbation theory is not appropriate, and in others questions of nonaxiality reduce the usefulness of the observed second-order effects. However, the case of $\text{Mn}_2(\text{CO})_9\text{PPh}_3$ proved⁶ to be appropriate, since the molecular symmetry has axiality and spinning sideband analysis indicates that this is retained in the solid state. Such an analysis also gives a value for $|D'|$, so that $|\chi|$ can be derived (42 MHz). The value of $\chi/2S(2S - 1)\nu_S$ for a spectrometer operating at 7.1 T is thus 0.028, which confirms that perturbation theory is applicable. Several (^{31}P , $^{63/65}\text{Cu}$) examples have been analyzed⁷ using perturbation theory to yield data for $\Delta J \sim 0.6$ kHz.

Numerous other examples of residual dipolar coupling have been reported, some of which come into the category of a perturbation treatment. In particular, examples of (^{13}C , ^2H) have been given.^{1,8,9} Although ^2H has a low value of χ , the residual effects of dipolar coupling are appreciable because r_{CH} is small and hence D is relatively large. With rigid molecules,^{1,8} there is a nice contrast to the (^{13}C , ^{14}N) case since, although 2:1 doublets are observed in both instances, the origins differ. For the (^{13}C , ^{14}N) pair J_{iso} can usually be ignored, so there is overlap for the lines connected to states $|+1\rangle$ and $|-1\rangle$ for ^{14}N , whereas for (^{13}C , ^2H), the overlap is of transitions involving $|0\rangle$ and $|-1\rangle$ for ^2H . The latter situation arises coincidentally because $|J_{\text{iso}}(^{13}\text{C}, ^2\text{H})|$ is approximately equal to $\frac{9}{10} D\chi/\nu_S$. The spectra have a different appearance⁹ for inclusion compounds of urea and thiourea with deuterated guest molecules, such as straight-chain alkanes and corresponding carboxylic acids. The guest molecules are relatively mobile, so that values of $\chi(^2\text{H})$ are substantially reduced (to ca. 50–70 kHz for CD_2 groups) by averaging. Second-order effects on the ^{13}C spectra are therefore relatively modest, simply resulting in a small asymmetry in the splittings

Figure 5 Phosphorus-31 CP MAS NMR spectra at 81.0 MHz for $(\text{C}_5\text{H}_5)(\text{Me}_3\text{P})\text{Cl}_2\text{Nb}=\text{N}(o\text{-tBuC}_6\text{H}_4)$, showing the second-order effects of coupling to the niobium nucleus: the multiplet spacing decreases slightly from high to low frequency. The lines outside the main decet are spinning sidebands. The markers are at 1 kHz intervals

of the 1:2:3:2:1 quintet patterns. The spectra can be used to determine, at least qualitatively, the relative values of χ at different positions in a chain, which in turn depend on variations in local molecular mobility.

Of course, the appearance of splittings arising from either dipolar coupling, whether residual or full, or indirect coupling is contingent upon the lifetimes of the quadrupolar spin states being long compared with the frequency separations in the spin- $\frac{1}{2}$ spectra. If spin-lattice relaxation times of the quadrupolar nuclei become sufficiently short, the result is 'self-decoupling' (such as is frequently observed in solution state situations). In such cases a single line will be seen in the spin- $\frac{1}{2}$ spectrum. This is the situation¹⁰ for the ^{31}P spectrum of PCl_5 where sharp singlets are observed for the PCl_4^+ and PCl_6^- ions at room temperature but multiplets at low temperature. Of course, molecular motion (e.g. rotation of ions, as for PCl_5) may affect residual dipolar splittings both directly (by averaging D) and indirectly (by relaxing the S nucleus). 'Self-decoupling' can in principle also occur because of chemical exchange involving I - S bond breaking.

5 DEPARTURE FROM PERTURBATION THEORY

The first clear case of effects of dipolar coupling residual which did not involve the (^{13}C , ^{14}N) nuclear pair concerned the (^{31}P , ^{63}Cu) nuclei in bis(triphenylphosphine)copper(I) and related complexes, presented by Menger and Veeman.⁵ These authors published detailed theory, but the situation was beyond the validity of perturbation theory. Many examples involving the (^{31}P , ^{63}Cu) pair have since come to light, though some are susceptible to the perturbation approach.

The (^{13}C , $^{35/37}\text{Cl}$) case is interesting.^{11,12} Although there are simplifying features, since chlorine is univalent (and hence coaxiality of $\mathbf{J}$ and $\mathbf{D}$ can be assumed) and $J(\text{C}, \text{Cl})$ is negligibly small, the value of $|\chi|$ is sufficiently large (ca.

Figure 6 Carbon-13 CP MAS NMR spectra of sodium monochloroacetate: (a) 75.4 MHz; (b) 50.3 MHz, showing the second-order effects of coupling to chlorine.¹² The insets show expansions of the carboxyl region. The asterisks denote spinning sidebands

–70 MHz) that departures from perturbation theory can be observed. At modest magnetic fields (7.1 T and above), the 1:1 doublet predicted by perturbation theory is indeed observed [Figure 6(a)], but the splitting is smaller than predicted and is not inversely proportional to B_0 . However, it has been shown¹³ by simulation using exact theory that for the case $S = \frac{3}{2}$ the doublet splitting, s , can be adequately represented in the range $0.8 < R = |\chi/\nu_S| < 3.0$ by the cubic polynomial

$$s = D(0.581R + 0.033R^2 - 0.021R^3) \quad (8)$$

A cubic equation for s has also been derived for the $S = \frac{3}{2}$ case in which J_{iso} cannot be ignored.

For the (^{13}C , $^{35/37}\text{Cl}$) case, even equation (8) is inadequate at 4.7 T, since a broad 2:1:1 triplet is both predicted and observed^{11,12} [Figure 6(b)]. Figure 7 shows the theoretical line positions (centers of gravity) as a function of R for the case $I = \frac{1}{2}$, $S = \frac{3}{2}$ for positive χ and in the absence of $\mathbf{J}$. At high values of R , four lines are expected, and this links up with the expectation from inverse perturbation theory discussed below.

Molecular-level motion has a drastic effect on the ^{13}C spectra of sodium chloroacetates.¹² For the monochloro compound a clear doublet is seen for both the CH_2Cl and carbonyl carbons at 7.1 T and above, with the expected 2:1:1 triplet at 4.7 T. However sodium trichloroacetate shows a sharp line for each carbon at 7.1 T, not only at room temperature but also down to 163 K. The reason for this behavior undoubtedly lies in the facile internal rotation of the $\text{C}-\text{CCl}_3$ group.

Figure 7 Line positions (centers of gravity, units of D) for a spin-1/2 nucleus coupled to a spin-3/2 nucleus as a function of $R = \chi/\nu_S$ as obtained¹³ by the full theory for positive χ and assuming $J_{\text{iso}} = \Delta J = \eta = \beta^D = 0$

When J_{iso} needs to be taken into consideration and perturbation theory is inadequate, it has been shown¹³ that the sign of J_{iso} can be obtained from the spectrum (if the sign of χ is known). Thence $J(^{63}\text{Cu}, ^{31}\text{P})$ has been found¹³ to be negative.

6 QUADRUPOLEAR COUPLING DOMINANT

Olivieri has considered^{14,15} the case where the quadrupole coupling constant is very large. The dipolar and indirect couplings will still transfer the quadrupole information to the spin- $\frac{1}{2}$ nucleus under MAS conditions, giving rise to splittings in the spectra. For the case where $\mathbf{J}$ is axially symmetric and the three tensors $\mathbf{D}$, $\mathbf{q}$, and $\mathbf{J}$ are all co-axial, Olivieri showed¹⁴ that a quartet results when $S = \frac{3}{2}$. Each component is a powder pattern, with the centers of gravity forming two doublets with splittings, independent of the applied magnetic field, given by

$$s(\pm\frac{1}{2}) = |1.709J_{\text{iso}} + D'| \quad (9a)$$

$$s(\pm\frac{3}{2}) = \frac{3}{2}|2D' - J_{\text{iso}}| \quad (9b)$$

When the Zeeman S term begins to be significant with respect to the quadrupolar interaction, an inverse perturbation approach ('inverse' when compared to the considerations of Section 2 above) may be used.¹⁴ In this case equations (9a) and (9b) need to be modified, and the four centers of gravity are

$$\langle \Delta\nu(\pm\frac{1}{2}) \rangle = \mp(0.8546J_{\text{iso}} + 0.5D')$$

$$-2(J_{\text{iso}} + D')\frac{\nu_S}{\chi} \quad (10a)$$

$$\langle \Delta\nu(\pm\frac{3}{2}) \rangle = \pm\frac{3}{4}(2D' - J_{\text{iso}}) + 2(J_{\text{iso}} + D')\frac{\nu_S}{\chi} \quad (10b)$$

The spectrum is no longer symmetric, and the sense of the asymmetry depends on the relative signs of $J_{\text{iso}} + D'$, ν_S , and χ . Olivieri has also extended calculations¹⁵ of this type to

situations where $\mathbf{q}$ is not axially symmetric and for arbitrary relative orientations of $\mathbf{q}$ and $\mathbf{D}$.

Frequently, large χ implies the likelihood of rapid spin–lattice relaxation and therefore self-decoupling of S from the spin- $\frac{1}{2}$ nucleus in question. However, (^{13}C , $^{79/81}\text{Br}$) systems have been shown¹⁶ to approach the inverse perturbation case, and an example of a (^{31}P , ^{201}Hg) spin pair (with $D \ll J_{\text{iso}}$ in magnitude) even nearer the low-field limit has been reported.^{15,17}

1 INTRODUCTION

If a sample of liquid benzene is exposed to the Earth's magnetic field passing through it along a north–south direction, there will be a slight tendency for the molecules to turn their faces east–west (or up–down) and away from north–south. The original meaning of ‘orient’ was to face the east, so one might describe the benzene as slightly oriented, or aligned. The normal thermal motions of the molecules largely overcome this tendency, and one can calculate that at any instant the excess of east–west facing molecules over north–south facing molecules is approximately 1 in 10^{15} . In the study of NMR, this tendency to align in the magnetic induction $\mathbf{B}_0$ has been ignored until recently, since the effects on the NMR spectra have been too small to observe. However, the degree of alignment increases as the square of $\mathbf{B}_0$, and in today's spectrometers with $\mathbf{B}_0$ values of 10^5 or more times the Earth's field, the alignment is sufficient that perturbations of the NMR spectrum are often readily observed. This article gives an outline of the origin of the alignment, the nature of the changes produced in the spectrum, and some applications of these to the structure determination of molecules in solution, to molecular angular correlation, to ions, and to paramagnetic species.

2 ENERGETICS OF A RIGID MOLECULE IN ISOTROPIC SOLUTION IN A MAGNETIC FIELD

All objects, molecules, men, or galaxies, possess the property called magnetic susceptibility,¹ usually denoted by χ . When the object is placed in a magnetic field $\mathbf{H}_0$, a magnetic dipole $\mathbf{m}$ is induced in it, according to the equation

$$\mathbf{m} = \chi \mathbf{H}_0 \quad (1)$$

For diamagnetic molecules or ions, χ is negative and small, for paramagnetic species, it is usually positive and larger.

The act of putting a molecule in the magnetic field results in a change in energy of the system:

$$\Delta E = -\chi \mathbf{H}_0 \cdot \mathbf{B}_0/2 \quad (2)$$

$\mathbf{B}_0$ is related to $\mathbf{H}_0$ by the fundamental relationship

$$\mathbf{B}_0 = \mu \mathbf{H}_0 \quad (3)$$

where μ is the permeability. In all cases discussed here, μ differs insignificantly from μ_0 , the permeability of free space, so that one can rewrite equation (3) as

$$\Delta E = -\chi B_0^2/2\mu_0 \quad (4)$$

In the SI system, standardized in this Encyclopedia, the units of ΔE are joules, those of χ are m^3 per molecule, those of $\mathbf{B}_0$ are tesla, and those of μ_0 are $4\pi \times 10^{-7} \text{ tesla}^2 \text{ m}^3 \text{ joule}^{-1}$. Much of the experimental work performed on magnetic alignment has been reported using cgs units, in which $\mu_0 = 1$ and χ is in cm^3 per molecule. These literature values of χ can be converted into the SI system by multiplying by $4\pi \times 10^{-6}$. A few papers give χ in units of joule tesla^{-2} , collapsing μ_0 into χ .

For molecules which are not of tetrahedral or higher symmetry, χ is expected to be anisotropic, that is to differ when measured parallel to the x , y , and z axes of a molecule-fixed coordinate frame.² χ is then represented as a second-rank tensor, which, if the correct axes are chosen, will be diagonal:

$$\chi = \begin{bmatrix} \chi_{xx} & 0 & 0 \\ 0 & \chi_{yy} & 0 \\ 0 & 0 & \chi_{zz} \end{bmatrix} \quad (5)$$

Equation (4) must then be written in tensor notation:

$$\Delta E = -\mathbf{B}_0 \cdot \chi \cdot \mathbf{B}_0/2\mu_0 \quad (6)$$

In the absence of a magnetic induction, the molecules in solution undergo a random tumbling motion as a result of collisions with solvent molecules. However, in the presence of $\mathbf{B}_0$ there will be a torque tending to turn the molecule into its minimum energy position. Taking benzene as an example, we note that the susceptibility is most negative when measured along the six-fold axis, so the energy is highest when the six-fold axis is parallel to $\mathbf{B}_0$, and the alignment of benzene molecules with their planes parallel to $\mathbf{B}_0$ is preferred.

The degree of alignment of a particular axis i relative to $\mathbf{B}_0$ in the molecule is specified by the parameter S_{iB} , defined by³

$$S_{iB} = \langle \frac{3}{2} \cos^2 \theta_{iB} - \frac{1}{2} \rangle \quad (7)$$

where θ_{iB} is the angle between the axis i and $\mathbf{B}_0$, and the angle brackets indicate the expectation value of the enclosed expression. If $S_{iB} = 1$, the axis i is perfectly aligned parallel to $\mathbf{B}_0$, while if $S_{iB} = -\frac{1}{2}$ the axis i is always perpendicular to $\mathbf{B}_0$. $S_{iB} = 0$ implies completely random tumbling. S_{iB} may be evaluated assuming a Boltzmann distribution in the energies.⁴ Then

$$S_{iB} = \frac{\int_0^{2\pi} \int_0^\pi (\frac{3}{2} \cos^2 \theta_{iB} - \frac{1}{2}) e^{-\Delta E/kT} \sin \theta_{iB} d\theta_{iB} d\phi}{\int_0^{2\pi} \int_0^\pi e^{-\Delta E/kT} \sin \theta_{iB} d\theta_{iB} d\phi} \quad (8)$$

2 MAGNETIC FIELD INDUCED ALIGNMENT OF MOLECULES

Since ΔE is very small, the exponential can be approximated by $1 - \Delta E/kT$, and explicit integration of equation (8) gives

$$S_{iB} = \Delta\chi_{ii} B_0^2 / 15kT\mu_0 \quad (9)$$

with $\Delta\chi_{ii}$ equal to $\chi_{ii} - (\chi_{jj} + \chi_{kk})/2$. It is obvious that $S_{xB} + S_{yB} + S_{zB} = 0$. The degree of alignment increases as the square of the magnetic induction and is inversely proportional to the temperature. Taking benzene as an example, with a value of $\Delta\chi_{zz}$ of $-1.27 \times 10^{-33} \text{ m}^3$, and assuming $B_0 = 14.1 \text{ T}$ (600 MHz magnet), S_{zB} at 300 K is calculated to be -3.2×10^{-6} .

3 EFFECTS OF ALIGNMENT ON HIGH-RESOLUTION NMR SPECTRA

Two types of nuclear interaction have been observed to give rise to new or additional splittings in high-resolution spectra of samples in which the molecules are partially aligned by the magnetic induction: magnetic dipole interaction,⁵ and electric quadrupole interaction.⁶ Completely random tumbling averages these interactions to zero, so no splitting is observed. The rapidly fluctuating torques resulting from these interactions are evidenced, however, by the relaxation. However, if the tumbling is nonrandom, such that a small alignment occurs, these interactions are not completely averaged to zero, and effects on line positions and splittings are observed.

3.1 Magnetic Dipolar Interaction

An (oversimplified) model may be used. Two magnetic nuclei A and B are attached to the framework of a molecule, which is undergoing rapid tumbling. The magnetic moment of nucleus A is taken as parallel to the magnetic induction. The component of the magnetic field parallel to $\mathbf{B}_0$ generated by nucleus A at nucleus B is then given by¹

$$H_B = m_A(3 \cos^2 \theta_{nB} - 1)/r_{AB}^3 \quad (10)$$

where θ_{nB} is the angle between the internuclear axis and $\mathbf{B}_0$. If all orientations of the internuclear axis are equiprobable, equation (10) integrates to give $\langle H_B \rangle = 0$. On the other hand, if the internuclear axis has a degree of alignment S_{nB} , then

$$\langle H_B \rangle = 2m_A S_{nB} / r_{AB}^3 \quad (11)$$

This field would add to $\mathbf{H}_0$ causing a shift in the frequency of the NMR signal from nucleus B. If the moment of A were antiparallel to $\mathbf{B}_0$, the opposite shift would be observed. Thus a doublet would be produced. In the quantum mechanical formulation, the strength of the interaction is represented by D_{AB} , which is given by

$$D_{AB} = -\gamma_A \gamma_B \hbar S_{nB} / 2\pi^2 r_{AB}^3 \quad (12)$$

The observable splittings are directly related to D_{AB} . It is now necessary only to relate S_{nB} to χ :⁴

$$S_{nB} = \frac{2}{3} \sum_{i=x,y,z} \Delta\chi_{ii} \left(\frac{3}{2} \cos^2 \theta_{in} - \frac{1}{2} \right) B_0^2 / 15kT\mu_0 \quad (13)$$

where θ_{in} is the angle between the i th axis of the susceptibility tensor and the internuclear axis. Combining equations (12) and (13), and noting that the spectrometer frequency ν_A is equal to $\gamma_A B_0 / 2\pi$, the practical formula is obtained:

$$D_{AB} = -5.10 \times 10^{15} \nu_A \nu_B \times \sum_{i=x,y,z} \chi_{ii} \left(\frac{3}{2} \cos^2 \theta_{in} - \frac{1}{2} \right) / T a_{AB}^3 \quad (14)$$

where a_{AB} is the internuclear distance (in nanometers).

The effect of D_{AB} on the spectrum has been thoroughly explored in studies of molecules partially aligned by solution in liquid crystal solvents.⁷ For two spins with identical Larmor frequencies, the spectrum is a doublet with splitting $3D_{AB}/2$. An example of such a splitting is shown in Figure 1. The signal arises from two methylene protons attached to a porphyrin ring in the zinc vinylphylloerythrin-pyridine complex (**1**), with the internuclear axis parallel to the four-fold symmetry axis of the ring. The observed doublet splitting of 1.98 Hz observed at 600 MHz, implies $D_{HH} = 1.32 \text{ Hz}$. Taking a as 0.178 nm, T as 296 K, $\theta_{zn} = 0$, and $\chi_{xx} = \chi_{yy}$, gives $\Delta\chi_{zz} = -11.9 \times 10^{-33} \text{ m}^3$. The $\Delta\chi_{zz}$ of the complex is the sum of $\Delta\chi_{zz}$ for the porphyrin ($-12.5 \times 10^{-33} \text{ m}^3$) and $-(\frac{1}{2})\Delta\chi_{zz}$ for the pyridine ligand ($-1.19 \times 10^{-33} \text{ m}^3$), in agreement with values obtained by other methods.⁸

If the Larmor frequencies of the two nuclei differ by much more than D_{AB} and J_{AB} , the observed doublet spacing is simply $J_{AB} + D_{AB}$. The addition is algebraic,⁷ so if the sign and magnitude of J_{AB} are known from other studies, the sign and magnitude of D_{AB} can be determined. As an example of this, a second porphyrin containing a similarly situated methylene group was studied in methyl pyropheophorbide A (**2**). The pyrrole ring adjacent to the methylene was reduced, rendering the methylene protons inequivalent. They now gave rise to AX type doublets, with a splitting $J_{HH} + D_{HH}$ of 20.17 Hz at 5.87 T, 19.95 Hz at 7.05 T, 19.51 Hz at 11.75 T, and 19.25 Hz at 14.09 T. The plot of these splittings versus B_0^2 is a straight line with intercept $J_{HH} = -20.25 \text{ Hz}$, and $D_{HH} = +1.00 \text{ Hz}$ at 14.09 T. Application of equation (14) yields $\Delta\chi = -10.1 \times 10^{-33} \text{ m}^3$. The reduction of the pyrrole ring has partially interrupted the circuit of π electrons responsible for the ring current and for the large anisotropic susceptibility of porphyrins.

Figure 1 The doublet arising from the direct magnetic dipole interaction in zinc vinylphylloerythrin-pyridine complex

Finally, if the Larmor frequency difference between A and B and $J_{AB} \pm D_{AB}$ is of comparable magnitude, second-order effects are expected. The exact calculation of J_{AB} and D_{AB} from such spectra has been worked out in detail, in connection with the spectroscopy of solutes in liquid crystal solvents.⁷ It has been shown⁹ that the observation of the second order effects in suitable cases provides a sensitive method for detecting and measuring very small values of D_{AB} .

3.2 Electric Quadrupole Interaction

For most quadrupolar nuclei, the relaxation induced by the interaction of the nuclear quadrupole moment with the electric field gradient at the nucleus broadens the signals sufficiently to obscure the effects produced by molecular alignment. However, the quadrupole coupling constant for deuterium in a large variety of molecules is small, lying in the range 100–300 kHz, and the broadening is small enough that splittings arising from the quadrupole interaction can be seen in the ^2H NMR spectrum.

For a single deuterium atom, if molecular tumbling is not random, the signal consists of a doublet: the transitions correspond to the changes $m(-1 \rightarrow 0)$ and $m(0 \rightarrow 1)$. The frequency separation of the doublet $\Delta\nu_Q$ is given by

$$\Delta\nu_Q = 3eQ\langle V_{B_0} \rangle / 2h \quad (15)$$

where eQ is the nuclear electric quadrupole moment, and $\langle V_{B_0} \rangle$ is the expectation value of the electric field gradient along the direction of B_0 . It is convenient to establish a second molecule-fixed coordinate frame, x', y', z' , in which the electric field gradient tensor is diagonal, and to define $\nu_{x'}$, $\nu_{y'}$, and $\nu_{z'}$ as the quadrupole splittings which would be observed if the molecule were fixed with the x' , y' , and z' axes parallel to B_0 , respectively. Then,⁷

$$\Delta\nu_Q = \frac{2}{3} \sum_{i=x',y',z'} \nu_i \sum_{j=x,y,z} \cos^2 \theta_{ij} S_{jj} \quad (16)$$

The electric field gradient tensor is traceless, implying $\nu_{x'} + \nu_{y'} + \nu_{z'} = 0$. Quadrupole coupling constants for carbon-bound deuterium have been measured by NMR relaxation methods, Zeeman microwave spectroscopy, NMR studies of deuterated molecules in liquid crystal solvents, and nuclear quadrupole resonance spectroscopy of solids.¹⁰ The maximum splittings, $\nu_{z'}$ range from 225 to 300 kHz, with ^2H in similar chemical environments clustered together: ^2H attached to a benzene ring has $\nu_{z'}$ equal to 275 ± 5 kHz. Returning once again to benzene as an example, with $\nu_{z'} = 279$ kHz, $\nu_{x'} \approx \nu_{y'} = -139.5$ kHz, $\Delta\chi = -1.27 \times 10^{-33} \text{ m}^3$, $B_0 = 14.09 \text{ T}$, $T = 300 \text{ K}$, and $\theta_{zz'} = 90^\circ$, ν_Q is calculated using equation (16) to be 0.45 Hz. Figure 2 shows a ^2H NMR spectrum of monodeuterobenzene; the spectrum is resolution enhanced, with proton decoupling. The observed splitting (0.46 Hz) agrees well with the expected value.

Second-order effects are observed in the spectra when chemical shifts are zero or of comparable magnitude to J_{AB} and ν_{QA} or ν_{QB} . This complication prevents the direct observation of ν_Q in hexadeuterobenzene, which gives rise to a spectrum with numerous overlapping transitions.¹¹

3.3 Anisotropic Chemical Shift

If the sample molecules possess anisotropic magnetic susceptibilities and also contain nuclei with anisotropic

Figure 2 Deuteron quadrupole splitting of the deuteron signal from benzene- d_1 , with proton decoupling

chemical shieldings, it is expected that the shift will not be linearly related to B_0 . The reason for this is clear: if the molecule is tumbling randomly, the average chemical shift $(\sigma_{xx} + \sigma_{yy} + \sigma_{zz})B_0/3$ will be observed; if the molecules are partly aligned, with alignment parameters S_{xB} , S_{yB} , and S_{zB} , the observed shift will be

$$2 \sum_{i=x, y, z} S_{iB} \sigma_{ii} B_0/3$$

Despite concerted effort, no such nonlinear shifts have been demonstrated to date. The difficulty is that the expected effects are very small, and easily masked by shifts arising from extraneous factors such as temperature.

4 APPLICATIONS

From the above, it can be seen that the dipolar splitting observed between two nuclei in a molecule in a high B_0 relates the length and direction of the internuclear vector to χ . Similarly, the observed quadrupole splitting relates the electric field gradient tensor $\mathbf{V}$ and χ . If χ is known, or can be estimated accurately, then information is obtained on the internuclear vector or on $\mathbf{V}$, i.e. structural information. On the other hand, if the structure is known (the length and direction of the internuclear vector relative to the principal axes, or direction and the strength of the electric field gradient), χ may be determined. For organically bound ^2H , the largest component of $\mathbf{V}$ (V_{zz}) is directed along the C– ^2H (or N– ^2H , O– ^2H , etc.) bond, and the asymmetry, $V_{xx} - V_{yy}$ is negligible. Even for ^2H attached to trigonal carbon, the asymmetry is normally less than 5% of V_{zz} .

4.1 χ , Systematics and Determination

In addition to the high-field NMR method, there are several methods for determining χ . In the crystal flip angle method,² a single crystal of the sample is suspended by a quartz fiber in a transverse magnetic induction and the torque required to cause the crystal to turn from its lowest energy state through its highest energy state is measured. In the Cotton–Mouton method,¹² the partial alignment of molecules in the liquid or gaseous state by B_0 is measured by observing the optical birefringence. In the Zeeman microwave method,¹³ the Zeeman effect on rotational spectra is observed. Extensive measurements have been made using all these methods, often on the same molecule; the results are generally in good agreement.¹⁴ For example, for benzene, single crystal measurements yielded a value for $\Delta\chi$ of $-1.24 \times 10^{-33} \text{ m}^3$, three independent measurements by the Cotton–Mouton method gave -1.31 , -1.32 , and $-1.33 \times 10^{-33} \text{ m}^3$, and measurements by high-field NMR gave $-1.27 \times 10^{-33} \text{ m}^3$. With no electric dipole moment, benzene could not be studied directly by rotational spectroscopy.

All these measurements have demonstrated that Pascal's additivity scheme¹⁵ for the isotropic diamagnetic susceptibility can be extended to χ , the molecular susceptibility tensor, i.e. that χ can be expressed as the sum of bond susceptibility tensors χ_b , or of atom susceptibility tensors χ_a , with the addition of χ_e (a susceptibility tensor ascribable to the

delocalized circulation of electrons).¹³ There is a considerable amount of literature covering χ_e in aromatic and antiaromatic compounds; an alternative name for this delocalized circulation is 'ring current'. In early studies the existence of the ring current and its magnitude were inferred from measurements of 'exaltation',¹⁵ the amount by which χ exceeds $\Sigma\chi_b$ or $\Sigma\chi_a$. The circulation is in the plane of the aromatic or antiaromatic systems, so χ_e has zero elements for χ_{xx} and χ_{yy} ; χ_{zz} is negative if the molecule is aromatic, and positive if it is antiaromatic.¹⁶

Acyclic compounds do not exhibit exaltations, and fit the additive scheme well, although multiple heavy atom substitution on carbon causes deviations. Single and triple bond susceptibility tensors are axial, that is $\chi_{xx} = \chi_{yy}$. If only single and triple bonds are present, S_{nB} for any axis can be determined using

$$S_{NB} = \sum_{\text{bonds}} \left(\frac{3}{2} \cos^2 \theta_{nB} - \frac{1}{2} \right) \Delta\chi_b B_0^2 / 15kT\mu_0 \quad (17)$$

Double bond susceptibility tensors have three different components, so the full version of equation (9) is required. Cyclic compounds, even saturated small ring compounds, such as cyclopropane, cyclobutane, and cyclopentane, show significant contributions from χ_e . The exact nature of the delocalization is uncertain, but three- and five-membered rings have negative χ_e , while four-membered rings have positive χ_e .

The susceptibility tensor for most rigid molecules is a hard property, i.e. it is not affected appreciably by the environment. χ is the same, within experimental error, whether measured in the gas, liquid, or solid phase. If the molecular electronic or geometrical structure is actually changed by the environment, χ will change. For example, different solvents which produce a different weighting of the polar and nonpolar resonance forms in *N*-methyl-2-pyridone cause different quadrupole splittings to be observed for the deuterated compound.

Extensive analyses of bond susceptibility additivity schemes have been presented in articles by Flygare¹³ and Haberditzl.¹⁷

4.2 Determination of Structure: Rigid Molecules

As an example of structural elucidation, we consider the study of the dihydrogen complex of the bridged bis(ruthenium porphyrin) · H_2 complex (3).¹⁸ The structure of the $\text{B}(\text{RuP})_2$ framework is well established. The structural question to be answered is: What is the arrangement of the H_2 ? How far apart are the hydrogen atoms, and what angle does the H–H axis make with the molecular z axis (Ru–Ru axis)?

The susceptibility tensor for the complex can be estimated within a few per cent by adding the known tensors for the two porphyrins, the phenylimidazolyl groups, and the biphenylene bridging group, using the summation

$$\Delta\chi_{zz} = \sum_{\text{groups}} \left(\frac{3}{2} \cos^2 \theta_{zz'} - \frac{1}{2} \right) \Delta\chi_g \quad (18)$$

with $\theta_{zz'}$ being the angle between the molecular z axis and the normals to the ring planes of the individual groups. The anisotropy of the C–C bonds joining the biphenylene and porphyrin groups and of H_2 are less than $0.1 \times 10^{-33} \text{ m}^3$ and do not contribute significantly to the sum, which gives

$\Delta\chi_{zz} = -24.0 \times 10^{-33} \text{ m}^3$. Measurements of the H–H magnetic dipolar splitting were made at 620 MHz (14.56 T). S_{zB} is calculated to be -6.61×10^{-5} at this B_0 .

The H_2 signal at 620 MHz is a doublet with a splitting of $\pm 7.37 \pm 0.05 \text{ Hz}$. D_{HH} is thus $\pm 4.91 \pm 0.03 \text{ Hz}$. Using equation (14), one finds:

$$\langle \frac{3}{2} \cos^2 \theta_{zn} - \frac{1}{2} \rangle / r_{\text{HH}}^3 = \pm 0.309 \times 10^{24} \quad (19)$$

The sign of D_{HH} was not known, but was determined by observing the field dependence of the splitting $J_{\text{HD}} + D_{\text{HD}}$ for the complex with HD. The sign of J_{HD} is known to be positive, so the decreasing magnitude of the splitting with increasing B_0 means that D_{HD} and thus D_{HH} are negative. The internuclear distance was deduced by relaxation time measurements to be $0.121 \pm 0.009 \text{ nm}$. This yields $\langle (3/2) \cos^2 \theta_{zn} - (1/2) \rangle = -0.54 \pm 0.05$. Since $\langle (3/2) \cos^2 \theta_{zn} - (1/2) \rangle$ cannot be more negative than $-\frac{1}{2}$, it appears that θ_{zn} must be very close to 90° ; the H–H axis is perpendicular to the molecular z axis.

4.3 Study of Molecules with Internal Motion

As an example, a study of styrene and 1- and 2-vinylnaphthalene is outlined.¹⁹ The motion of interest is the rotation of the vinyl group about the single bond joining it to the aromatic ring. The parameter measurable by high field studies is the expectation value, $\langle \sin^2 \alpha \rangle$, where α is the dihedral angle between the planes of the vinyl group and the ring. In the study, the quadrupole splittings of the deuteron signals were measured for styrene with deuterium substituted in all positions of the vinyl and phenyl groups.

Addition of the known group susceptibility tensors for vinyl and phenyl groups suggests that the principal axis z of styrene is very nearly perpendicular to the phenyl ring, regardless of α , and that $\chi_{xx} \approx \chi_{yy}$. The equality of the observed splittings for the *ortho*, *meta*, and *para* deuterons in the phenyl group is consistent with this, and their magnitude at 14.57 T indicates a value of $\Delta\chi_{zz} = -1.45 \times 10^{-33} \text{ m}^3$. The determination of $\langle \sin^2 \alpha \rangle$ is then an exercise in solid trigonometry: one has to calculate $\langle \cos^2 \theta_{zz'} \rangle$ relating the molecular z axis to the z' axis

of the electric field gradient tensor (the C–D bond axis) for the α and *trans*- β deuterons in the vinyl group. These are related by

$$\langle \cos^2 \theta_{zz'} \rangle = \langle \sin^2 \alpha \rangle \langle \sin^2 \beta \rangle \quad (20)$$

where β is the angle between the C–D bond and the C–C bond joining the vinyl and phenyl groups. For the deuteron in the *cis*- β position, $\beta \approx 0^\circ$, the C–D axis is parallel to that of the *para*-deuteron, regardless of internal rotation of the vinyl group. The ratio of the splittings is thus a measure of the ratio of the quadrupole couplings for the phenyl–D and vinyl–D nuclei (185 and 181 kHz, respectively), which is in agreement with previous measurements. For the α and *trans*- β deuterons, β is taken as 71° . From the observed splittings, it is then found that $\langle \sin^2 \alpha \rangle$ is 0.081 and $\sin^{-1} \langle \sin^2 \alpha \rangle^{1/2}$ is 16.5° . If the splitting were negative rather than positive, one would obtain $\langle \sin^2 \alpha \rangle = 0.666$ and $\sin^{-1} \langle \sin^2 \alpha \rangle^{1/2} = 55^\circ$, but this can be eliminated, because the value of $\Delta\chi_{zz}$ obtained would be $-1.31 \times 10^{-33} \text{ m}^3$, which is a much smaller value than that indicated by the phenyl–D splittings. Similar measurements on 2-vinylnaphthalene indicated $\langle \sin^2 \alpha \rangle$ gave values the same as those for styrene, within experimental error, while for 1-vinylnaphthalene, $\sin^{-1} \langle \sin^2 \alpha \rangle^{1/2} \approx 40^\circ$, suggesting steric interference between the vinyl group and the *peri*-hydrogen atom in the planar arrangement.

4.4 Angular Correlation in the Liquid State

Even in the absence of a magnetic flux, a molecule (A) which is not isotropic interacts with neighboring anisotropic molecules (B) in such a way that they do not tumble randomly, but adopt preferred orientations with respect to A. A strong limiting case of this is association; if molecule A binds to molecule B, for example with a hydrogen bond or by ionic attraction, then A and B do not move independently, but tumble together synchronously. More subtle interactions can also induce molecular correlation: the electric polarizability, electric dipole moment, quadrupole moment, or higher moments, may interact with any of these of the B molecules; the shapes of molecules A and B may be conducive to better packing in particular mutual orientations. Molecule A may influence several molecules of molecule B, and vice versa. Finally, A and B may be different species (solute and solvent), or the same (neat liquids). Angular correlations may also be characterized by ordering parameters $S_{ij'} = \langle (3/2) \cos^2 \theta_{ij'} - (1/2) \rangle$, where $\theta_{ij'}$ is the angle between the i th axis of A and the j th axis of B. If molecules A and B are identical, one may define Kirkwood's²⁰ parameter $g_{ii'}$ as

$$g_{ii'} = 1 + \sum_n S_{ii'} \quad (21)$$

The summation is taken over all neighboring B molecules, and the unity term represents the angular correlation of A with itself. For example, if $g_{zz'}$ were found to be 2.00 for neat benzene, a conceivable (though incorrect) explanation would be that neat benzene consists entirely of face-to-face dimers, with parallel z axes. For neat samples,

$$S_{iB}^A = g_{ii'} \Delta\chi_{ii} B_0^2 / 15kT\mu_0 \quad (22)$$

while for solute A in solvent B

$$S_{iB}^A = \left(\Delta\chi_{ii}^A + \frac{2}{3} \sum_n \sum_{j'=x',y',z'} (S_{ij'} \Delta\chi_{jj'}) \right) B_0^2 / 15kT\mu_0 \quad (23)$$

In order to measure the degree of molecular alignment caused by the induction, free of solvent angular correlation effects, it is customary to employ dilute solutions in solvents which are themselves exactly or nearly magnetically isotropic. Ideal solvents would include CCl₄, SiMe₄, CMe₄, and SF₆. Good, though not perfect, solvents include water, liquid ammonia, diethyl ether, and cyclohexane. The angular correlation in a number of neat liquids has been studied by comparing the alignments observed in dilute solution in isotropic solvents, and in the neat liquid. The value of $g_{zz'}$ found for benzene was 0.86, which implies a negative value for $S_{zz'}$. The rings of neighboring benzene molecules tend to form angles greater than 54.7°, rather than stack, pancake fashion.¹⁰

4.5 Paramagnetic and/or Charged Species

Paramagnetic or charged species are partially aligned in a magnetic field in the same way as neutral diamagnetic molecules. Since paramagnetic susceptibilities are usually much larger than diamagnetic susceptibilities, it is not surprising that the anisotropies of the paramagnetic susceptibilities are also much larger, and the degree of alignment correspondingly greater. Thus the first observation⁵ of a dipolar splitting in isotropic solution was made on the paramagnetic cobalt complex bis[*p*-tolyl-tris(pyrazolyl)borato]cobalt(II) (4). Lanthanide shift reagents exert their effects by virtue of their large anisotropic susceptibilities; consequently, molecules complexed with shift reagents exhibit large dipolar and quadrupolar splittings of the type described here, even at moderate field strengths. A very interesting study of the susceptibility tensor for a ferric porphyrin has been reported.²¹

Studies of organic cations and anions have also been made.²² Ion pairing probably occurs in the cases studied, although the counterions are expected to be nearly isotropic and thus correlation effects would be negligible. Of course the electronic structure of the organic ion itself may be strongly affected by the counterion. Values of χ_e have been deduced and related to the electronic structure of the ions.

1 INTRODUCTION

NMR's ability to probe the structure of materials strongly depends upon the availability of high-resolution spectra, which serve as fingerprints of the physico-chemical surroundings of the studied nuclei. In powdered solids, the nuclear spins experience various anisotropic interactions, which broaden their spectra and render NMR more difficult for structural determinations. For spin-1/2 nuclei these interactions include dipole-dipole coupling between spins, chemical shift anisotropy (CSA), indirect spin–spin coupling and interaction with unpaired electrons.¹ The resolution and sensitivity gaps between liquid and solid state NMR began to decrease in the 1960s and 1970s with the introduction of radio frequency (RF) decoupling, magic angle spinning (MAS) and cross polarization (CP) methods.^{2–5} These developments, in concert with the continuing advances in NMR hardware and software allowed for increasingly precise measurement of the spin interactions in solid samples, including the isotropic chemical shifts of spin-1/2 nuclei.

Until recently, however, these techniques could not overcome the line broadening in NMR spectra of the quadrupolar nuclei with spin greater than 1/2. This broadening arises from the coupling of the non-spherical charge distribution of such nuclei with the gradient of the electric field created by the surrounding electrons. The quadrupolar broadening is 'more anisotropic' than the first order interactions (CSA and dipolar coupling), in the sense that it contains higher order orientational terms of significant magnitude. Thus, more complex

motions of the sample, or of the spin magnetization, are needed in order to achieve the highest possible resolution.^{6–8} This article will focus on some of the concepts and experiments associated with the acquisition of isotropic solid state spectra of the quadrupolar nuclei by combining the multiple quantum (MQ) NMR with MAS.^{8,9} In the last years MQMAS has revolutionized solid state NMR of the so-called half-integer quadrupolar spins. The most prominent nuclei that are amenable to this technique include ¹¹B ($S = 3/2$), ¹⁷O ($S = 5/2$), ²³Na ($S = 3/2$) and ²⁷Al ($S = 5/2$).

The theory necessary for understanding of the quadrupolar interaction has been described before in numerous textbooks, monographs and reviews.^{1,10–13} We first note that the size of the quadrupolar interaction can be described by the quadrupolar frequency ν_Q , which is proportional to the quadrupole moment Q of a nucleus and the electric field gradient (EFG). Depending upon the size of Q and the local electronic environment, the values of ν_Q can range from zero to several hundred of MHz. In NMR, we generally consider the strong field case, $\nu_0 > \nu_Q$, where ν_0 is the Larmor frequency in the static field $\mathbf{B}_0$. In this approximation, the first- and second-order quadrupolar energies can be easily calculated using the perturbation theory. For half-integer spins, the first-order quadrupolar effect on the satellite transition frequencies ($m - 1 \leftrightarrow m$, $m \neq 1/2$) is of the order of ν_Q . Thus, in a powdered sample, the NMR spectrum is spread over a frequency range that for most nuclei exceeds the range of chemical shifts and the bandwidth of the spectrometer under pulse excitation. However, the central transition ($-1/2 \leftrightarrow 1/2$) is not affected to first order. In the absence of additional line broadenings from chemical shift and/or dipolar interaction, the width of the powder spectrum for the central transition is determined only by the second order quadrupolar terms. Since this contribution is typically 10^2 to 10^3 times smaller than ν_Q , the central transition yields a narrower and more intense spectrum, which is the subject of most studies on half-integer quadrupolar nuclei. We note that in this approximation the width of the central transition spectrum is inversely proportional to the magnitude of magnetic field $\mathbf{B}_0$.

The detection of broad quadrupolar lineshapes can rarely be accomplished with single pulse excitation because of the loss of magnetization within the dead time of the receiver. This necessitates the use of multi-pulse excitation, with the two-pulse spin-echo sequences being the most common.^{14,15} In case of sufficiently broad lines, the acquisition of spectra can be accomplished by scanning the frequency, or the magnetic field $\mathbf{B}_0$, and via point by point acquisition of the echo intensity.¹⁶ While the static, spin-echo experiments continue to be used in the case of strong quadrupolar interactions, most studies of quadrupolar nuclei in the last two decades utilized the line-narrowing effect of spinning the sample under MAS or variable angle (VASS) conditions.^{17,18} MAS eliminates the first order broadening completely and reduces the quadrupolar contribution to the central transition line width by a factor of approximately three. Consequently, the experimental strategies applied in the MAS experiments depend on the size of quadrupolar coupling. For ν_Q s not exceeding few hundred kHz, it is often possible to observe the whole spectrum, which appears as a wide manifold of spinning sidebands. The spacing between sidebands is equal to the spinning speed ν_R , whereas their individual widths and shapes are governed both by ν_R and the second order quadrupolar interaction. The width

and the shape of the entire manifold allow one to determine ν_Q and the asymmetry parameter of the EFG tensor η_Q .^{17,19} The accuracy of such measurements strongly depends on the uniformity of the RF excitation, precise setting of the magic angle, probe bandwidth and tuning of the spectrometer. For large values of ν_Q , the spinning sidebands for the satellite transitions are often distorted, overlapping and embedded in background noise. Consequently, it becomes advantageous to use the MAS lineshape corresponding to the central transition for determination of the NMR parameters. While this strategy often relies upon the availability of high magnetic fields and high spinning speeds, trustworthy values of ν_Q , η_Q and the isotropic chemical shift δ_{CS} can be obtained from the computer simulations of the observed lineshapes.²⁰ In favorable cases, several distinct resonances can be fully characterized in a single MAS spectrum.

Several other strategies have been developed for improving the resolution of quadrupolar NMR spectra. These include static and MAS two-dimensional (2D) nutation experiments that utilize the correlation between the quadrupolar parameters and the precession frequencies induced by RF pulses of different lengths and intensities.^{21–23} For moderate values of ν_Q not exceeding 1 MHz, SATRAS (satellite transition spectroscopy) can be used to determine the quadrupole and chemical shift parameters.^{24,25} The problem of overlapping spinning sidebands in the MAS spectra of quadrupolar nuclei can be overcome using the recently proposed QPASS (quadrupolar phase alternated sideband suppression) sequence.²⁶ Finally, several techniques combined with MAS have been developed that allow for studies of dipolar interactions between the quadrupolar and spin-1/2 nuclei. These include the CP experiment, REDOR (rotational echo double resonance), TEDOR (transferred echo double resonance), TRAPDOR (transfer of populations double resonance) and REAPDOR (rotational echo adiabatic passage double resonance).^{27–35}

As mentioned above, the second order quadrupolar interaction is not averaged to zero by MAS alone. However, remarkable developments have been made recently in this area of solid state NMR. The theoretical foundations and two different experimental realizations of complete spatial averaging of the second order broadening of the central transition were published in the late 1980s by the groups of Pines and Virlet.^{6,7,36} It was shown that such spatial averaging requires mechanical rotation of the sample around an axis that has time dependent orientations. In the one-dimensional DOR (double rotation) experiment, the sample is spun in a small inner rotor, which is rotating inside an outer rotor.⁶ The rotation axis of the outer rotor is set at the magic angle ($\chi_m = 54.74^\circ$ with respect to $\mathbf{B}_0$), while the rotation axis of the inner rotor moves continuously on a cone of an aperture of 61.12° . In contrast with DOR, the DAS (dynamic angle spinning) technique uses two discrete rotational orientations (commonly tilted 37.38° and 79.19° away from $\mathbf{B}_0$) and correlates the corresponding resonance frequencies in a 2D experiment.⁷ In general, DOR results in better averaging of the dipolar interactions and allows for studying of samples with fast relaxation times. DAS, on the other hand, provides a better filling factor and separates the anisotropic lineshapes associated with each isotropic resonance. The line narrowing abilities of DOR and DAS are best demonstrated in crystalline materials, where resolution enhancement by one or two orders of magnitude has been reported.³⁷ Most recently, it has been proposed and demonstrated by Frydman

et al. that the line narrowing of the central transition can be obtained without changing the orientation of the spinning axis, as long as the motion of this axis in space is replaced by changing the coherence state of the observed spins.^{8,9} This experiment is referred to as multiple quantum magic angle spinning (MQMAS) NMR. Similar to DAS, MQMAS is a two-dimensional method, which correlates the phase evolutions of the MQ and single quantum (1Q) coherences and allows for observation of a purely isotropic echo. The change of the coherence state of half-integer quadrupolar spins can be effectively accomplished by strong RF irradiation.^{38,39} The MQMAS method precludes most of the shortcomings of DOR (presence of closely spaced spinning sidebands) and DAS (loss of magnetization during the reorientation of the spinner axis) and, being technically straightforward, has found enthusiastic approval in the NMR community. The resolution enhancement that this technique can provide is demonstrated in Figure 1, which compares static, MAS and MQMAS spectra of ^{87}Rb in well-crystallized LiRbSO_4 .⁴⁰ The observed line width in LiRbSO_4 changed from approximately 400 ppm in a static spectrum to 150 ppm under MAS and 1.5 ppm in MQMAS. Hundreds of applications of this technique in the studies of catalysts, glasses and other amorphous and crystalline inorganic solids have been published.

In the six years since its inception, a great body of work has been reported that extended the efficiency and the analytical capabilities of the MQMAS method. Extensive

Figure 1 Static, MAS and MQMAS (isotropic projection) spectra of ^{87}Rb in polycrystalline LiRbSO_4 taken at 130.88 MHz

theoretical background and explanation of spin manipulations involved in MQMAS, including excitation, conversion and selection of transfer pathways for MQ coherences, is given by L. Frydman (see **Multiple-quantum Magic-angle Spinning Experiments on Half-integer Nuclei: Fundamentals**). In this article, only a brief description of the fundamental principles of the MQMAS experiment is presented. Subsequently, we review the schemes for detection of pure-phase spectra, the data processing methods (including referencing, quantitative analysis and interpretation of MQMAS spectra) and the MQMAS-based double resonance experiments.

2 THEORETICAL BACKGROUND

We consider an ensemble of nuclei with half-integer spin quantum number $S > 1/2$ in a strong magnetic field. There are $2S + 1$ Zeeman energy levels associated with such spins that can be labeled with their magnetic quantum number m . The existence of a non-vanishing (m, m') element in the density matrix shows that there is a p -quantum coherent superposition of the states $|m\rangle$ and $|m'\rangle$ with multiplicity defined by $p = m - m'$. Thus, the diagonal elements of the density matrix (m, m) , which represent the relative populations of the Zeeman states $|m\rangle$, correspond to zero-quantum coherences. It can be shown that these are the only coherences present in the density matrix of a system at thermal equilibrium. Under the conditions normally encountered in NMR the reduced density matrix can be used, which describes the relative deviations from a completely uniform distribution. The reduced density matrix at thermal equilibrium is proportional to S_z (the z component of the total spin angular momentum operator S).

In the frame of the Zeeman interaction, i.e., the 'rotating frame', the secular second order Hamiltonian governing the S spin system can be written as

$$H = H_{Q1} + H_{Q2} + [\nu_0 \Delta\delta + m_I J + F(\alpha_s, \beta_s)] S_z \quad (1)$$

where

$$H_{Q1} = \bar{\nu}_Q(\alpha_s, \beta_s, \eta_Q) [S_z^2 - S^2/3] \quad (2)$$

$$H_{Q2} = -\frac{\nu_Q^2}{2\nu_0} [V_1 V_{-1} (4S^2 - 8S_z^2 - 1) + V_2 V_{-2} (2S^2 - 2S_z^2 - 1)] S_z \\ = B(\alpha_s, \beta_s, \eta_Q) S_z + D(\alpha_s, \beta_s, \eta_Q) S_z^3 \quad (3)$$

with

$$\bar{\nu}_Q(\alpha_s, \beta_s, \eta_Q) = 1.5\nu_Q [3 \cos^2 \beta_s - 1 + \eta_Q \sin^2 \beta_s \cos 2\alpha_s] \quad (4)$$

and

$$\nu_Q = \frac{e^2 q Q}{4S(2S-1)\hbar} = \frac{C_Q}{4S(2S-1)} \quad (5)$$

In the above equations H_{Q1} and H_{Q2} represent the first and second order perturbation terms for the quadrupole interaction, $\Delta\delta$ is the resonance offset (in ppm), J is the scalar coupling constant between spin S and another spin I with magnetic number m_I , $e q$ is the largest principal axis value of the EFG tensor, C_Q is the quadrupole coupling constant, while ν_0 and $\hbar$ have their usual meaning. The last term in equation (1) accounts for CSA, the anisotropy of J coupling and heteronuclear dipolar

couplings, $\bar{\nu}_Q$ is the quadrupole splitting, and V_1, V_{-1}, V_2 and V_{-2} are the eigenvalues of the quadrupolar tensor in the laboratory frame. The orientation dependencies of $F, \bar{\nu}_Q, V_1, V_{-1}, V_2$ and V_{-2} can be described in terms of two polar angles α_s and β_s orienting the direction of $\mathbf{B}_0$ in the principal axis system (PAS) of the EFG tensor. Implicit in F is the dependence of the non-quadrupolar anisotropic interactions on their orientation with respect to the quadrupolar tensor, which can be described using additional sets of Euler angles.

The MQ transitions are induced using RF pulses. Following these excitations, coherences freely precess during the evolution periods. We first consider the free evolution of phase Φ^{stat} associated with the coherence (m, m') in a single crystallite within a static sample under the Hamiltonian H described in equation (1). In the absence of RF magnetic field and relaxation processes this evolution can be written as

$$\Phi^{\text{stat}}(m, m') = [\bar{\nu}_Q(m + m') + \nu_0 \Delta\delta + m_I J + F(\alpha_s, \beta_s) \\ + B(\alpha_s, \beta_s, \eta_Q) + D(\alpha_s, \beta_s, \eta_Q) \\ \times (m^2 + mm' + m'^2)](m - m')t \quad (6)$$

It is clear that none of the internal Hamiltonians in equation (1) has an effect on the zero-quantum coherences (m, m) . In nuclei with moderate or large ν_Q values, the first term in equation (6) is dominant. As a result, all non-diagonal elements $(m \neq \pm m')$ are quickly dephased, which prevents their further detection. For the anti-symmetric p -quantum coherences $(p/2, -p/2)$, the evolution phase can be written as

$$\Phi^{\text{stat}}(p/2, -p/2) = \left\{ p[\nu_0 \Delta\delta + m_I J + F(\alpha_s, \beta_s)] \right. \\ \left. + \sum_{k=0,2,4} A_k^Q(\alpha_s, \beta_s, \eta_Q) C_k(S, p) \right\} t \quad (7)$$

Explicit expressions for $A_k^Q(\alpha_s, \beta_s, \eta_Q)$ and $C_k(S, p)$ can be found in Amoureux.⁴¹

Under high-speed sample spinning at an angle χ with respect to $\mathbf{B}_0$, the evolution phase changes to

$$\Phi^\chi(p/2, -p/2) = \{ p[\nu_0 \Delta\delta + m_I J] + A_0^Q(\eta_Q) C_0(S, p) \\ + [pF(\alpha_R, \beta_R) + A_2^Q(\alpha_R, \beta_R, \eta_Q) C_2(S, p)] P_2(\cos \chi) \\ + A_4^Q(\alpha_R, \beta_R, \eta_Q) C_4(S, p) P_4(\cos \chi) \} t \quad (8)$$

where the polar angles α_R, β_R describe the orientation of the rotor axis with respect to the EFG tensor, and equation (9) shows the second and fourth order Legendre polynomials

$$P_2(\cos \chi) = \frac{1}{2} (3 \cos^2 \chi - 1) \\ P_4(\cos \chi) = \frac{1}{8} (35 \cos^4 \chi - 30 \cos^2 \chi + 3) \quad (9)$$

Equation (8) illustrates the challenge associated with observing high resolution spectra of half-integer quadrupolar spins: in a standard, single pulse experiment with a fixed rotation axis, the anisotropic broadening cannot be completely removed because no value of χ can simultaneously satisfy the condition $P_2(\cos \chi) = P_4(\cos \chi) = 0$. Consequently, the efficient line

narrowing methods must utilize more complex motions of the sample, or the spin magnetization. MQMAS technique achieves high resolution by involving both spatial and spin manipulations of the broadening interactions.⁸ Under fast MAS rotation ($\chi_m = 54.74^\circ$), the simplified evolution phase can be written as

$$\Phi^{\text{MAS}}\left(\frac{p}{2}, -\frac{p}{2}\right) = \{p[v_0\Delta\delta + m_I J] + A_0^Q(\eta_Q)C_0(S, p) + A_4^Q(\alpha_R, \beta_R, \eta_Q)C_4(S, p)P_4(\cos \chi_m)\}t \quad (10)$$

The remaining anisotropic broadening originates from the last term in equation (10), which is scaled with respect to a static case, but not eliminated by MAS alone. The unconventional aspect of the MQMAS approach is that the selective averaging of second-order quadrupolar broadening is completed by forcing the spin system to evolve outside of the ‘allowed’ central transition coherence, i.e., by transferring it into the multiple quantum coherences ($\mp p/2, \pm p/2$) with $p > 1$. After letting the spins evolve during time t_1 , the spin system is transferred back to the $(-1/2, 1/2)$ coherence and allowed to freely evolve again during time t_2 . The evolution phases in t_1 and t_2 are then correlated in a 2D experiment. The isotropic echo is observed as shown in equation (11), where $R(S, p)$ is

$$t_{2e} = -[C_4(S, p)/C_4(S, -1)]t_1 = R(S, p)t_1 \quad (11)$$

$$R(S, p) = \frac{p[36S(S+1) - 17p^2 - 10]}{36S(S+1) - 27} \quad (12)$$

As the sign of $C_4(S, p)$ is reversed when changing that of p , it is always possible to obtain a positive ratio for $R(S, p)$, which leads to a detectable echo at positive time t_{2e} . This echo signal corresponds to the selection of $p < 0$ for $|p| = 2S$ and $p > 0$ for $|p| < 2S$. Therefore, the echo pathway for spin $S = 3/2$ nuclei can be described using the notation $0 \rightarrow p = -3 \rightarrow -1$. Correspondingly, the correlation of $p = 3$ and $p = -1$ coherences ($0 \rightarrow 3 \rightarrow -1$ pathway) represents the so-called antiecho pathway, where the anisotropic quadrupolar broadening refocuses at negative values of the acquisition time t_2 . The concept of antiecho will be later used in describing the experiments that allow for the acquisition of pure absorption spectra (Section 3).

A 2D Fourier transformation of the time domain signal provides a correlation spectrum, which consists of narrow resonance bands with ridges extended along the direction given by

$$F_1 = R(S, p)F_2 \quad (13)$$

where F_2 and F_1 represent frequencies in the single and multiple quantum dimensions, respectively. It is convenient to apply a shearing transformation in order to align these ridges with the F_2 direction. The shearing process transforms F_1 into a new isotropic dimension, which will be denoted F_{ISO} (see Section 4.2).

The basic MQMAS experiment consists of four steps:

- (i) RF excitation of MQ coherences
- (ii) evolution of these coherences under the internal Hamiltonian H during time t_1

Figure 2 Schematic diagram of the original MQMAS experiment.⁸ Time evolution of the reduced density matrix of spin-3/2 nuclei is also shown, with darker squares representing the increased amount of (m, m') coherence

- (iii) reconversion of the MQ coherences into the observable single quantum coherence, again using suitable RF sequence, and
- (iv) detection of the signal as a function of time t_2 .⁸

The pulse sequence used in the original MQMAS experiment contains two strong continuous wave (CW) RF pulses of duration τ_1 and phase ϕ_1 , used for preparation (MQ excitation) and mixing (MQ $\rightarrow$ $-1Q$ conversion): $H_1(\tau_1)_{\phi_1} - t_1 - H_2(\tau_2)_{\phi_2} - t_2$, as shown in Figure 2. The role of the excitation pulse (or sequence) is to create the largest possible amount of p -quantum coherence along the anti-diagonal of the density matrix ($(\pm p/2, \mp p/2)$, $3 \leq |p| \leq 2S$), as shown schematically on top of the figure for $S = 3/2$. The dephasing that this coherence acquires during the evolution time t_1 is then selectively transferred to the observable $-1Q$ central transition by the second pulse (or sequence) where it refocuses according to equation (11).

Considerable research effort targeted two main weaknesses of MQMAS, namely the limited efficiency of excitation and reconversion, and sensitivity to the magnitude of C_Q . The efficiency could be significantly increased by using the highest possible RF magnetic field ν_{RF} (the so-called hard pulses), fast amplitude modulation (FAM), double frequency sweeps (DFS), rotary resonance excitation and rotation-induced adiabatic coherence transfer method (RIACT).^{42–47} FAM, DFS and RIACT are least sensitive to C_Q and thus extend the range of quadrupolar couplings that are accessible to MQMAS to larger values. The most commonly used coherence pathways and acquisition schemes include the split- t_1 scheme with shifted (whole) echo and the z-filter method.^{48–51} Several studies were reported that reviewed these schemes and evaluated their performance using standard samples.^{40,52,53} At present, it appears that the split- t_1 whole echo scheme with FAM conversion could become a method of choice in MQMAS NMR, as it combines high efficiency with quantitative accuracy and is easy to implement in standard NMR spectrometers.

3 DETECTION OF PURE-PHASE SPECTRA

In general, the time domain signal corresponding to a single resonance in a given crystallite is given by a phase-modulated

function

$$s(t_1, t_2) = s_p \exp(2\pi i \nu_p t_1) \exp(2\pi i \nu_{-1} t_2) \exp[-(\lambda_p t_1 + \lambda_{-1} t_2)] \quad (14)$$

where s_p represents the amplitude of signal derived via the $0 \rightarrow p \rightarrow -1$ pathway, ν_p and ν_{-1} are the resonance frequencies of the symmetric coherences in p-quantum ($p/2$, $-p/2$) and single quantum ($-1/2$, $1/2$) dimensions, and λ 's represent the respective transverse relaxation rates (note that $\lambda_p = \lambda_{-p}$). Phase modulation of the detected signal is invariably encountered in 2D spectroscopy while using a single coherence transfer pathway.⁵⁴ A complex 2D Fourier transformation of $s(t_1, t_2)$ yields the frequency spectrum

$$S(F_1, F_2) = s_p [a(F_1, \nu_p) + id(F_1, \nu_p)][a(F_2, \nu_{-1}) + id(F_2, \nu_{-1})] \quad (15)$$

where $a(F_i, \nu_j)$ and $d(F_i, \nu_j)$, with $i = 1, 2$ and $j = p, -1$, are the absorptive (real) and dispersive (imaginary) parts of the spectrum along the multiple and single quantum dimensions

$$\begin{aligned} a(F_i, \nu_j) &= \frac{\lambda_j}{\lambda_j^2 + (F_i - \nu_j)^2} \\ d(F_i, \nu_j) &= \frac{F_i - \nu_j}{\lambda_j^2 + (F_i - \nu_j)^2} \end{aligned} \quad (16)$$

The absorptive and dispersive components are superimposed in equation (15), giving rise to phase-twisted lineshapes. This problem cannot be avoided simply by the adjustment of the phase sensitive detector. Although such a procedure allows the selection of the real part of $S(F_1, F_2)$

$$S^R(F_1, F_2) = s_p [a(F_1, \nu_p)a(F_2, \nu_{-1}) - d(F_1, \nu_p)d(F_2, \nu_{-1})] \quad (17)$$

the absorptive and dispersive components remain mixed in the spectrum. Such mixed-phase spectra were observed in the first MQMAS experiments that used the selection of a single coherence pathway, sometimes referred to as simple echo or simple antiecho (see Figure 3a). This is a major shortcoming, especially in cases where the observation of undistorted lineshapes in the anisotropic dimension is of significant interest or when two resonances are located in close proximity in a 2D spectrum (compare spectrum (b) with a properly acquired and phased spectrum (b) in Figure 3). The basic concepts of phase separation were first developed to facilitate the analysis of 2D correlation spectra in solutions.⁵⁴ Since the inception of MQMAS, several strategies for the collection and processing of the data have been proposed, which in essence allow for the 2D phase-adjustment. These strategies can be classified into two categories, based on the appearance of the maximum echo signal in the first row (i.e., $t_1 = 0$) of the 2D data set. The first involves a phase modulated procedure in which the maximum signal (echo) is delayed to $t_{2e} > 0$ by applying one or several $\pm 1Q \rightarrow \mp 1Q$ Hahn echoes.¹⁴ The second category includes amplitude modulated experiments in which $t_{2e} = 0$ for $t_1 = 0$. The performance of various approaches has been thoroughly examined and compared by Brown and Wimperis.⁵² We will review these methods briefly in Sections 3.1 and 3.2. Sections 3.3 and 3.4 will describe the methods that allow determination of the sign

Figure 3 Sheared 3QMAS spectra measured for ^{87}Rb in RbNO_3 . The following experimental conditions were used: $\nu_0 = 196.4$ MHz, $\nu_{\text{RF}} = 70$ kHz, $\nu_{\text{R}} = 10$ kHz. Positive and negative levels are represented on the contour plots by solid and dashed lines, respectively. Spectrum (a) results from acquisition of an echo coherence transfer pathway ($0 \rightarrow -3 \rightarrow -1$). When both echo and antiecho pathways ($0 \rightarrow \pm 3 \rightarrow -1$) are properly used, see spectrum (b), the dispersive parts disappear and all three Rb species present in this compound can be distinguished

of frequency in the F_1 dimension for experiments involving amplitude modulation.

3.1 Phase Modulation during t_1 ; Shifted Echo and Antiecho

The method of shifting the echo (and/or antiecho) eliminates the dispersive components from the spectrum by utilizing the symmetry properties of the time domain signals and their complex Fourier transforms. The complex Fourier transform of the two halves of a suitably phased symmetrical NMR echo is real. Each half yields the absorption components with the same phase and the dispersion components with opposite phases, which thus cancel. In MQMAS, the shifted echo (antiecho) approach relies upon the introduction of a refocusing π pulse at the end of the pulse sequence in order to delay the formation of an echo (antiecho) in the t_2 domain by a time interval τ .^{50,52}

The time domain signals, the pulse sequence and the corresponding coherence transfer pathways for these experiments are schematically shown in Figure 4. As mentioned earlier, the 2D data set that results from the use of a single coherence pathway exhibits phase modulation. In such case, the 2D time-domain signal can be written as shown in equations (18) and (19)

$$s(t_1, t_2, \tau) = s_p \exp(2\pi i \nu_p t_1) \exp(2\pi i \nu_1 \tau) \exp(2\pi i \nu_{-1} t_2) \times \exp[-(\lambda_p t_1 + \lambda_1 \tau + \lambda_{-1} t_2)] \quad (18)$$

Since $\nu_1 = -\nu_{-1}$,

$$s(t_1, t_2, \tau) = s(t_1, t_2, 0) \exp[-(2\pi i \nu_{-1} + \lambda_1) \tau] \quad (19)$$

In the time domain, the signal first appears at $t_2 < \tau + t_{2e}$, where t_{2e} is given by equation (11) for echo and antiecho. The signal then rises until reaching a maximum at $t_2 = \tau + t_{2e}$, and decays to zero at $t_2 > \tau + t_{2e}$. The echo and antiecho signals (Figures 4a and 4b) shift forward and backward, respectively, as the time t_1 increases. It is important that the delay time τ be long enough to avoid truncation of the signal at any

value of t_1 . In this case, the shifted echo and shifted antiecho methods are referred to as whole echo experiments.⁵⁰ Clearly, the delay τ has to be longer in the case of the shifted antiecho, which can result in noticeable loss of signal due to transverse relaxation. A complex 2D Fourier transformation of $s(t_1, t_2, \tau)$, followed by a first-order phase correction of $2\pi \nu_{-1} \tau$ in the F_2 dimension, yields a spectrum described by

$$S(F_1, F_2) = 2s_p [a(F_1, \nu_p) + id(F_1, \nu_p)] a(F_2, \nu_{-1}) \exp(-2\lambda_1 \tau) \quad (20)$$

Hence, a pure phase spectrum is obtained in spite of the fact that the time domain signal given by equation (18) is phase modulated. The signal to noise (S/N) ratio is multiplied by $\sqrt{2} \exp(-2\lambda_1 \tau)$, compared to the standard (non-shifted) method, and thus can be increased when the transverse losses are minor. An added advantage here is that phase modulation in itself yields sign discrimination in the F_1 domain. It is important to note that the success of these techniques in obtaining pure-phase spectra relies upon the ability of obtaining a symmetric function in the time domain for each value of t_1 . Thus, it is essential that inhomogeneous second order quadrupolar broadening dominates the homogeneous effect due to, for example, the homonuclear dipolar interaction (see also Section 4.3). However, there appears to be no difference in resolution between the techniques leading to the shifted echo or antiecho.⁵²

While the above method utilizes sequences for acquisition of signals via the echo or antiecho pathways in separate experiments, the shifted echo and shifted antiecho can be detected simultaneously (Figure 4c). By using the schemes that yield equal intensities of these two signals, an amplitude modulated spectrum can be obtained as described in the next section.⁵⁰

3.2 Amplitude Modulation during t_1 ; Z-filter Method

A frequently used approach for phase separation is to produce a time domain signal with amplitude modulation. In MQMAS this can be easily accomplished by using a linear combination of the signals from echo and antiecho coherence pathways. In general, this signal can be written as

$$s(t_1, t_2) = [s_p \exp(2\pi i \nu_p t_1) + s_{-p} \exp(2\pi i \nu_{-p} t_1)] \times \exp(2\pi i \nu_{-1} t_2) \exp(-\lambda_p t_1) \quad (21)$$

where $\nu_p = -\nu_{-p}$. When $s_p = s_{-p}$, the evolution during t_1 can be described by a cosine amplitude-modulated function

$$s(t_1, t_2) = 2s_p \cos(2\pi \nu_p t_1) \exp(2\pi i \nu_{-1} t_2) \exp[-(\lambda_1 t_2 + \lambda_p t_1)] \quad (22)$$

A 2D Fourier transform of this signal (complex in t_2 and complex in t_1 of the real part of $S(t_1, F_2)$) yields the spectrum $S(F_1, F_2)$ with a purely absorptive real part

$$S(F_1, F_2) = s_p \{ [a(F_1, \nu_p) + a(F_1, -\nu_p)] + i[d(F_1, \nu_p) - d(F_1, -\nu_p)] \} a(F_2, \nu_{-1}) \quad (23)$$

Figure 4 (a) Pulse sequence and coherence transfer pathways for the whole echo (antiecho) experiments, with $S = 3/2$ nuclei. Nonselective (hard) and selective (soft) pulses are represented by black and gray rectangles, respectively. (b) Time domain signals for shifted echo (E) and shifted antiecho (AE) phase modulated experiments. The signal is observed after the third pulse at $t_{2e} = \tau + Rt_1$ for the echo and at $t_{2e} = \tau - Rt_1$ for the antiecho. (c) Similar representation of the whole echo experiment in which shifted echo and shifted antiecho signals are acquired simultaneously

Figure 5 Pulse sequence and coherence transfer pathway for z-filter MQMAS

Note that the same purely absorptive real part can also be obtained by a 2D Fourier transform that is complex in t_2 and real (cosine) in t_1

$$S(F_1, F_2) = s_p[a(F_1, \nu_p) + a(F_1, -\nu_p)][a(F_2, \nu_{-1}) + id(F_2, \nu_{-1})] \quad (24)$$

When $s_p = -s_{-p}$, the evolution during t_1 becomes a sine amplitude-modulated function

$$s(t_1, t_2) = 2is_p \sin(2\pi\nu_p t_1) \exp(2\pi i\nu_{-1} t_2) \exp[-(\lambda_1 t_2 + \lambda_p t_1)] \quad (25)$$

and the same purely absorptive spectrum can be obtained in similar ways.

Although the acquisition of signals from the coherence transfer pathways leading to echo and antiecho can be done in two consecutive experiments, e.g., by proper selection of $0 \rightarrow +p \rightarrow -1$ and $0 \rightarrow -p \rightarrow -1$ pathways, it is more suitable to acquire these signals simultaneously.⁴² For spin-3/2 nuclei, by choosing the length of the conversion pulse such that the corresponding flip-angle is approximately 90° and by using a 6-phase cycling scheme, one can acquire a single, sine amplitude-modulated free induction decay (FID) from these two pathways. The equalization $s_p = -s_{-p}$ does not merely reflect an average over the powdered sample, but occurs for each crystallite regardless of its orientation, at least for moderate values of H_{Q2} . It has been shown, that such acquisition can be also applied in concert with RIACT method.^{47,55} In this technique, the efficiencies of both pathways $0 \rightarrow \pm 3 \rightarrow -1$ are essentially the same when a sufficiently large RF magnetic field is used.

However, the simultaneous balancing of the echo and antiecho intensities in 3QMAS becomes increasingly difficult for higher spin quantum numbers. Under no conditions can the echo and antiecho intensities be equalized for all individual crystallites, and only a powder-averaged matching of intensities is possible when $S > 3/2$. Although this matching can be obtained with relatively good efficiency, the resulting spectra invariably exhibit a dispersive phase. The difficulties are further increased for MQ experiments of higher order, where this equalization procedure causes a significant loss of signal.

The shortcomings of the above method can be quite easily overcome by using a so-called ‘z-filter’.^{48,51} This approach to eliminate phase distortions has been used earlier in 1D and 2D liquid state NMR and in DAS experiments.^{54,56} The

implementation of the z-filter into the 3QMAS experiment utilizing two hard pulses and the corresponding coherence transfer pathways are shown in Figure 5.⁵¹ The z-filter consists of a short delay τ during which all magnetizations are stored along $\mathbf{B}_0$ (z-axis of the laboratory frame) as zero quantum coherences, and then transferred back to the observable single quantum coherences using a ‘soft’ pulse with selective $\pi/2$ flip angle. Thus, the sequence utilizes the $(0 \rightarrow \pm p \rightarrow 0 \rightarrow -1)$ coherence pathway, which results in the contributions of the echoes and anti-echoes being completely symmetric in terms of coherence transfers during the first and second hard pulses. Consequently, the efficiencies of both pathways are equal for all crystallites, leading to cosine amplitude-modulation of the 2D signal (Figure 6). An added advantage of this method is that it is robust and easy to optimize. The first pulse is adjusted to generate the maximum amount of the desired MQ coherences, and the second pulse maximizes their transfer to the zero quantum level. The delay τ must be long enough to eliminate the ‘undesired’ coherences that may be present due to incomplete MQ filtering, and short enough to prevent the line broadening and signal loss due to homogeneous dipolar effects and chemical exchange processes. A delay equivalent to few rotor periods is usually a good trade-off. This delay can be extended and used as a mixing time in the measurement of relative orientation of quadrupole tensors in well crystallized compounds.⁵⁷ The choice of a suitable ν_{RF} level for the soft z-filter pulse is also a compromise, in this case between selectivity and completeness of irradiation of the central transition. This is illustrated in Figure 7, which shows the relative intensities of z-filter MQMAS signals as a function of ν_{RF} applied to generate the soft pulse. This figure shows that although only a part of the signal is generated at very low values of ν_{RF} (i.e., when ν_{RF} is smaller than the MAS line width divided by $(S + 1/2)$), the use of very high strength of RF field diminishes the signal due to excitation of the undesired coherences. Setting ν_{RF} at 10–20 kHz is usually a good choice for the selective pulses in these types of experiments.

The amplitude modulated signals can be also obtained by simultaneous acquisition of the shifted echo and shifted antiecho signals, as shown schematically in Figure 4c.⁵⁰ A complete amplitude modulation is only observed when the contributions of the shifted echo and shifted antiecho are equal and, as was the case in the phase modulated whole echo experiments, when the inhomogeneous broadening dominates the lineshape. However, even when the contributions from

Figure 6 Two matching sections of ^{27}Al 3QMAS spectra in $\text{AlPO}_4\text{-14}$ recorded using two hard RF pulses: (a) phase modulated spectrum obtained without the z-filter (pathway $0 \rightarrow \pm 3 \rightarrow -1$) and (b) amplitude modulated spectrum measured using the z-filter (pathway $0 \rightarrow \pm 3 \rightarrow 0 \rightarrow -1$)

Figure 7 Evolution of the signal detected with the standard z-filter MQMAS experiment, as a function of ν_{RF} for the soft pulse. The following assumptions were made: the length of the soft pulse (in μs) is equal to $250\,000/(S + 1/2)\nu_{\text{RF}}$, the hard pulses use $\nu_{\text{RF}} = 300\text{ kHz}$, the irradiation is made on resonance at $\nu_0 = 100\text{ MHz}$, $\nu_{\text{R}} = 15\text{ kHz}$ and $\eta_Q = 0$. The full MAS line width is 19.3 kHz and the C_Q values are 6, 12.2, 18.8, and 25.5 MHz for $S = 3/2, 5/2, 7/2$ and $9/2$, respectively. All curves are normalized to the maximum intensity value obtained with $\nu_{\text{RF}} = 20\text{ kHz}$

these two pathways are not equal, the 2D Fourier transform performed as described earlier in this section yields pure phase lineshapes.

The disadvantage of amplitude-modulated methods is that the resulting spectrum, described by equations (23) and (24), is fully symmetric with respect to $F_1 = 0$, i.e., the signals appearing at $F_1 = \nu_p$ and $F_1 = -\nu_p$ are indistinguishable. Thus, folding of frequencies in F_1 domain occurs in the 2D spectra obtained with such methods of acquisition. In principle, the problem of foldover can be avoided by locating the carrier frequency to one side of all spectral lines. Since this simple method causes loss of signal due to off-resonance irradiation and is often inconvenient, the so-called time-proportional

phase increments (TPPI) approach or the hypercomplex data acquisition is often used to restore sign discrimination in F_1 .

3.3 TPPI

In TPPI,⁵⁸ the phase ϕ^{prep} of the RF preparation pulse (or sequence) is incremented linearly with t_1

$$\phi^{\text{prep}} = \frac{\pi t_1}{2p\Delta t_1} \quad (26)$$

where Δt_1 is the time increment in t_1 . The amplitude-modulated time domain signal, equation (22), then becomes

$$\begin{aligned} s(t_1, t_2) &= 2s_p \cos \left[2\pi \left(\nu_p t_1 + \frac{p\phi^{\text{prep}}}{2\pi} \right) \right] \\ &\quad \times \exp(2\pi i \nu_{-1} t_2) \exp[-(\lambda_1 t_2 + \lambda_p t_1)] \\ &= 2s_p \cos \left[2\pi \left(\nu_p + \frac{1}{4\Delta t_1} \right) t_1 \right] \\ &\quad \times \exp(2\pi i \nu_{-1} t_2) \exp[-(\lambda_1 t_2 + \lambda_p t_1)] \end{aligned} \quad (27)$$

After Fourier transformation, the spectrum is as described by equations (23) and (24). Its real part is purely absorptive and equal to

$$\begin{aligned} S^R(F_1, F_2) &= s_p \left[a \left(F_1, \nu_p + \frac{1}{4\Delta t_1} \right) \right. \\ &\quad \left. + a \left(F_1, -\nu_p - \frac{1}{4\Delta t_1} \right) \right] a(F_2, \nu_{-1}) \end{aligned} \quad (28)$$

i.e., the resulting spectrum is shifted along F_1 by $+1/4\Delta t_1$ for ν_p and by $-1/4\Delta t_1$ for its folded resonance. Thus, it becomes possible to place the carrier frequency in the center of the spectral region and discriminate between positive and negative offsets as if the signal were acquired in quadrature mode. It is advisable to decrease Δt_1 (increase the Nyquist frequency) by a factor of two with respect to an experiment done without TPPI, in order to avoid the frequency foldover between $a(F_1, \nu_p)$ and $a(F_1, -\nu_p)$.

3.4 Hypercomplex Data Acquisition (States Method)

The hypercomplex approach, also known as the States method, relies upon acquisition of signals from two complementary experiments, which provide the distinction of real and imaginary parts in t_1 in the same way as the classical quadrature detection does in t_2 .⁵⁹ Both echo and antiecho signals in MQMAS are acquired simultaneously in this method. For each increment in t_1 , two time domain signals s_X and s_Y are created and measured with the phases ϕ^{prep} of the preparation sequence equal to 0 and $\pi/2p$, respectively (see equations (29) and (30)).⁵⁰

$$\begin{aligned} s_X(t_1, t_2) &= 2s_p \cos(2\pi \nu_p t_1) \exp(2\pi i \nu_{-1} t_2) \\ &\quad \times \exp[-(\lambda_1 t_2 + \lambda_p t_1)] \end{aligned} \quad (29)$$

$$\begin{aligned} s_Y(t_1, t_2) &= 2s_p \cos(2\pi \nu_p t_1 + p\phi^{\text{prep}}) \exp(2\pi i \nu_{-1} t_2) \\ &\quad \times \exp[-(\lambda_1 t_2 + \lambda_p t_1)] \\ &= -2s_p \sin(2\pi \nu_p t_1) \exp(2\pi i \nu_{-1} t_2) \\ &\quad \times \exp[-(\lambda_1 t_2 + \lambda_p t_1)] \end{aligned} \quad (30)$$

We assume here that the echo and antiecho contribute equally to the observed signal, i.e., that the condition $s_p = s_{-p}$ holds for s_X and s_Y . This can be accomplished using the methods described in Section 3.2. The complex Fourier transformation in t_2 yields equations (31) and (32)

$$s_X(t_1, F_2) = 2s_p \cos(2\pi \nu_p t_1) [a(F_2, \nu_{-1}) + id(F_2, \nu_{-1})] \exp(-\lambda_p t_1) \quad (31)$$

$$s_Y(t_1, F_2) = -2s_p \sin(2\pi \nu_p t_1) [a(F_2, \nu_{-1}) + id(F_2, \nu_{-1})] \exp(-\lambda_p t_1) \quad (32)$$

The real parts of s_X and s_Y are then combined to produce a new complex signal

$$s(t_1, F_2) = s_X^R(t_1, F_2) - is_Y^R(t_1, F_2) = 2s_p a(F_2, \nu_{-1}) \times \exp(2\pi i \nu_p t_1) \exp(-\lambda_p t_1) \quad (33)$$

A complex Fourier transformation of $s(t_1, F_2)$ with respect to t_1 then produces, for the real part, a pure-phase spectrum

$$S(F_1, F_2) = 2s_p a(F_2, \nu_{-1}) [a(F_1, \nu_p) + id(F_1, \nu_p)] \quad (34)$$

with a single resonance located at $(F_1, F_2) = (\nu_p, \nu_{-1})$.

The TPPI and hypercomplex methods result in the same S/N ratio per unit of experimental time. However, the hypercomplex method allows for separating of the echo and antiecho signals according to

$$\begin{aligned} s_E(t_1, t_2) &= s_X(t_1, t_2) - is_Y(t_1, t_2) \\ s_A(t_1, t_2) &= s_X(t_1, t_2) + is_Y(t_1, t_2) \end{aligned} \quad (35)$$

which can be independently processed (e.g., apodized).

4 PROCESSING AND INTERPRETATION OF MQMAS SPECTRA

One of the primary benefits of MQMAS is that it allows for separation and measurement of the isotropic chemical and quadrupolar-induced shifts by analyzing a single 2D spectrum.⁹ However, proper assignment of the resonance shifts along the F_1 and F_2 dimensions in such an analysis is not immediately obvious. In this section, we examine the distribution of resonances in MQMAS spectra and discuss the interpretation of resonance shifts that result from processing the data with and without the shearing transformation.

4.1 Unsheared Spectrum

A typical MQMAS spectrum, resulting from a standard 2D Fourier transformation of a temporal data set obtained with the methods described in the previous sections, consists of several extended bands similar to those depicted in Figure 8a. Analysis and interpretation of such an unsheared spectrum is facilitated by introducing the chemical shift (CS) axis, the anisotropic (A) axis and the quadrupolar induced shift (QIS) axis. In a hypothetical spectrum with negligible quadrupolar interactions, the resonances would be sharp and located on the CS axis at $-p\nu_0\Delta\delta$ and $\nu_0\Delta\delta$ in the multiple and single quantum dimensions, respectively. The slope of the CS axis

Figure 8 (a) Unsheared and (b) sheared 3QMAS spectra of ^{27}Al in $\text{AlPO}_4\text{-14}$ acquired at $\nu_0 = 104.2$ MHz using the z-filter sequence with rotor synchronization, $\nu_R = 14.5$ kHz, and $\nu_{\text{RF}} = 200$ kHz. The CS, A and QIS axes are plotted, as described in the text. Two tetrahedral sites (1 and 2), one fivefold coordinated site (3) and one sixfold coordinated site (4) are resolved, in agreement with crystallographic data. Note that resonance 4 is folded over in (a) due to the limited spectral width in rotor-synchronized spectra

is either $-p$ when resonances are expressed in Hz or 1 when ppm scales are used instead (vide infra). The A axis is defined by the orientation of anisotropic ridges in MQMAS spectra (see equation (13)) and has a slope $R(S, p)$ given by equation (12). In the MQMAS experiment, which detects only species with a non-zero quadrupolar interaction, the center of gravity of a given resonance is displaced from the CS axis, in both dimensions, by the quadrupolar-induced shift. Assuming that the efficiency of MQMAS is constant for all crystallite orientations, this shift [see equation (10)] can be expressed (in Hz) as

$$\nu_{\text{QIS}}(S, p) = A_0^Q(\eta_Q)C_0(S, p) \quad (36)$$

The direction in which this displacement occurs defines the QIS axis, which has a slope ξ given by

$$\xi(S, p) = \frac{\nu_{\text{QIS}}(S, p)}{\nu_{\text{QIS}}(S, -1)} = \frac{-p[4S(S+1) - 3p^2]}{[4S(S+1) - 3]} \quad (37)$$

Since for a given pair (S, p) the quadrupolar induced shifts have a unique sign, all observed resonances (except for the spinning sidebands) must appear on the same side of the CS axis, as seen in Figure 8. The factors R and ξ have been given in Amoureux and Fernandez for all experimentally accessible values of S and p .⁶⁰ With the help of these parameters, both the chemical shift and quadrupolar parameters can be extracted from the unsheared spectra in a straightforward manner. The isotropic chemical shift of a given resonance is simply found by projecting its center of gravity on the CS axis along the QIS direction. Similarly, the displacement of this resonance from the CS axis measured along F_1 and F_2 and given (in Hz) by

$$\nu_{\text{QIS}}(S, p) = \frac{3p}{10\nu_0} \frac{[4S(S+1) - 3p^2]}{[4S(2S-1)]^2} P_Q^2 \quad (38)$$

can be used to evaluate the second-order quadrupolar effect parameter P_Q

$$P_Q = C_Q \sqrt{1 + \eta_Q^2/3} \quad (39)$$

From equation (39), the quadrupolar coupling constant C_Q can be determined accurately, provided the asymmetry parameter η_Q is known, e.g., from simulation of MAS lineshape.

4.2 Shearing Transformation; Referencing of MQMAS Spectra

MQMAS spectra can be most conveniently analyzed by applying a shearing transformation, which places the A axis parallel to the F_2 axis (Figure 8b) and creates a new dimension labeled F_{ISO} (or δ_{ISO}). The direct advantage of such an approach is that the orthogonal projection of MQMAS spectrum onto the F_{ISO} axis does not include the anisotropic quadrupolar and chemical shift contributions. A similar projection onto the F_2 axis yields the pQ -filtered anisotropic MAS powder pattern. This pattern should not be generally used for the accurate determination of C_Q and η_Q due to the distortions of the observed intensities, which can be severe for large values of C_Q . In addition, for a given value of C_Q these distortions increase with increasing $|p|$ (Figure 9a). More reliable values of C_Q and η_Q can be obtained from the simulation of the MAS spectra acquired using a short RF pulse.

In the sheared spectrum, the frequency F_{ISO} can be conveniently expressed as a linear combination of F_1 and F_2

$$F_{\text{ISO}} = F_1 + RF_2 \quad (40)$$

where R is given by equation (12). This convention allows for direct determination of the sample rotation rate from the sheared spectrum when it is plotted in Hz.⁶⁰ In order to introduce the referencing in ppm, let us first consider a single resonance that is not affected by the quadrupole interaction, located at coordinates $(-p\nu_0\Delta\delta, \nu_0\Delta\delta)$ on the CS axis of

Figure 9 ^{27}Al NMR spectra of $\text{AlPO}_4\text{-14}$ obtained at 156.4 MHz: (a) simulated and experimental MAS spectrum obtained using a $\pi/12$ flip angle, compared with the anisotropic projections of 3QMAS and 5QMAS spectra; (b) isotropic projections of ^{27}Al MQMAS spectra. The isotropic resonances are labeled following Figure 8, the remaining peaks represent spinning sidebands

an unsheared spectrum. After the shearing transformation, its coordinate F_{ISO} in the isotropic dimension is given in

$$F_{\text{ISO}} = (R - p)\nu_0\Delta\delta \quad (41)$$

The ppm scales δ_1 , δ_2 and δ_{ISO} use the apparent Larmor frequencies, which are equal to ν_0 , $-\nu_0$, and $(R - p)\nu_0$ along F_2 , F_1 and F_{ISO} , respectively. In the absence of the quadrupole interaction, this convention results in the shifts being identical and equal to $\Delta\delta$ along the three axes.

We have seen above (equation (38)), that the quadrupole interaction shifts the resonance away from the CS axis in both dimensions. In an unsheared spectrum, this shift can be

expressed in ppm as equation (42) with equation (43)

$$\delta_{\text{QIS}}(S, p) = -\frac{\nu_{\text{QIS}}(S, p)}{p\nu_0} 10^6 = -\frac{3}{10} \frac{[4S(S+1) - 3p^2]}{[4S(2S-1)]^2} \frac{P_Q^2}{\nu_0^2} 10^6$$

$$= k_{|p|} P_Q^2 \quad (42)$$

$$k_{|p|} = -\frac{3}{10} \frac{[4S(S+1) - 3p^2]}{[4S(2S-1)]^2} 10^6 \quad (43)$$

Clearly, $\delta_{\text{QIS}}(S, p)$ is always negative along the δ_2 dimension ($k_1 < 0$), but can be positive or negative along δ_1 , depending on S and $|p|$. After the shearing transformation, the quadrupolar-induced shift in the F_{ISO} dimension becomes always positive and independent of p

$$\delta_{\text{QIS,ISO}} = \frac{\nu_{\text{QIS,ISO}}(S, p)}{(R-p)\nu_0} 10^6 = -\frac{10}{17} \delta_{\text{QIS}}(S, -1) = -\frac{10}{17} k_1 P_Q^2 \quad (44)$$

Thus, the QIS direction in the 2D sheared spectrum expressed in ppm has a constant slope of $-10/17$, regardless of the values of S and p . Since the CS axis of such a spectrum has a constant slope of 1, the MQMAS sheared spectra displayed using these ppm scales are independent of p for a given spin system. To illustrate this point, the isotropic projections of 3QMAS and 5QMAS spectra of ^{27}Al in aluminophosphate $\text{AlPO}_4\text{-14}$ are compared in Figure 9b.⁶¹

Finally, it is interesting to note that MQMAS can be also useful in determination of the indirect scalar spin-spin coupling.⁶² Indeed, while the J values are often small with the common quadrupolar nuclei, the J dephasing is proportional to p in the multiple quantum dimension [equation (10)] thus increasing the corresponding splitting in this dimension. Along the isotropic axis of the sheared spectrum, this splitting becomes independent of p when expressed in ppm

$$\delta_{\text{ISO}} = \Delta\delta + \delta_{\text{QIS,ISO}} + 10^6 m_I J / \nu_0 \quad (45)$$

and therefore should preferentially be observed in 3QMAS for best sensitivity. Thus, in well crystallized samples, the presence of scalar coupling multiplets can be detected by recording the MQMAS spectra at different fields.

It should be noted that the above referencing scheme is directly applicable to the spectra obtained using satellite transitions and magic angle spinning (STMAS) NMR.⁶³ Again, the QIS slope of $-10/17$ is observed provided that the appropriate values of R are used. The apparent Larmor frequencies used to calculate the normalized shifts along the δ_{ISO} axis [see equation (41)] are half of those calculated for 3QMAS.

4.3 Split- t_1 Method

The split- t_1 method of data acquisition relies upon the splitting of time t_1 into single and multiple quantum evolution periods in proportion to the ratio $R(S, p)$.⁴⁸ By doing so, the fourth-order anisotropic term given in equation (10) can be always refocused at the end of the t_1 period. After 2D Fourier transformation, the inhomogeneously broadened ridges appear parallel to the F_2 axis, which eliminates the need for the shearing transformation. As is shown below, the split- t_1 method has been combined with the whole echo experiment

to provide a very efficient scheme for MQMAS. Another advantage of an echo being stationary within the acquisition period is that the time domain signal is easier to apodize by using t_1 -independent weighting functions. This split- t_1 mode of data acquisition can be conveniently used in MQMAS-based heteronuclear correlation spectroscopy (MQ-HETCOR) experiments and in the Carr–Purcell–Meiboom–Gill (CPMG) MQMAS experiments (see Sections 5.1 and 6).

In the split- t_1 amplitude modulated methods, for each crystallite, the echo and antiecho coherence pathways must contribute to the processed signal with equal amplitude in order to obtain a pure absorption lineshape (see Section 3.2). For spin-3/2 nuclei, this can be achieved by using the coherence transfer pathway with the z-filter, $0 \rightarrow \pm 3 \rightarrow \pm 1 \rightarrow 0 \rightarrow -1$, as shown in Figure 10a.^{52,64} The efficiency of this four-pulse method can be improved by using FAM, DFS or RIACT methods for the $\pm 3Q$ to $\pm 1Q$ conversion.^{43–45,47,55,65,66} This scheme

Figure 10 (a) Amplitude modulated split- t_1 pulse sequence and coherence pathway for $p = 2S$. For $p < 2S$, the experiment can be performed using the same pulse sequence and the coherence pathway as shown in figure (b). (c) and (d) Phase modulated split- t_1 pulse sequences and coherence pathways for $p = 2S$ and $p < 2S$

can easily be extended to 5-, 7-, and 9 QMAS experiments with spin-5/2, -7/2 and -9/2 nuclei. The symmetric split- t_1 pathways $0 \rightarrow \pm 3 \rightarrow \mp 1 \rightarrow 0 \rightarrow -1$ were also proposed for 3QMAS experiments with spins $S > 3/2$ (see Figure 10b). However, such experiments are relatively inefficient, as they involve the coherence change of $|\Delta p| = 4$ during $\pm 3 \rightarrow \mp 1$ conversion.

The split- t_1 method can be also used in phase modulated (shifted echo) experiments, which generate pure phase spectra through the acquisition of the whole echo. The coherence pathway displayed in Figure 10c ($0 \rightarrow 3 \rightarrow 1 \rightarrow -1$), uses $|\Delta p| = 2$ and requires a short spin echo interval.⁵² For spin-3/2 systems in which the loss of magnetization due to T_2 effects is not significant, this MQMAS scheme has been recommended as the most efficient, especially when used with the FAM or DFS conversion.^{40,52} This scheme works equally well in 5-, 7- and 9 QMAS experiments for spins 5/2, 7/2 and 9/2, respectively. For the MQMAS experiments with $|p| < 2S$, this scheme can be modified, as shown in Figure 10d. The referencing of split- t_1 spectra can be performed using the same method as described in Section 4.2.

4.4 Resolution of MQMAS Spectra

The timing of the echo formation, as described by equation (11), is independent on the size of quadrupolar and CSA interactions, the orientation of crystallites, and the experimental conditions (ν_{RF} and ν_R). Thus, isotropic resolution should be consistently achieved by the MQMAS method, at least in the absence of strong dipolar broadening. The isotropic line width has been analyzed in several 3QMAS spectra of $RbNO_3$ and $LiRbSO_4$, which were obtained using various schemes for coherence transfer with CW nutation, RIACT and FAM pulses.⁴⁰ $LiRbSO_4$ was particularly useful in these tests due to exceptionally narrow line observed in this compound (see Figure 1). Indeed, no significant changes in resolution were observed while switching between different coherence transfer schemes, ν_{RF} frequencies and conversion methods.

However, several authors have reported an enhancement of resolution upon increasing the MQ order p from three to five (and seven) both in crystalline and amorphous samples (see Figure 9b and Figure 11).^{61,67,68} It should be noted that due to the presence of p -dependent scaling factors (see Section 4.2), non-uniform RF excitation, dipolar effects, and spinning

Figure 11 ^{27}Al MQMAS spectra of $SrAl_{12}O_{19}$: (a) unsheared 3QMAS, (b) sheared 3QMAS, (c) unsheared 5QMAS, and (d) sheared 5QMAS. Note the different appearance of spectral features in the Figures (a) and (c) due to the relocation of A and QIS axes

sidebands, a comparison between MQMAS experiments of different order is not straightforward. The improvement of resolution between 3QMAS and higher-order MQMAS spectra cannot be easily determined from the line width in ppm (which is arbitrary), or from the line width in Hz (due to different scaling factors involved). Instead, the dispersion of shifts relative to the observed line width along the isotropic dimension should be used when comparing these experiments.

However, it has also been noticed that this increase in the apparent resolution is not uniform among different spin systems. Recent investigations have attributed these effects to the interplay between inhomogeneous and homogeneous contributions to the isotropic line width.^{67,68} In the case of well-crystallized samples, the inhomogeneous contributions may be due to inhomogeneity of the static magnetic field, changes in magnetic susceptibility, incomplete heteronuclear decoupling and second-order quadrupolar-dipolar couplings.^{69,70} Since the Hamiltonians associated with these interactions are linear in S_z , under the p-quantum evolution the corresponding inhomogeneous broadening scales in the same way as the dispersion of isotropic shifts. Consequently, no apparent increase in resolution should be observed in higher-order MQMAS spectra.^{60,68} The homogeneous contribution, however, is not expected to increase with p.⁶⁸ Therefore, in crystalline samples with strong homogeneous contribution to the line broadening, considerable enhancement of the isotropic resolution may be observed by moving to higher-order MQMAS schemes. This enhancement is less evident in amorphous samples, where the distribution of isotropic shifts dominates the spectra. In such cases, the more sensitive 3QMAS experiments are recommended.

Interestingly, the presence of dipolar interactions may have an opposite effect on the resolution. Since in a static sample the dipolar dephasing is proportional to p [F term in equation (7)], MAS averaging becomes less efficient in higher order multiple quantum experiments.⁷¹ In the presence of strong dipolar interactions, continuous wave decoupling may be insufficient during t_1 , and composite decoupling may be necessary to obtain a well resolved spectrum.^{72,73} In the majority of applications, however, the most practical way to achieve efficient homo- and hetero-nuclear decoupling in MQMAS experiments is to use the highest possible spinning speed. The added advantage of using high spinning speed is the increased spectral width along F_1 in the experiments performed with rotor synchronization. The rotor-synchronized spectra have improved S/N ratio, although their spectral width is limited along the F_1 dimension.⁷⁴

Finally, the resolution enhancement in MQMAS can be also due to the narrowing in the MQMAS efficiency curves that is observed for higher values of p. Therefore, for each species, the relative intensities of various parts of the 2D spectra may become distorted in such a way that they appear narrower when |p| increases, especially in highly disordered samples with wide distributions of quadrupolar and/or chemical shift parameters. Most likely, this effect is negligible when using transfer methods that are less sensitive to the quadrupole splitting (FAM, DFS, or RIAC).

4.5 Quantification of MQMAS Intensities

The great advantage of MQMAS over the standard MAS experiment is the high resolution that it provides. However,

MQMAS skews the spectral intensities, due to the strong dependence of the multiple quantum excitation and conversion on the quadrupole splitting $\bar{\nu}_Q$, which, in turn, is a function of C_Q , η_Q and the crystallite orientation [see equations (4) and (5)]. The resulting spectra are not quantitative in the isotropic dimension and have distorted lineshapes in the MAS dimension. Examples of such effects are shown in Figures 9 and 11. In order to minimize these distortions it is always advisable to use the aforementioned FAM, DFS and RIAC schemes for excitation and conversion. We now describe additional strategies to retrieve quantitative intensities from the MQMAS spectra.

One of these strategies relies upon combining the information given by MQMAS and MAS. In short, MQMAS can be used to obtain highly resolved spectra and to determine the isotropic chemical shifts and the quadrupolar parameters for different sites. This provides a starting set of parameters for simulation of the MAS spectra in order to obtain accurate intensities. Special care must be taken to assure the quantitative accuracy of the MAS spectra by using short RF pulses (small tip angles) for excitation. We note that this method is suitable for analysis of spectra that are not significantly broadened due to dipolar interactions and/or distribution of chemical shift and quadrupolar parameters.

Secondly, quantitative information can be obtained by calculating the theoretical powder-averaged efficiency curves for MQMAS experiments as a function of P_Q . The efficiency curves for 3QMAS and 5QMAS experiments performed using an RF magnetic field of 70 kHz are depicted in Figure 12.⁶¹ Since the parameter P_Q can be easily derived from analysis of the first moment of the MQMAS spectrum, these curves can be used to offset the quantitative distortions. Indeed, in case of $\text{AlPO}_4\text{-14}$ this method yielded correct concentrations of various aluminum species.⁶¹ This technique is suitable for

Figure 12 Relative intensities of 3QMAS (dashed lines) and 5QMAS (solid lines) spectra versus P_Q , calculated for $\nu_{\text{RF}} = 70$ kHz (Δ , $\circ$: $\eta_Q = 0$, ∇ , $\square$: $\eta_Q = 1$)

Figure 13 Schematic representations of a Gaussian distribution of (a) δ_{CS} and (c) P_Q . The individual slices add up to form the isotropic and anisotropic projections of the 2D spectra. (b) and (d) show the experimental examples of such distributions found in amorphous B_2O_3 and γ -alumina, respectively

the analysis of spectra with substantial broadening, e.g., due to amorphous nature of the sample.

4.6 Analysis of Distribution of Quadrupolar and Chemical Shift Parameters

Many samples of interest in chemistry and materials science do not have a well-organized structure with long range order. In such systems, the resonances cannot be described with a unique set of quadrupolar and chemical shift parameters. Instead, the distributions of these parameters must be considered to properly interpret the spectra. However, the numerical analysis of MQMAS spectra can provide a complete quantitative determination of the distribution of the isotropic chemical shifts δ_{CS} and the quadrupolar parameters (P_Q or

C_Q and η_Q). In partly disordered or amorphous materials, this information can be used to assess the degree of disorder and can be further utilized to evaluate other properties, such as inter-nuclei distances or bond angle distributions. For example, ^{27}Al distributions can be interpreted using relationship between δ_{CS} and the T–O–T angle, or between C_Q and the O–T–O angle, where $t = Al, Si$. In the same way, the distribution of ^{17}O parameters can be used to analyze the Si–O–Si and Al–O–Si angles.^{75–78}

To illustrate how these distributions are manifested in the MQMAS spectrum, let us first consider a single site that is characterized by a unique set of parameters δ_{CS} , C_Q and η_Q . Let us further assume that the residual line broadening due to dipolar interactions with other spins can be ignored. This leads to a second-order quadrupolar pattern with a well-defined

lineshape in an MAS spectrum and a narrow pattern in the corresponding MQMAS spectrum. In the sheared MQMAS spectrum, the center of gravity of this pattern is given by

$$\delta_2^g = \delta_{CS} + k_{||} P_Q^2 \quad (46)$$

$$\delta_{ISO}^g = \delta_{CS} - \frac{10}{17} k_{||} P_Q^2 \quad (47)$$

where $k_{||}$ is given by equation (43) and P_Q is given by equation (39). As explained in Section 4.2, any changes of δ_{CS} or P_Q cause shifts of the spectrum along the CS or QIS directions, respectively. Consequently, a distribution of these parameters broadens the observed 2D patterns. The numerically generated illustrations of the spectral changes due to the distribution of chemical shift and P_Q are shown in Figures 13a and 13c, respectively. The corresponding examples of experimental distributions are shown in Figures 13b and 13d. We note that a Gaussian distribution of chemical shifts results in a Gaussian broadening along the isotropic and anisotropic projections. However, since the intensities and widths of the individual spectra depend on the quadrupolar parameters, an asymmetrical broadening of the projections occurs in the case of a Gaussian distribution of P_Q . In most practical applications, the distributions of δ_{CS} and P_Q are encountered simultaneously, which makes the spectral analysis more complex. Nevertheless, these distributions can be separated because the directions of CS and QIS axes differ by approximately 75° .

The sheared MQMAS spectrum S_e measured experimentally is described by an integral of the individual two-dimensional MQMAS spectra over all possible combinations of chemical shift and quadrupolar parameters

$$S_e(\delta_2, \delta_{ISO}) = \int_{-\infty}^{+\infty} d\delta_{CS} \int_0^{+\infty} dC_Q \int_0^1 S_c(\delta_2, \delta_{ISO}; \delta_{CS}, C_Q, \eta_Q) \times \Pi(\delta_{CS}, C_Q, \eta_Q) d\eta_Q \quad (48)$$

In equation (48), S_c is the calculated MQMAS spectrum corresponding to a single set of lineshape parameters δ_{CS} , C_Q and η_Q , based on the evolution of the spin density matrix during the entire MQMAS experiment. The probability function $\Pi(\delta_{CS}, C_Q, \eta_Q)$ characterizes the distribution of δ_{CS} , C_Q and η_Q . The propagation of the density matrix results from the first (H_{Q1}) and second (H_{Q2}) order quadrupole interactions, as well as the RF Hamiltonians during the pulses. As a result

of sample spinning, all these interactions are rendered time-dependent, which requires the use of sophisticated routines, such as MQSIM, PULSAR, SIMPSON, or GAMMA.^{55,60,79,80}

Two different strategies can be used for solving equation (48) to obtain $\Pi(\delta_{CS}, C_Q, \eta_Q)$. The so-called direct method relies upon iterative fit of $\Pi(\delta_{CS}, C_Q, \eta_Q)$ using, e.g., linear least square procedure to minimize the deviation between the experimental and simulated spectra. The second method directly computes the distribution from the experimental MQMAS spectrum by performing the so-called inversion of the 2D spectrum.⁸¹

In the direct method, it is assumed that the chemical shift and quadrupolar parameters are statistically independent, i.e.,

$$\Pi(\delta_{CS}, C_Q, \eta_Q) = \Pi_{CS}(\delta_{CS}) \Pi_Q(C_Q, \eta_Q) \quad (49)$$

It is further assumed that the distribution of δ_{CS} may be described by a Gaussian distribution

$$\Pi_{CS}(\delta_{CS}) = \frac{1}{\sqrt{2\pi}\sigma_{CS}} \exp \left[-\frac{(\delta_{CS} - \langle \delta_{CS} \rangle)^2}{2\sigma_{CS}^2} \right] \quad (50)$$

where σ_{CS} is the variance of the chemical shift distribution around its average value $\langle \delta_{CS} \rangle$. This assumption is applicable to various distributed systems (e.g., glasses), in which bond angles are randomly distributed around an average value, and for which a linear correlation exists between the bond angles and the isotropic chemical shifts of nuclei involved in these bonds.⁷⁵

When considering the quadrupole interaction, it has been shown that the distributions of C_Q and η_Q can be fitted by a two dimensional probability function⁸²

$$\Pi_Q(C_Q, \eta_Q) = \frac{C_Q^4 \eta_Q}{\sqrt{2\pi}\sigma_Q^5} \left(1 - \frac{\eta_Q^9}{9} \right) \exp \left[-\frac{C_Q^2 \left(1 + \frac{\eta_Q^2}{3} \right)}{2\sigma_Q^2} \right] \quad (51)$$

In this model, the quadrupolar probability function only depends on a single parameter σ_Q , and the marginal distribution profiles are given by⁸²

$$\Pi_Q(C_Q) = \int_0^1 \Pi_Q(C_Q, \eta_Q) d\eta_Q \quad (52a)$$

$$\Pi_Q(\eta_Q) = \int_0^\infty \Pi_Q(C_Q, \eta_Q) dC_Q \quad (52b)$$

Figure 14 (a) Schematic representation of an experimental slice at position δ_{ISO} , composed of narrow bands defined by a large number of sets (δ_{CSi} , P_{Qi}) that fulfill equation (47). (b) Representation of the quadrupolar parameter P_{Qi} versus the chemical shift δ_{CSi} . Each isotropic slice on the spectrum (a) provides, after inversion, a specific curve in this 2D representation

Figure 15 (a) ^{27}Al 3QMAS spectrum of the calcined and fully rehydrated $\text{AlPO}_4\text{-11}$.⁸⁵ The spectrum was acquired at $\nu_0 = 104.2$ MHz using ^1H decoupling, $\nu_R = 14$ kHz and $\nu_{\text{RF}} = 300$ kHz. (b) Distributions of δ_{CS} and P_Q obtained from the inversion of spectrum (a)

The average values $\langle C_Q \rangle$ and $\langle \eta_Q \rangle$ can be easily obtained from these equations (52). Thus only three parameters ($\langle \delta_{\text{CS}} \rangle$, σ_{CS} , σ_Q) are used to fit the MQMAS spectrum when using the direct method.

In the inverse method, the simulations can be simplified by assuming that the spectra are governed by a distribution of chemical shift and second order quadrupolar parameter P_Q , thus reducing the number of unknown functions to two. In cases when an approximate value of η_Q is unknown, a value of η_Q of approximately 0.5 is used in order to calculate S_c for a given value of P_Q . In a distributed resonance, a slice located at δ_{ISO} in the sheared spectrum results from a superposition of all one-dimensional MQ-filtered spectra that satisfy the condition given by equation (47) for δ_{CS} and P_Q . Thus, the two-dimensional integral of equation (48) can be reduced to a single integral with respect to P_Q

$$S_c(\delta_2)_{\delta_{\text{ISO}}} = \int_0^\infty S_c(\delta_2; \delta_{\text{CS}}(P_Q), P_Q) \Pi(\delta_{\text{CS}}(P_Q), P_Q) dP_Q \quad (53)$$

with δ_{CS} given by equation (47). Solving equation (53) to obtain $\Pi(\delta_{\text{CS}}(P_Q), P_Q)$ corresponds to inversion of the 2D

spectrum. The solution can be drawn for different slices δ_{ISO} of the 2D spectrum. For each slice, the distribution function Π is evaluated versus the P_Q parameter, and for each P_Q value the corresponding δ_{CS} value is determined from equation (47). This corresponds to the determination of a particular curve in the complete two-dimensional parameter space (see Figure 14). The superposition of the curves obtained for all slices yields the final two-dimensional distribution function $\Pi(\delta_{\text{CS}}, P_Q)$. As previously noticed, solving this integral equation is not straightforward and requires the use of regularization methods.^{81,83,84}

The inversion method was initially applied to analyze the 3QMAS spectra of ^{27}Al in crystalline aluminophosphate $\text{AlPO}_4\text{-11}$.⁸⁵ The 3QMAS spectrum of a crystalline aluminophosphate $\text{AlPO}_4\text{-11}$ is displayed in Figure 15a, which shows the five crystallographic sites resolved by this technique. The distribution analysis based on this spectrum leads to the canonical representation displayed in Figure 15b. As expected, the intensities of the five Al species are equal and the average values of δ_{CS} and P_Q agree very well with the literature data. A study that compares the quality of the direct and inverse approaches is yet to be reported.

5 MEASUREMENTS OF DIPOLAR CONNECTIVITIES

As a rule, the development of new high-resolution methods in NMR inspires progress in measurements of interactions between the observed nuclei and their neighbors. Such measurements provide means for analyzing the intermediate range ordering in these spin systems. The development of DOR, DAS and MQMAS offered no exception. Several methods that measure the dipolar connectivities between quadrupolar and spin-1/2 nuclei under high-resolution followed the inception of these techniques. Most of these methods utilize indirect excitation via cross polarization for spectral editing of the DOR and MQMAS spectra or for the DAS-based and MQMAS-based HETCOR experiments.^{86–91} As the spin dynamics of the CP transfer that involves quadrupolar nuclei is very complex, CP-based methods may suffer from quantitative uncertainties. However, analysis of internuclear interactions between spin-1/2 and quadrupolar nuclei can also be made by reintroducing the heteronuclear dipolar dephasing between these spins using RF pulses that are synchronized with the MAS rotor. One of such methods, REDOR, capable of measurement of dipolar interactions and internuclear distances, has been combined with MQMAS.^{30,31,92,93} An attempt has been also made to replace cross polarization with the coherence transfer via TEDOR.⁹⁴

5.1 Cross Polarization and MQMAS

The dipolar coupling between two spins can be used to indirectly produce nuclear magnetization of the observed spins via CP transfer from another spin system. The standard spin-1/2 $\rightarrow$ spin-1/2 CP experiments are usually performed between abundant and rare spins to enhance the nuclear magnetization of the latter.⁹⁵ The polarization transfer in such systems is well understood, and obtaining quantitative spectra

Figure 16 Pulse sequences and coherence transfer pathways for (a) 1QCP-3QMAS and (b) 3QCP-3QMAS experiments with z-filter. The phase cycling used in these experiments must include spin temperature inversion, to avoid direct observation of spins S

Figure 17 2D NMR spectra of ^{27}Al in $\text{AlPO}_4\text{-CHA}$ obtained using (a) 3QMAS and (b) $^{19}\text{F} \rightarrow ^{27}\text{Al}$ 1QCP-3QMAS.⁸⁷ The experiment was performed using $\nu_0 = 104.2\text{ MHz}$, $\nu_R = 20\text{ kHz}$, CP contact time of 0.3 ms and $\nu_{\text{RF}}^{\text{S}}$ field strengths of approximately 250 kHz, 20 kHz and 5 kHz during hard pulses, soft pulses and CP transfer, respectively. ^{19}F decoupling was applied during evolution and acquisition times using $\nu_{\text{RF}}^{\text{I}} \approx 80\text{ kHz}$. SS denotes the spinning sideboard

is relatively easy. For reasons to be discussed later, CP between spin-1/2 and quadrupolar nuclei does not generally lead to enhanced sensitivity. However, it is of interest as method for spectral editing. When appropriate line narrowing methods are applied to both spins, the CP transfer can be further employed to obtain high-resolution HETCOR spectra.

It has been shown that the use of cross polarization can be coupled with the MQMAS experiment. The 1QCP-MQMAS experiment shown in Figure 16a, transfers the magnetization of spins I into the $\pm 1Q$ central transition of spins S. The resulting single quantum coherence is converted into a population inversion between the states with $m = \pm 1/2$ by a selective $\pi/2$ pulse. After a short delay, a standard MQMAS is performed, e.g., using the scheme with z-filter.^{85,87} More direct approaches, relying on polarization transfer to multiple quantum coherences (MQCP-MQMAS), have been successfully implemented by several authors.⁹⁶⁻⁹⁹ The possibility of CP transfer directly to MQ coherences has been demonstrated earlier for $^1\text{H} \rightarrow ^{23}\text{Na}$ system under static conditions.¹⁰⁰ One of the pulse sequences and coherence transfer schemes proposed for the MQCP-MQMAS experiment is shown in Figure 16b.⁹⁹ Theoretical analysis of multiple quantum cross polarization of quadrupolar nuclei has been reported under static and MAS conditions.^{97,98,100}

The 1QCP-3QMAS experiment has been carried out between ^{19}F and ^{27}Al nuclei in fluorinated triclinic chabazite-like AlPO_4 aluminophosphate, which contains one octahedral site Al_1 coordinated to fluorine, and two sites labeled Al_2 and Al_3 representing aluminum in AlO_4 tetrahedra. The octahedral aluminum site Al_1 that is bonded to fluorine can be easily distinguished by this method (Figure 17).⁸⁷ A $^1\text{H} \rightarrow ^{27}\text{Al}$ 1QCP-3QMAS experiment was applied for probing the interaction of water with the framework aluminum of fully rehydrated AlPO_4 -11 aluminophosphate, where it allowed for distinguishing the Al sites that are most and least susceptible to hydration.⁸⁵ Such distinction would not be possible without the separation of ^{27}Al resonances under high-resolution conditions. Figure 18 shows the 5QMAS and 5QCP-5QMAS spectra of ^{45}Sc ($S = 7/2$) in scandium sulfate pentahydrate, where CP to all sites is observed.⁹⁹ The 3QMAS experiments did not allow for complete resolution of sites 1 and 2. Cross polarization to seven quantum coherences has been also demonstrated for the same sample (not shown). It has been noted that the matching parameters differed for different coherence orders and should be determined separately in each experiment.

The first high-resolution HETCOR NMR spectroscopy involving quadrupolar nuclei used DAS to average the second-order quadrupolar interaction.⁸⁹ Experimental schemes of Figure 16 can be easily modified to achieve a 3D high-resolution HETCOR-MQMAS experiment by inserting an additional evolution period between the initial ($\pi/2$) pulse on spins I and the CP transfer. However, due to unfavorable relaxation rates such experiments would require very long acquisition times. Therefore, it is advantageous to use the 2D MQMAS-HETCOR schemes shown in Figure 19, which utilize the $S \rightarrow I$ polarization transfer from fast relaxing quadrupolar nuclei.⁹⁰ The experiment can be designed for $S = 3/2$ (Figure 19a) or $S > 3/2$ (Figure 19b), and is performed by spin-locking the isotropic echo that forms at time Rt_1 after the second pulse, followed by CP transfer and acquisition of spins I signal in the t_2 domain.

Figure 18 2D NMR spectra of ^{45}Sc in $\text{Sc}_2(\text{SO}_4)_3 \cdot 5\text{H}_2\text{O}$ obtained using (a) 5QMAS and (b) $^1\text{H} \rightarrow ^{45}\text{Sc}$ 5QCP-5QMAS.⁹⁹ The experiment was performed at $\nu_0 = 97.2$ MHz with $\nu_R = 6.5$ kHz. The CP transfer used $\nu_{\text{RF}}^S \approx 100$ kHz, $\nu_{\text{RF}}^I \approx 50$ kHz and a contact time of 1 ms. ^1H decoupling was applied during evolution and acquisition times

The 3QMAS-HETCOR method has been first used to obtain the spectrum shown in Figure 20a, which correlates the isotropic resonances of ^{23}Na and ^{31}P in $\text{Na}_3\text{P}_3\text{O}_9$.⁹⁰ Figure 20b

Figure 20 (a) $^{23}\text{Na} \rightarrow ^{31}\text{P}$ 3QMAS-HETCOR spectrum of $\text{Na}_3\text{P}_3\text{O}_9$.⁹⁰ (b) $^{27}\text{Al} \rightarrow ^{31}\text{P}$ HETCOR spectrum of VPI-5⁹¹

depicts the $^{27}\text{Al} \rightarrow ^{31}\text{P}$ 3QMAS-HETCOR spectrum of the large-pore aluminophosphate molecular sieve VPI-5 in a fully hydrated state.⁹¹ In both spectra, significant increase of resolution has been achieved with respect to a standard (CPMAS) version of the HETCOR experiment.

5.2 MQMAS with TEDOR and REDOR

The application of CP transfer to half-integer quadrupolar nuclei is difficult due to the complicated spin dynamics involved in both the spin locking and the cross polarization processes under MAS. These dynamics are strongly anisotropic with respect to crystallite orientation and depend on the relative size of the quadrupole frequency ν_Q , the amplitudes of the RF magnetic field applied to the I and S spins ($\nu_{\text{RF}}^{\text{I}}$ and $\nu_{\text{RF}}^{\text{S}}$), the spinning speed ν_R and the resonance offsets $\delta\nu_{\text{OI}}$ and $\delta\nu_{\text{OS}}$. Significant progress in understanding of these processes has been made recently due to several excellent contributions.^{28,29,86,96–99} Some of the challenges involved in such experiments are briefly reviewed below.

The Hartmann-Hahn matching condition for CP requires that $\nu_{\text{RF}}^{\text{I}} = \nu_{\text{nut}}$, where ν_{nut} is one of the nutation frequencies associated with the cross polarized coherence of the S spin.¹⁰¹ In case of static CP between spin-1/2 nuclei and the single quantum central transition coherence of quadrupolar nuclei under on-resonance irradiation, this translates to

$$\nu_{\text{RF}}^{\text{I}} = \nu_{\text{RF}}^{\text{S}}, \quad |\bar{\nu}_Q| \ll \nu_{\text{RF}}^{\text{S}} \quad (54)$$

$$\nu_{\text{RF}}^{\text{I}} = (S + 1/2)\nu_{\text{RF}}^{\text{S}}, \quad |\bar{\nu}_Q| \gg \nu_{\text{RF}}^{\text{S}} \quad (55)$$

where $\bar{\nu}_Q$ is given by equation (4).²⁹

The Hartmann-Hahn condition for CP of the $(\pm 3/2, \mp 3/2)$ 3Q transitions cannot be well defined in a polycrystalline sample, as it depends on the crystallite orientation

$$\nu_{\text{RF}}^{\text{I}} = A_{\text{nut}}(\nu_{\text{RF}}^{\text{S}})^3/(\bar{\nu}_Q)^2, \quad |\bar{\nu}_Q| \gg \nu_{\text{RF}}^{\text{S}} \quad (56)$$

where, again, the conditions $\nu_R = \delta\nu_{\text{OI}} = \delta\nu_{\text{OS}} = 0$ are assumed, and $A_{\text{nut}} = 1.5, 6, 15$, and 30 for $S = 3/2, 5/2, 7/2$ and $9/2$, respectively.^{99,100}

Figure 21 (a) Pulse sequence and coherence transfer pathways used in TEDOR-3QMAS experiment. (b) $^1\text{H} \rightarrow ^{27}\text{Al}$ TEDOR-3QMAS spectrum of aluminophosphate $\text{AlPO}_4\text{-CJ2}$

Sample spinning makes $\bar{\nu}_Q$ time dependent and thus complicates both spin locking and polarization transfer.^{28,29} The effect of MAS can be described by using the parameter $\alpha_{\text{ad}} = (\nu_{\text{RF}}^S)^2 / \nu_Q \nu_R$ that is related to the speed with which $\bar{\nu}_Q$ crosses zero during sample spinning.²⁸ It has been shown that efficient spin-locking can be maintained when $\alpha_{\text{ad}} \ll 1$ (sudden passage) or when $\alpha_{\text{ad}} \gg 1$ (adiabatic passage), whereas the intermediate case $\alpha_{\text{ad}} \approx 1$ results in a loss of the spin-locked state. In addition, rotational modulation of the I-S dipolar interaction has profound effect on the CP process itself.^{29,102}

The sudden regime ($\alpha_{\text{ad}} \ll 1$) implies the use of low RF magnetic fields, such that $\nu_{\text{RF}}^S \ll |\bar{\nu}_Q|$ for most crystallites. Under such conditions, the polarization is transferred predominantly to the single quantum central transition coherence of

the S spins. The corresponding Hartmann-Hahn matching condition is

$$\nu_{\text{RF}}^I = \pm \left(S + \frac{1}{2} \right) \nu_{\text{RF}}^S \pm n \nu_R, \quad n = 1, 2 \quad (57)$$

Optimization of the Hartmann-Hahn match becomes very ambiguous in this regime due to the extreme sensitivity to off-resonance effects. Inhomogeneities of the RF magnetic field in doubly tuned probes further complicate the situation. As a result, the absence of a resonance in the CP spectrum should not be used as evidence for the lack of I $\leftrightarrow$ S connectivity without some careful experimentation.

The spin dynamics under adiabatic passage condition ($\alpha_{\text{ad}} \gg 1$) is also complex. Experimentally, this regime can be

approached by reducing the spinning speed and/or increasing the strength of RF field. Since there are significant benefits of using the highest available ν_R in MQMAS, we consider only the latter option.^{74,103} Under typical conditions of $\nu_R \geq 10$ kHz and $\nu_Q = 1$ MHz, this translates to ν_{RF}^S being much greater than 100 kHz. In this case, the condition $|\bar{\nu}_Q| \gg \nu_{RF}^S$ is no longer satisfied for most of the crystallites and the nutation behavior of the S spins varies strongly with changing orientation. Consequently, no simple Hartmann-Hahn formula can be derived for 1Q and MQCP transfers. Numerical simulations show that such CP transfer is not strongly affected by the interference from ν_R , $\delta\nu_{OI}$ and $\delta\nu_{OS}$, but depends on the quadrupolar parameters, the dipolar coupling D between I and S, and the RF magnetic fields ν_{RF}^I and ν_{RF}^S .^{96–99} In general, 1QCP transfer with strong RF fields ($\alpha_{ad} \gg 1$), is less efficient than with weak RF fields ($\alpha_{ad} \ll 1$), except for samples with relatively low values of C_Q and large dipolar couplings. Under fast MAS, there is a striking similarity between the 1Q, 3Q and 5Q intensities obtained with each set of C_Q and D values. A detailed analysis shows that two processes are involved here: a slow CP transfer (with the time constant of the order of $1/D$) to all $(p/2, -p/2)$ coherences followed by equilibration of these coherences via a RIACT-like mechanism, which generates fast $1Q \leftrightarrow 3Q \leftrightarrow 5Q$ transfers (with the time constant of $\sim 1/4\nu_R$) in cross polarized nuclei.

The quantitative uncertainties associated with the complex dynamics of spin-locking and CP transfer could be avoided by using TEDOR NMR. This technique has been successfully used in the studies of HETCOR spectra and dipolar couplings in spin systems involving spin-1/2 and quadrupolar nuclei under MAS.^{31,32} In the TEDOR method, the magnetization is transferred in a way that is similar to an INEPT experiment in liquids. The dipolar interaction between spins I and S, which is refocused every rotor period in the standard MAS experiments, can be reintroduced by using properly spaced rotor-synchronized RF pulses. It has recently been shown that TEDOR can be used in concert with MQMAS by replacing the Hartmann-Hahn CP transfer in the scheme of Figure 16a, as shown in Figure 21a.⁹⁴ The TEDOR pulses must be selective for the central transition of S spins, and thus of weak amplitude. The TEDOR-MQMAS method has been tested on borax and $AlPO_4$ -CJ2 aluminophosphate, where $^1H \rightarrow ^{11}B$, $^1H \rightarrow ^{27}Al$ and $^{19}F \rightarrow ^{27}Al$ spectra were acquired (see Figure 21b). A reverse experiment, similar to that used in the MQMAS-HETCOR scheme can be also considered. According to numerical simulations, TEDOR-MQMAS appears to be less sensitive to off-resonance effects than CP-MQMAS. However the applicability of this technique to nuclei with strong quadrupole interactions has yet to be tried.

Another version of an approach without the use of CP has been proposed, which combines the high-resolution capabilities of MQMAS with the direct determination of hetero-nuclear dipolar couplings via REDOR. Figure 22 shows the schematic diagrams of two MQ-REDOR experiments, referred to as MQ- t_1 -REDOR and MQ- t_2 -REDOR. The MQ- t_2 -REDOR technique (Figure 22a), employs two strong and two selective RF pulses at the Larmor frequency ν_{OS} with phases cycled to select the $0 \rightarrow \pm p \rightarrow 0 \rightarrow +1 \rightarrow -1$ coherence pathway.⁹² When spaced by an integer number of rotor periods $n t_R$, the selective pulses create two windows in which the sequences of π pulses can be applied to the spin-1/2 nuclei. Similar to the standard REDOR experiment, the role of the π

pulses is to prevent MAS from refocusing the dephasing due to the dipolar interaction between spins I and S.³⁰

The spectral editing capabilities of MQ- t_2 -REDOR method are illustrated in Figure 23, which shows several ^{27}Al NMR spectra of $AlPO_4$ -CHA aluminophosphate (see also Figure 17).⁹² The tetrahedral sites Al_2 and Al_3 are not well resolved by MAS alone (spectrum (a)), but are easily distinguished by using the MQMAS method (spectrum (b)). The so-called REDOR difference spectra, obtained by subtracting the MQMAS spectra obtained without and with the dephasing pulses are shown in Figures 23c–d. As expected, only the resonance from fluorinated site (Al_1) remains strong in the spectrum of Figure 23c. However, the capabilities of the MQ- t_2 -REDOR method extend beyond spectral editing. By changing the number of rotor cycles, one can measure the REDOR curves for all three Al species and estimate their distances from the nearest fluorine.³⁰ The results (see Figure 24) are in good agreement with the results inferred from synchrotron radiation experiments. The MQ- t_1 -REDOR experiment (see Figure 22b), employs the REDOR sequence during multiple rather than single quantum evolution.⁹³ Because the dipolar effect is enhanced by a factor of p during the p-quantum evolution (see F term in equation (7)), this technique has potential for improved sensitivity toward weak dipolar interactions. Indeed, the results of Figure 24 show

Figure 22 Pulse sequences and coherence transfer pathways used in (a) MQ- t_2 -REDOR and (b) MQ- t_1 -REDOR experiments

Figure 23 ^{27}Al NMR spectra of fluorinated $\text{AlPO}_4\text{-CHA}$ aluminophosphate: (a) MAS, (b) 3QMAS, (c) $3\text{Q-}t_2\text{-REDOR}$ difference for $n = 5$, and (d) $3\text{Q-}t_2\text{-REDOR}$ difference for $n = 29$

that in $\text{AlPO}_4\text{-CHA}$ the apparent size of $^{19}\text{F-}^{27}\text{Al}$ coupling measured using $3\text{Q-}t_1\text{-REDOR}$ was higher by a factor of 3 when compared with the data obtained with $3\text{Q-}t_2\text{-REDOR}$.⁹³

Although the concept of dipolar recoupling during MQ evolution is attractive, the $3\text{Q-}t_1\text{-REDOR}$ experiment has potential limitations. First, the more complex coherence pathway employed by this method causes a loss of sensitivity of approximately 2–8, depending on the C_Q and S spin values. Another potential drawback of both MQ-REDOR experiments stems from non-uniform response of the quadrupolar spins to the RF pulses used in the MQMAS experiment. One may expect the effect that the orientational anisotropy of MQ excitation has on the $\text{MQ-}t_1\text{-REDOR}$ curves to be enhanced, especially in samples with significant C_Q values. However, both experimental and theoretical results show that the experiment is surprisingly robust. Indeed, the initial slope of the REDOR curve is nearly independent of C_Q for small or moderate quadrupolar interactions, and the quality of the fit improves markedly when the strength of RF field is increased, even for large C_Q values.⁹³ REDOR recoupling during triple quantum evolution has been recently used to determine the relative orientations of the quadrupolar and dipolar principal axis systems.¹⁰⁴ In this

Figure 24 Experimental and simulated $\text{MQ-}t_1\text{-REDOR}$ and $\text{MQ-}t_2\text{-REDOR}$ curves for $\text{ALPO}_4\text{-CHA}$.⁹³ The values of dipolar coupling D between ^{19}F and ^{27}Al corresponding to the simulated curves are given in parentheses

experiment, the REDOR recoupling immediately follows the excitation of $3Q$ coherences. After the $\pm 3Q \rightarrow \mp 3Q$ inversion, a $\pi/2$ pulse is applied to spins I to create a mixture of heteronuclear $2Q$ and $4Q$ coherences, which are subsequently allowed to precess during evolution period t_1 . The t_1 period is followed by a similar REDOR recoupling period to recover the $3Q$ coherences, which are then converted into the observable $-1Q$ coherence. The resulting spectrum exhibits patterns of spinning sidebands along the MQ dimension, which depend on the dipolar coupling, the quadrupolar parameters and the relative orientation of the quadrupolar and dipolar PAS.

Another experiment, referred to as MQMAS with dipolar dephasing (DD-MQMAS) is shown in Figure 25. It uses the standard z-filtered MQMAS scheme for spins S , while the dipolar recoupling with spins I is accomplished using a series of π pulses applied synchronously with the rotor frequency to the I spins during the multiple quantum evolution.¹⁰⁵ The simple $0 \rightarrow \pm p \rightarrow 0 \rightarrow -1$ coherence pathway that is used here results in line broadening, but allows for fast,

Figure 25 DD-MQMAS experiment: pulse sequence and coherence transfer pathway

yet only semi-quantitative, determination of the internuclear connectivities in well crystallized compounds.

6 SENSITIVITY ENHANCEMENT VIA CPMG METHOD

Advances in manipulating the MQ coherences considerably improved the sensitivity of the MQMAS experiment. Additional gain in the S/N ratio can be accomplished by applying a CPMG train of rotor-synchronized, selective π pulses during the acquisition of data in t_2 .^{106–108} The resulting CPMG-MQMAS spectrum is split into periodic combs of spin-echo sidebands that spread along the anisotropic dimension. Since the integrated spectral intensity is not affected by this procedure, the apparent S/N ratio for individual spikes can be significantly enhanced. The gain in S/N ratio is governed by periodicity τ_a of the CPMG train and the homogeneous spin–spin relaxation time T_2 . The truncation effects require that τ_a exceeds the net dephasing time of transverse magnetization T_2^* , which determines the maximum gain available by this method.

An example of the experimental scheme for CPMG-MQMAS experiment with spin-3/2 nuclei, based on the split- t_1 method, is shown in Figure 26.¹⁰⁸ In this experiment the excitation of MQ coherences and their reconversion to the single quantum coherence is achieved following the usual rules. The CPMG sequence uses selective π pulses of the same strength of RF field as the soft pulse in the z-filter method. The phase cycling of each sequence follows the standard procedures, and the phases of the CPMG train are adjusted according to the Meiboom-Gill scheme. The sequence in Figure 26 utilizes contributions from the echo and antiecho coherence pathways, which leads to cosine modulated FIDs. Approaches suitable for spin-5/2 nuclei have been also proposed.¹⁰⁹

The appearance of CPMG spectrum is determined by the sampling conditions: smaller separation τ_a between the echoes in time domain increases the S/N ratio in frequency domain at the expense of anisotropic line shape, which is determined by a reduced number of sidebands. Although the spin-echo sidebands are regularly spaced with respect to the carrier frequency, the sideband manifolds corresponding to different sites are usually well separated along the isotropic dimension. This is manifested in Figure 27, which shows a series of

Figure 26 CPMG-3QMAS pulse sequence and coherence transfer pathway for spin-3/2 nuclei.¹⁰⁸ The part of the sequence shown in parenthesis is rotor-synchronized according to $2Nt_R = \tau + \tau_a$, where τ is the duration of the selective π pulse (including the transient effects) and τ_a is the echo sampling period

Figure 27 ^{23}Na MQMAS (a) and CPMG-MQMAS (b–e) spectra of an equimolar mixture of Na_2SO_4 and $\text{Na}_2\text{C}_2\text{O}_4$ recorded at $\nu_0 = 105.8\text{ MHz}$ using ν_R rates between 10 and 11 kHz and $\nu_{\text{RF}} = 58\text{ kHz}$ for all pulses.¹⁰⁸ All CPMG-MQMAS spectra used $\tau = 150\text{ }\mu\text{s}$ and the following values of τ_a and M : (b) 4 ms, 9; (c) 2 ms, 19; (d) 1 ms, 39, and (e) 0.5 ms, 80

^{23}Na MQMAS and CPMG-3QMAS spectra of an equimolar mixture of Na_2SO_4 and $\text{Na}_2\text{C}_2\text{O}_4$.¹⁰⁸ Although each spectrum has been recorded with the same number of scans, spectra b-e corresponded to S/N gain factors of 5, 8, 12 and 20, respectively.

It has been shown that accurate parameters for quadrupole and chemical shift interactions can be extracted from the CPMG-MQMAS spectra via numerical simulation that accounts for the time-modulation of quadrupolar interaction in the course of RF pulses.¹¹⁰ In addition, several methods for the numerical treatment of the CPMG spectra have been proposed, which further improve the S/N ratio and allow for full recovery of the echo envelope. These include modification of the sideband envelope through echo shifting, reconstruction of the full spectrum by superimposing the echoes, and various schemes for noise filtering via apodization.¹⁰⁹ Additional improvement of the numerical analysis is possible by the use of data processing techniques that are alternative to discrete Fourier transform. Recently, a simple processing technique, referred to as ANAFOR, has been proposed based on the least squares method used in linear prediction and the TIGER routines.^{111,112} These methods allow for precise determination of intensities in truncated multidimensional spectra based on outside information about the line shape parameters. ANAFOR can be especially useful in the CPMG-MQMAS experiments, where the positions of sidebands are known in advance and other line shape parameters can be obtained using, e.g., one-dimensional methods. By using truncated time-domain data sets, ANAFOR offered further significant gain in sensitivity. For example, this method has been applied to ^1H - ^{27}Al MQ- t_2 -REDOR measurements in $\text{AlPO}_4\text{-ZON}$ where the experimental time has been decreased by a factor of six.¹¹¹

7 CONCLUSION

Since its development, MQMAS has matured to become a powerful investigative tool that benefits various areas of chemistry and materials science. Many research groups have applied this method to the studies of catalytic materials, glasses, numerous other crystalline and amorphous inorganic compounds and even biological samples. A wide-ranging description of these applications would warrant a separate review.

In spite of recent advances, the MQMAS method itself continues to evolve. Most of the recent effort targets the improvement of sensitivity, which may offer new perspectives for high resolution studies of inherently challenging nuclei, such as ^{17}O . New types of correlation schemes are being considered in order to increase the sensitivity and/or resolution. For example, the recently proposed schemes that use two different MQ coherences during t_1 may have the potential of improved resolution over the standard MQMAS experiment.¹¹³ Also recently, a technique referred to as satellite transition MAS (STMAS) has been proposed, which provides isotropic spectra of half-integer quadrupolar nuclei by correlating the evolution of single quantum inner-satellite transitions in t_1 with that observed during t_2 for the $(-1/2, 1/2)$ central transition (see 'Satellite Transition NMR Spectroscopy of Half-Integer Quadrupolar Nuclei under Magic Angle

Spinning').⁶³ This is also the case for the CESAME (central satellite MAS experiment) which has been proposed most recently.¹¹⁴

1 INTRODUCTION

As pointed out in the article *Rudimentary NMR: The Classical Picture*, the natural motion of a magnetic moment in a field is a precession, or nutation, of the moment $\mathbf{M} = \gamma \mathbf{I}$ about the field $\mathbf{B}$ with nutation frequency $\omega = \gamma B$. It is this nutation in the rotating frame of the Zeeman interaction, as applied to the NMR spectra of nuclei with quadrupolar moments $I \geq 1$ that is the subject of this discussion. The main difference between the case discussed here and NMR of spin- $\frac{1}{2}$ nuclei is that in general the condition $\hat{\mathcal{H}}_{\text{rf}} > \hat{\mathcal{H}}_{\text{int}}$ is not met, so the condition for assuming that the rf pulses take place in an infinitely short time compared with the effects of internal Hamiltonians is violated.

In this case, we must consider the time development of the system when both the quadrupolar Hamiltonian and the rf Hamiltonian are of the same order of magnitude, or even when $\hat{\mathcal{H}}_Q > \hat{\mathcal{H}}_{\text{rf}}$. It was realized¹ that even in this case quite useful information could be extracted if the experiment was made into a two-dimensional situation, where the system evolves in time under $\hat{\mathcal{H}}_{\text{rf}} + \hat{\mathcal{H}}_Q$ for a time t_1 , and then evolves under just $\hat{\mathcal{H}}_Q$ for a time period t_2 . The double Fourier transform on both times then yields the nutation spectrum, e.g. in Figure 1, from which may be inferred the number of different chemical species in the sample under investigation, and the relative values of the quadrupole versus the rf interactions, as discussed below.

2 GENERAL CONSIDERATIONS: HAMILTONIANS

As discussed by Mehring in *Internal Spin Interactions and Rotations in Solids*, the form of the rf Hamiltonian for, e.g. a pulse with x phase, is

$$\hat{\mathcal{H}}_{\text{rf}} = -\omega_1 \hat{I}_x \equiv -\omega_{\text{rf}} \hat{I}_x \quad (1)$$

The pertinent Hamiltonian for a static sample during the evolution period under the influence of an rf pulse turned on for a time t_1 , with x phase and a quadrupolar interaction not small compared with the pulse strength Ω_1 , including and offset from resonance is

$$\begin{aligned} \hat{\mathcal{H}}^1(t_1) &= [\hat{\mathcal{H}}_{\text{off}} + \hat{\mathcal{H}}_{\text{rf}} + \hat{\mathcal{H}}_Q^1] \\ &= \delta \hat{I}_z - \omega_1 \hat{I}_x + \omega_Q^* [3\hat{I}^2 - I(I+1)] \end{aligned} \quad (2)$$

where $\omega_Q^* = \omega_Q(3 \cos^2 \theta - 1 + \eta \sin^2 \theta \cos 2\phi)$, and $\omega_Q = 2\pi e^2 q Q / 8hI(I+1) \equiv 2\pi \chi / 8I(I+1)$, and θ, ϕ are the polar angles orienting the electric field gradient (EFG) tensor with respect to the static field axis, taken to be the z axis in the laboratory, and η is the asymmetry of the EFG tensor. Dipolar interactions and nonsecular quadrupolar interactions (second-order terms) have been neglected.

After the rf pulse, assumed to be strong compared with the magnitude of the shielding Hamiltonian, the system evolves for time t_2 under shielding, chemical shift, and the nonsecular quadrupolar terms (taking into account only the central $\frac{1}{2} - \frac{1}{2}$ transition),

$$\hat{\mathcal{H}}^2(t_2) = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_{\text{CS}} + \hat{\mathcal{H}}_Q^2 \quad (3)$$

where Z stands for Zeeman, CS is chemical shift, and the superior 2 means the nonsecular second-order terms which have the major effect on the central transition. Using the density matrix formalism,² with the equilibrium density operator in the high temperature form, in the frame of detection of the signal which is the rotating frame (the Zeeman interaction disappears from the description), the evolution during time t_1 is

$$\hat{\rho}(t_1) = \exp\{-i\hat{\mathcal{H}}_1 t_1\} \hat{\rho} \exp\{i\hat{\mathcal{H}}_1 t_1\} \quad (4)$$

While the Zeeman states $|I, m\rangle$ are not exact eigenfunctions of the first- and second-order quadrupolar Hamiltonians, their linear combinations will be and can be found by diagonalization of the total Hamiltonian. If $\mathbf{T}$ is the orthogonal transformation which diagonalizes the Hamiltonian, then we may express the density operator at time t_1 in matrix form as

$$\rho(t_1) = \mathbf{T} \cdot \exp\{-i\mathbf{D}t_1\} \mathbf{T}^+ \rho(0) \mathbf{T} \exp\{i\mathbf{D}t_1\} \mathbf{T}^+ \quad (5)$$

$\mathbf{D}$ represents the diagonalized matrix of the Hamiltonian $\hat{\mathcal{H}}^1$ with eigenvalues

$$E_j = \sum_p T_{pj}^* H_{pq}^1 T_{qj} \quad (6)$$

and eigenfunctions

$$|j\rangle = \sum_k T_{kj}^* |I, m_k\rangle \quad (7)$$

Assuming that only coherence between states $|\frac{1}{2}\rangle$ and $|\frac{1}{2}\rangle$ is detected during time t_2 , so only the elements $\rho_{1/2, -1/2}$ need

Figure 1 (a) Pulse scheme of the experiment; a free induction decay is acquired during t_2 as a function of the pulse length t_1 . Subsequent Fourier transformation of the signals obtained yields a typical 2D powder pattern as shown in (d). This spectrum was calculated for $I = \frac{5}{2}$ with a ratio $\omega_Q/\omega_{rf} = 0.45$ and $\eta = 0$. The F_2 projection of this pattern (c) gives the second-order quadrupole powder pattern, and the F_1 projection (b) is a characteristic nutation spectrum for the ratio ω_Q/ω_{rf}

be evaluated, the signal from the central transition $S(t_1, t_2)$ can then be evaluated as follows:

$$\begin{aligned} S(t_1, t_2) &= \text{Tr}\{\hat{\rho}(t_1, t_2)(\hat{I}_x + i\hat{I}_y)\} \propto \hat{\rho}(t_1)_{1/2, -1/2} \exp\{-i\omega_2 t_2\} \\ &= \sum_{k,j} (R_{-1/2, 1/2})_{k,j} \exp\{i\omega_{k,j} t_1\} \exp\{-i\omega_2 t_2\} \end{aligned} \quad (8)$$

Here, ω_2 represents the Larmor precession of the spins during the time t_2 and ω_{kj} is the transition frequency in the rotating frame between states $|k\rangle$ and $|j\rangle$. The coefficients $(R_{-1/2, 1/2})_{kj}$ represent the contributions from coherence between states $|k\rangle$ and $|j\rangle$ in the rotating frame during t_1 to the $\frac{1}{2}, -\frac{1}{2}$ coherence detected during t_2 :

$$(R_{-\frac{1}{2}, \frac{1}{2}})_{k,j} = T_{\frac{1}{2}, k}^* T_{-\frac{1}{2}, j}^* \sum_m T_{m, k}^* T_{m, j} \rho(0)_{m, m} \quad (9)$$

The states of an isolated spin- $\frac{7}{2}$ in the presence of magnetic field B , with quadrupole coupling constant $2\pi\chi = 1$ MHz and asymmetry $\eta = 0$, are shown in Figure 2.

In summary, during time t_1 the system develops in time with eigenfunctions and eigenvalues which depend upon the ratio of ω_Q^* and ω_{rf} . The coherences between these levels, with frequency ω_{kj} , develop during time t_1 and contribute to the

coherence detected between the state $|\frac{1}{2}\rangle, |-\frac{1}{2}\rangle$ detected during time t_2 . Therefore, a 2D Fourier transform of the acquired signal will give a characteristic powder pattern [Figure 1(d)], with projection on the F_2 axis shown in Figure 1(c) being the normal powder pattern of the $\frac{1}{2}-\frac{1}{2}$ transition associated with

Figure 2 Energy diagram of an isolated spin $I = \frac{7}{2}$ in the presence of a magnetic field B with quadrupole parameters $e^2qQ/h = 1$ MHz and $\eta = 0$. On the left is the low field situation $\mathcal{H}_Z < \mathcal{H}_Q$ and on the right is the situation $\mathcal{H}_Z \gg \mathcal{H}_Q$, where $\mathcal{H}_Q$ appears to be negligible

shielding anisotropy and second-order quadrupole broadening. Projection onto the F_1 axis [Figure 1(b)] gives the nutation spectrum which depends upon the quadrupole parameters χ and η , the spin quantum number I , and the rf field strength ω_1 , and is independent of chemical shift.

3 THE NUTATION SPECTRUM

As an example, the calculated nutation spectra as a function of ω_Q/ω_{rf} is shown in Figure 3.

Figure 3 Calculated nutation spectra as a function of ω_Q/ω_{rf} ($\eta = 0$)

When there is only one site for the species under study, a 1D nutation spectrum suffices to characterize this species. When nuclei of a given spin are present in more than a single environment, it is advantageous to study the entire 2D powder pattern.

4 EXPERIMENTAL CONSIDERATIONS

To obtain experimental nutation spectra which can be compared with the calculated spectra, it is important to keep several experimental conditions in mind.

The first of these is the resonance offset. Thus, when the system is irradiated on-resonance ($\omega = \omega_0$) then the matrix of H_1 in equation (10) becomes symmetric with respect to both diagonals of the matrix. As a result of this

$$\left. \begin{aligned} (R_{-1/2,1/2})_{i,j} &= -(R_{-1/2,1/2})_{j,i}, & i \neq j \\ \text{and} \\ (R_{-1/2,1/2})_{i,j} &= 0, & i = j \end{aligned} \right\} \quad (10)$$

Substitution in equation (8) shows that the signal then becomes

$$S(t_1, t_2) = \sum_{i < j} (R_{-1/2,1/2})_{i,j} \sin\{\omega_{ij}t_1\} \exp\{-i\omega_2t_2\} \quad (11)$$

The amplitude of the signal detected during t_2 is sine-modulated, which allows us to obtain pure absorption spectra. The presence of an off-resonance term in B_1 lowers the symmetry of its matrix and the modulation now becomes a phase modulation, which cannot be changed to amplitude modulation by phase cycling. Thus there will be dispersive contributions to the lineshapes which can easily distort powder patterns.

Another effect of off-resonance irradiation is the appearance of a dispersive line at $\omega_1 = 0$. This is due to the magnetization component along the B_{eff} field in the rotating frame which does not evolve during t_1 . Both effects of off-resonance irradiation can even be observed for spins with $I = \frac{1}{2}$ for which the signal in such a case can be written as:

$$S(t_1, t_2) \sim [A(1 - \cos(\omega_{eff}t_1) + iB \sin(\omega_{eff}t_1)] \times \exp\{-i\omega_2t_2\} \quad (12)$$

where $A = \omega_{rf}\Delta\omega/2(\omega_{rf}^2 + \Delta\omega^2)$ and $B = \omega_{rf}/2\sqrt{(\omega_{rf}^2 + \Delta\omega^2)}$. When $\Delta\omega = \omega - \omega_0 \neq 0$, then $A \neq 0$ and thus a constant and a $\cos(\omega_{eff}t_1)$ term is introduced, causing respectively the $\omega_1 = 0$ signal and the phase modulation. To avoid complications it is clearly recommendable to irradiate on-resonance, i.e. with the excitation frequency ω equal to the Larmor frequency γB_0 . That on-resonance in this case does not mean equal to the $\frac{1}{2}, -\frac{1}{2}$ transition frequency is shown by the following magic angle spinning (MAS) experiment. Here the Larmor frequency lies outside the quadrupole lineshape and Figure 4 shows the nutation spectra of NaNO_2 ($e^2qQ/h = 1.1 \text{ MHz}$, $\eta = 0.1$) as a function of the excitation frequency. In this case we are in the extreme situation $\omega_Q \gg \omega_{rf}$ and MAS does not influence the nutation spectrum. It is clear that the line at $\omega_1 = 0$ increases relative to the line at $2\omega_{rf}$. The line at $\omega_1 = 0$ is

Figure 4 MAS spectra of NaNO_2 together with their nutation spectra as a function of the excitation frequency ω . (a) Off-resonance irradiation; in the nutation spectrum we see a large line at $\omega_1 = 0$. (b) Irradiation close to the Larmor frequency (outside the powder pattern) gives the best nutation spectrum. (c) With the carrier frequency equal to the average $\frac{1}{2}, -\frac{1}{2}$ transition frequency (in the middle of the powder pattern), the line at $\omega_1 = 0$ increases again

minimal when we irradiate outside the powder pattern near the Larmor frequency. An easy method to reduce the line at $\omega_1 = 0$ is to subtract the last (longest t_1 value) experiment in the 2D experiment from all the previous experiments. When enough t_1 experiments are performed, the quadrupolar modulation has damped out, and the only signal emerging after a long rf pulse is that of the magnetization causing the zero frequency signal in the F_1 direction. Because the magnetization component along B_{eff} has the same magnitude in every experiment (assuming no relaxation), subtraction of the last experiment reduces its influence on the spectrum.

5 PHASING OF THE SPECTRA

It is important to obtain pure absorption spectra when one wants to obtain 2D powder patterns which can be analyzed in a straightforward way. Because we want no dispersion signals to appear in the spectrum, it is not possible to perform an absolute value calculation. Therefore, the spectra have to be phased manually. As we have seen in the preceding paragraph, off-resonance irradiation introduces phase modulation and thus dispersive lineshapes are introduced in the spectra. This makes it very difficult to phase the spectra properly. This is so difficult because when phasing a 2D spectrum one has to set the phase correction on one slice (row or column) of the spectrum and it is not possible to inspect the effect of such a phase correction on the total spectrum. It would be desirable to have a program that shows the phase corrections of the whole spectrum directly on the display. As modern NMR spectrometers are equipped with minicomputers using array processors, it should be possible to do so because nutation spectra are generally of small size.

When one is only interested in the 1D nutation spectrum (the F_1 projection) of a sample, there is a way to avoid phasing the whole 2D spectrum. In this case we can take the first point of every FID emerging directly after the pulse of length t_1 . If we arrange these points as a function of t_1 , we have the amplitude modulation of the detected t_2 signal as a 1D interferogram. A straightforward 1D Fourier transform of this interferogram will give us the nutation spectrum which can be phased easily.

6 LINE BROADENING

An important cause of line broadening in the F_1 dimension is the inhomogeneity of the rf magnetic field. The effect of rf inhomogeneity cannot simply be described with a Lorentzian broadening $\exp(-t_1/\tau_1)$ because a spread in ω_{rf} will also cause a spread in the ratio $\omega_Q/\omega_{\text{rf}}$, and will thus change the whole nutation spectrum. Furthermore the lineshapes due to rf inhomogeneity will not be Lorentzian but asymmetric. Only in the extreme case $\omega_{\text{rf}} \gg \omega_Q$ do we get a line at nutation frequency ω_{rf} with a linewidth directly determined by the rf inhomogeneity. In the other extreme case $\omega_{\text{rf}} \ll \omega_Q$, there will be a line at $(I + \frac{1}{2})\omega_{\text{rf}}$, so the linewidth will be $(I + \frac{1}{2})\gamma$ -times the rf inhomogeneity. It is therefore important to use a probe with an accurately formed rf coil to reduce rf inhomogeneity as much as possible, and care should be taken that the whole sample is in the coil.

Figure 5 Two-dimensional nutation spectrum of ^{45}Sc in $\text{Sc}_2(\text{SO}_4)_3$ recorded on a Bruker WM-500 instrument, together with its F_1 projection (256 t_1 increments of $1.5 \mu\text{s}$ with a 70 kHz rf field)

7 EFFECT OF RECYCLE DELAY

Another important experimental aspect in the nutation experiment is that one has to ensure that the recycle delay or relaxation delay is long enough for the system to return to equilibrium before the next pulse arrives. If the recycle delay is short with respect to T_1 then the build up of magnetization along the z axis is incomplete. This will distort the pure sine amplitude modulation of the FID. Fourier transformation of a distorted $\sin \omega_1 t$ wave will give a line at frequency ω_1 plus a number of harmonics at $2\omega_1, 3\omega_1, \dots$. The number and amplitude of these harmonics depend on the distortion of the sine wave, and they can easily be mistaken for components with a large quadrupole frequency.

8 AN EXAMPLE: ^{45}Sc IN $\text{Sc}_2(\text{SO}_4)_3$

An example is the ^{45}Sc ($I = \frac{7}{2}$) nutation spectrum of $\text{Sc}_2(\text{SO}_4)_3$ (Figure 5). The spectrum of the central transition measured at 121.5 MHz is 2.6 kHz wide and shows no structure; MAS narrows the spectrum to 600 Hz. The MAS spectrum recorded at 43.8 MHz does show some structure from which it becomes clear that there must be sites with different quadrupole parameters but the same chemical shift. The 2D nutation spectrum is well structured. Comparing its projection to our set of calculated spectra reveals that the major constituent has $e^2qQ/h \sim 2 \text{ MHz}$ with a low asymmetry parameter ($\eta \sim 0.2$).

1 INTRODUCTION

In the context of NMR, ‘overtone spectroscopy’ refers to the direct excitation of nuclear spin transitions and coherences and the direct detection of NMR signals at frequencies that are nearly multiples of the Larmor frequency ν_0 . Overtone spectroscopy depends on the excitation and detection of ‘forbidden’ transitions, i.e. transitions that cannot be excited or detected directly in the limit of very strong external dc magnetic fields but that become excitable or detectable directly when the interactions of nuclear spins with the dc field are not very much stronger than the internal nuclear spin couplings. Recent interest in overtone spectroscopy grew out of the work of Bloom and LeGros,¹ who showed that overtone transitions have sufficient intensity in practice to be of experimental utility. Subsequent work^{2,3} showed that overtone spectroscopy has real advantages when applied to solid state NMR measurements of integer-spin nuclei with large quadrupole couplings. Since ^{14}N is the most important nucleus of this type from the standpoint of chemistry and biochemistry, recent work has focused on ^{14}N overtone NMR.

Overtone spectroscopy should be distinguished from multiple quantum spectroscopy. In multiple quantum spectroscopy, one typically applies rf pulses with a carrier frequency close to ν_0 in order to excite nuclear spin coherences with oscillation frequencies that are nearly multiples of ν_0 . The oscillation of these coherences is then detected indirectly through its effect on the single quantum signals near ν_0 . In overtone spectroscopy, the rf carrier frequency is about equal to the oscillation frequency of the coherences, and the oscillation of the coherences is detected directly. Conceptually speaking, overtone spectroscopy can be thought of as a single photon spectroscopy, while multiple quantum spectroscopy can be thought of as a multiple photon spectroscopy. In some cases, the same coherences may be excited and detected either by overtone NMR or by multiple quantum NMR. As a general rule, overtone methods are probably more effective than multiple quantum methods when the nuclear quadrupole splittings exceed 1 MHz.

Figure 1 shows a spin energy level diagram for a spin-1 nucleus such as ^{14}N . A spin-1 nucleus has three possible eigenstates. In the absence of all spin interactions, the three

Figure 1 Spin energy levels for a spin-1 nucleus. The splitting of the energy levels due to a strong magnetic field and the first-order and second-order perturbations of the energy levels due to a quadrupole coupling are shown. (Adapted by permission of the American Chemical Society from R. Tycko and S. J. Opella, *J. Am. Chem. Soc.*, 1986, **108**, 3531)

states are degenerate. The interaction with an external dc field produces three equally spaced energy levels and two allowed, single quantum transitions at frequency ν_0 . A nuclear quadrupole coupling that is weaker than the interaction with the external field perturbs the energy levels. To first order, a quadrupole coupling with coupling constant ν_Q shifts the middle ($m = 0$) level relative to the upper and lower ($m = \pm 1$) levels by an amount $\nu_Q^{(1)}$ proportional to ν_Q . This produces the first-order quadrupole splitting, with single quantum transitions at $\nu_0 \pm \nu_Q^{(1)}$. To second order, the quadrupole coupling additionally shifts the upper and lower levels by amounts $\pm \nu_Q^{(2)}$ proportional to ν_Q^2/ν_0 . This is the second-order quadrupole shift. The single quantum transitions are then at $\nu_0 \pm \nu_Q^{(1)} + \nu_Q^{(2)}$. In addition, the overtone transition at frequency $2\nu_0 + 2\nu_Q^{(2)}$ becomes weakly allowed, producing signals and nutation frequencies proportional to ν_Q/ν_0 in pulsed NMR experiments. Although the overtone signals are intrinsically weaker than the allowed single quantum (or ‘fundamental’) signals, the fact that the overtone spectrum spans a frequency range that is narrower than the single quantum spectrum by a factor of the order of ν_Q/ν_0 makes measurement of the overtone signals substantially more tractable, especially in polycrystalline and noncrystalline solids (where the resonance lines are inhomogeneously broadened powder patterns) and in single crystals with several inequivalent sites. Thus, particularly in ^{14}N NMR, overtone spectroscopy allows NMR signals to be obtained and nuclear relaxation rates to be measured in systems where NMR experiments would otherwise be extremely difficult or impossible. Overtone spectra also contain structural information that is absent in single quantum spectroscopy, through the dependence of the overtone transition moment on the molecular or crystal orientation and on the direction of the applied rf field.

Overtone NMR spectroscopy of spin-1 nuclei is analogous to earlier ‘half-field’ electron paramagnetic resonance (EPR) studies of triplet states,^{4,5} with the nuclear quadrupole coupling taking the place of the electronic spin–spin coupling or zero field splitting. Calculations of lineshapes and transition probabilities carried out for half-field EPR^{6,7} are therefore applicable to overtone NMR of spin-1 nuclei.

2 THEORY

A detailed description of the theory and the implementation of overtone spectroscopy has been given by Tycko and Opella.³ The essential theoretical points follow from consideration of the spin Hamiltonian $\hat{\mathcal{H}}$ for a quadrupolar nucleus with spin $\hat{S}$:

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_S + \hat{\mathcal{H}}_{rf} \quad (1)$$

$$\hat{\mathcal{H}}_S = -h\nu_0 \hat{S}_z + h\nu_Q [3\hat{S}_z^2 - \hat{S}^2 + \eta(\hat{S}_x^2 - \hat{S}_y^2)] \quad (2)$$

$$\hat{\mathcal{H}}_{rf} = 2\hbar\gamma_S B_1 (\hat{S}_x \cos \theta + \hat{S}_z \sin \theta) \cos(2\pi\nu t + \phi) \quad (3)$$

$\hat{\mathcal{H}}_S$ includes the interaction with the external dc field along z (the Zeeman interaction) and the quadrupole coupling. The principal axes of the quadrupole coupling tensor are $x'y'z'$. ν_Q is defined as $(e^2qQ)/[4S(2S-1)]$. $\hat{\mathcal{H}}_{rf}$ is the interaction with an rf field with amplitude B_1 , frequency ν , phase ϕ , and direction in the xz plane at angle θ to x . γ_S is the nuclear gyromagnetic ratio. In the limit $\nu_0 \gg \nu_Q$, the eigenstates of $\hat{\mathcal{H}}_S$ are simply the eigenstates of S_z , i.e. $\{|m\rangle\}$. When this limit does not apply, but $\nu_0 > \nu_Q$, the eigenstates are $\{|\psi_m\rangle\}$, given by

$$|\psi_m\rangle = |m\rangle + \sum_{m' \neq m} C_{mm'} |m'\rangle \quad (4)$$

If the laboratory axes (xyz) and quadrupole principal axes ($x'y'z'$) are related by Euler angles α , β , and γ , the coefficients $C_{mm'}$ are given to first order in ν_Q/ν_0 by

$$\begin{aligned} C_{mm'} = \frac{\nu_Q}{2(m'-m)\nu_0} \{ & -\delta_{m', m+1} [S(S+1) \\ & -m(m+1)]^{\frac{1}{2}} (2m+1) F(\alpha, \beta, \gamma) - \delta_{m', m-1} \\ & \times [S(S+1) - m(m-1)]^{\frac{1}{2}} (2m-1) F^*(\alpha, \beta, \gamma) \\ & + \delta_{m', m+2} \{ [S(S+1) - m(m+1)] [S(S+1) \\ & - (m+1)(m+2)] \}^{\frac{1}{2}} G(\alpha, \beta, \gamma) \\ & + \delta_{m', m-2} \{ [S(S+1) - m(m-1)] [S(S+1) \\ & - (m-1)(m-2)] \}^{\frac{1}{2}} G^*(\alpha, \beta, \gamma) \} \end{aligned} \quad (5a)$$

$$\begin{aligned} F(\alpha, \beta, \gamma) = e^{i\gamma} [& 3 \sin \beta \cos \beta - \eta (\cos 2\alpha \sin \beta \cos \beta \\ & + i \sin 2\alpha \sin \beta)] \end{aligned} \quad (5b)$$

$$\begin{aligned} G(\alpha, \beta, \gamma) = e^{2i\gamma} \left\{ & \frac{3}{2} \sin^2 \beta \right. \\ & \left. + \eta \left[\frac{1}{2} \cos 2\alpha (1 + \cos^2 \beta) + i \sin 2\alpha \cos \beta \right] \right\} \end{aligned} \quad (5c)$$

To second order in ν_Q/ν_0 , the energy E_m of the state $|\psi_m\rangle$ is

$$\begin{aligned} E_m = h\nu_0 \left\{ & -m + \frac{\nu_Q}{2\nu_0} [3m^2 - S(S+1)] (3 \cos^2 \beta - 1) \right. \\ & \left. + \eta \cos 2\alpha \sin^2 \beta + \sum_{m' \neq m} (m' - m) |C_{mm'}|^2 \right\} \end{aligned} \quad (6)$$

The orientation-dependent frequency of the overtone transition in a spin-1 nucleus is then

$$\nu_{1,-1}(\alpha, \beta, \gamma) = 2\nu_0 + \frac{\nu_Q^2}{\nu_0} (|F(\alpha, \beta, \gamma)|^2 + |G(\alpha, \beta, \gamma)|^2) \quad (7)$$

and the orientation-dependent transition moment is

$$\begin{aligned} M_{1,-1}(\alpha, \beta, \gamma) &= \langle \psi_1 | S_x \cos \theta + S_z \sin \theta | \psi_{-1} \rangle \\ &= \frac{\nu_Q}{\nu_0} [\sin \theta F(\alpha, \beta, \gamma) + \cos \theta G(\alpha, \beta, \gamma)] \end{aligned} \quad (8)$$

The nutation frequency (i.e. the inverse of the 2π pulse length) for excitation of the overtone transition is given by $\gamma_S B_1 |M_{1,-1}|/\pi$. The overtone signal amplitude is proportional to $|\rho_{1,-1} M_{1,-1}|$, where $|\rho_{1,-1}|$ is the amplitude of the overtone coherence excited by rf pulses. Thus, equation (8) displays the unusual features of overtone spectroscopy that the nutation frequency depends on the orientation of the quadrupole tensor principal axis system, that overtone transitions can be excited by rf fields applied parallel to the external dc field ($\theta = \pi/2$), and that signals can be detected by rf solenoid coils wound parallel to the dc field. Overtone powder pattern lineshapes in polycrystalline and noncrystalline solids are determined by the orientation-dependent overtone frequency in equation (7) weighted by an orientation-dependent function related to $M_{1,-1}$. The precise details of the weighting function depend on the excitation method. In the linear (i.e. small flip-angle pulse) regime, the weighting function is $|M_{1,-1}|^2$. Equation (8) shows that the weighting function, and hence the observed lineshape, depends on θ .

Since the coefficients $C_{mm'}$ are nonzero only for $|m - m'| = 1$ or 2 , only the first ($\nu \approx 2\nu_0$) and second ($\nu \approx 3\nu_0$) overtone transitions have transition moments proportional to ν_Q/ν_0 , and only the first overtone transition has a transition moment proportional to ν_Q/ν_0 when $\theta = \pi/2$. Higher overtone transitions are weaker, with transition moments proportional to higher powers of ν_Q/ν_0 .

3 EXPERIMENTS

3.1 Detection of ^{14}N Overtone Transitions by CW NMR

Creel et al.⁸ have reported the detection of the ^{14}N spectrum of hexamethylenetetramine by CW NMR methods in fields up to 2.2 T, where $\nu_0 = 6.6$ MHz. The quadrupole coupling frequency $\nu_Q = (e^2qQ)/4h$ is roughly 1.1 MHz in hexamethylenetetramine. Although the fields in these experiments were low by modern standards, they were high enough that the highest frequency ^{14}N signals can be considered to be overtones of the lower frequency signals.

3.2 Indirect Detection of ^{14}N Overtone Transitions

Blinc et al.⁹ measured the ^{14}N NMR spectrum of triglycine sulfate by means of the Hartmann–Hahn double resonance, indirect detection technique.¹⁰ Working in a 0.42 T field, they determined the ^{14}N resonant frequencies by observing proton NMR signals following an adiabatic demagnetization–adiabatic remagnetization cycle, with rf irradiation of the ^{14}N nuclei during a delay period between the demagnetization and remagnetization steps. In such an experiment, the proton NMR signals are destroyed or attenuated whenever the rf frequency is close to a ^{14}N resonance. In the work of Blinc et al., three resonances were observed for a single ^{14}N site, but the dc field was so low that it would be improper to call one resonance an overtone of the others. Essentially the same method was later applied to overtone spectroscopy at considerably higher fields by Tycko and Opella and by Garroway and Miller.¹¹ Related experiments, but involving double quantum rather than overtone excitation, were carried out by Schnur et al.¹² The indirect detection method is a comparatively simple way to locate overtone resonances in organic compounds, with high sensitivity (in favorable cases, on a single transient) but with low resolution. Figure 2 shows double resonance rf pulse sequences for the indirect detection of overtone signals.

3.3 Direct Detection of ^{14}N Overtone Signals Following Double Quantum Excitation

Bloom and LeGros¹ showed that the ^{14}N overtone signals from a single crystal of NaNO_2 , with $\nu_Q = 1.4$ MHz, could be detected directly with adequate sensitivity in a 5.4 T field

Figure 2 Sequences of rf pulses applied to proton (^1H) spins and to an overtone (OT) transition for the indirect detection of overtone transitions in organic solids. (a) Proton dipolar order is created by a two pulse Jeener–Broekaert sequence. A train of OT pulses, with alternating rf phases, destroys part of the dipolar order when the OT carrier frequency is close to a nuclear resonance. Proton NMR signals, proportional to the remaining dipolar order, are detected after the final proton pulse. In a typical application, one scans the OT carrier frequency and looks for a reduction in the proton signal at the OT resonance. (b) Same procedure as (a), but with dipolar order created by adiabatic demagnetization in the rotating frame (ADRF) and proton signals detected after adiabatic remagnetization in the rotating frame (ARRF). A signal enhancement by a factor of 4 over the Jeener–Broekaert method is possible

($\nu_0 = 16.6$ MHz). In the experiments of Bloom and LeGros, rf pulses were not applied at the overtone resonant frequency. Instead, the overtone coherence was excited by the double quantum excitation technique of Vega and Pines,¹³ in which a rf pulse at frequency $\nu_0 + \nu_Q$ ⁽²⁾, with amplitude less than ν_Q/γ_S , is applied for a time about equal to $3\pi\nu_Q/2(\gamma_S B_1)^2$. Thus, signals were detected at twice the frequency of the applied pulses. So far, this method of exciting overtone transitions has been of interest primarily from the standpoint of pure spectroscopy. Excitation near the overtone resonant frequency itself has proven to be a more practical approach.

3.4 Direct Detection and Direct Excitation of ^{14}N Overtone Transitions

Tycko and Opella^{2,3} carried out a series of experiments that demonstrated the feasibility of the direct excitation and direct detection of ^{14}N overtone spectra in single crystal and polycrystalline organic solids. They showed that overtone coherences could be excited both by direct pulsed excitation of the overtone transition and by cross polarization from proton magnetization. They demonstrated the high resolution inherent in overtone spectroscopy when high-power proton decoupling is employed (overtone resonances in single crystals subject to small strains and small degrees of disorder are broadened by second-order rather than first-order quadrupole effects). They showed that quadrupole coupling constants and asymmetry parameters could be determined from overtone lineshapes of polycrystalline samples and that the powder pattern lineshapes depend on the direction of the rf coil used for excitation and detection. They also demonstrated two-dimensional overtone nutation spectroscopy, for measuring overtone nutation frequencies, and two-dimensional overtone separated-local-field spectroscopy, for measuring ^{14}N – ^1H dipole–dipole couplings. Radiofrequency pulse sequences for the acquisition of one-dimensional ^{14}N overtone spectra of organic solids are shown in Figure 3. Examples of one-dimensional ^{14}N overtone spectra are shown in Figures 4 and 5.

Tycko and Opella³ have discussed the comparative sensitivities of ^{14}N overtone spectroscopy and single quantum spectroscopy. Because of the reduced spectral widths and linewidths in typical overtone spectra, overtone spectroscopy has sensitivity at least comparable to that of single quantum spectroscopy despite the weakly allowed nature of overtone transitions.

Tycko and Opella³ have also carried out preliminary experimental investigations of the effects of rapid sample spinning on ^{14}N overtone spectra of polycrystalline solids. They found that spinning about a single axis changed, but did not narrow, the overtone powder pattern lineshape. Takegoshi and Hikichi¹⁴ performed calculations of overtone lineshapes under sample spinning that supported the experimental results. They have also discussed the use of double rotation (DOR) and dynamic angle spinning (DAS) methods as a means of narrowing the second-order quadrupole shift powder patterns observed in ^{14}N overtone spectroscopy.¹⁴ Although this approach to line narrowing has not been demonstrated in experiments, it may turn out to be a valuable one. In principle, either the DOR or the DAS technique, or some suitable variant of these techniques, may allow one to obtain resolved ^{14}N

Figure 3 Pulse sequences for the direct detection of overtone spectra in organic solids. (a) Direct excitation of overtone coherences with a single OT pulse. High-power proton decoupling is applied during the acquisition of the overtone signals. (b) A Jeener–Broekaert sequence is used to create proton dipolar order. Overtone coherences are generated by cross polarization from dipolar order. (c) Adiabatic demagnetization in the rotating frame is used to create proton dipolar order. Overtone coherences are generated by cross polarization from dipolar order. (d) Overtone coherences are generated by cross polarization from transverse proton magnetization, prepared by pulsed spin locking. Pulsed, rather than continuous, spin locking reduces the effective proton rf field, allowing a Hartmann–Hahn match to be achieved despite the relatively weak effective OT rf field (due to the weakly allowed nature of the overtone transitions). (Adapted by permission of the American Institute of Physics from Tycko and Opella, *J. Chem. Phys.*, 1987, **86**, 1761)

overtone NMR lines from chemically inequivalent nitrogen sites in a complex polycrystalline solid (i.e. a polycrystalline peptide or oligonucleotide). The resonant frequencies in such an experiment would be determined by the isotropic parts of the chemical shift and the second-order quadrupole shift. In addition, one expects a small contribution to the overtone lineshapes from a spinning sample due to Berry's phase, as observed in pure NQR spectra of spinning samples.¹⁵ The effects of Berry's phase, which arise because the nuclear spin eigenstates are functions of orientation when the quadrupole coupling is large, are expected to be of the order of $|C_{mm'}|^2 \nu_R$, where ν_R is the sample spinning frequency, which is less than 100 Hz for typical experimental conditions.

Takegoshi and Hikichi¹⁶ have also carried out a rotation study of a single crystal of L-alanine to determine the ^{14}N quadrupole coupling constant and asymmetry parameter in this compound. The observed angular dependences of the overtone frequency and intensity were well described by the expressions derived by perturbation theory.

Ramanathan and Opella¹⁷ have investigated the effects of irradiation of ^{14}N overtone resonances on the ^{13}C NMR spectrum of a single crystal of *N*-acetyl-D,L-valine. The ^{13}C NMR lineshapes at 3.52 T are asymmetric triplets

Figure 4 ^{14}N overtone NMR spectra of a 50 mg single crystal of *N*-acetyl-D,L-valine, obtained at 5.89 T ($2\nu_0 = 36.118$ MHz). The two lines result from the two magnetically inequivalent molecules in the unit cell. All spectra result from the acquisition of 1024 transients. (a) Direct excitation, using the pulse sequence in Figure 3(a). (b) Cross polarization, using the pulse sequence in Figure 3(b). (c) Cross polarization, using the pulse sequence in Figure 3(b), after an arbitrary 10° rotation of the crystal. The change in the overtone resonant frequencies is due to the orientation dependence of the second-order quadrupole shifts. (Adapted by permission of the American Chemical Society from Tycko and Opella, *J. Am. Chem. Soc.*, 1968, **108**, 3531)

for carbon atoms that are coupled to ^{14}N nuclei in this crystal, with asymmetry due to the large ^{14}N quadrupole coupling ($\nu_Q = 0.8$ MHz). Irradiation of the ^{14}N overtone resonances caused the triplet ^{13}C lineshapes to collapse into unresolved doublets. Ramanathan and Opella showed that this 'overtone decoupling' could be carried out selectively, allowing particular ^{14}N overtone resonances to be correlated with particular ^{13}C resonances. Selective overtone decoupling may be useful in the assignment of resonances in single crystal NMR studies.

4 CONCLUSIONS

Overtone spectroscopy is a useful addition to the techniques of solid state NMR. The reduced spectral widths and linewidths of ^{14}N overtone spectra compared with traditional single quantum spectra clearly make overtone spectroscopy the preferred means of applying ^{14}N NMR to the study of many classes of solids. In many cases, overtone spectroscopy is the only practical way to observe ^{14}N NMR signals. At the very least, this allows measurements of spin relaxation rates and approximate quadrupole coupling constants to be performed. Such measurements can probe the chemical, structural, dynamical, and electronic properties of solids.

Extensions of overtone spectroscopy to NMR of nuclei with spins greater than one are possible, but have not yet been

Figure 5 Experimental (a–d) and (e–h) calculated ^{14}N overtone NMR spectra of *N*-acetyl-D,L-valine powder, obtained at 5.89 T (a,b,e,f) and 3.54 T (c,d,g,h) with the pulse sequence in Figure 3(c). The rf solenoid coil used for excitation and detection of overtone signals is perpendicular to the external magnetic field in (a), (c), (e), and (g), and parallel to the external magnetic field in (b), (d), (f), and (h). Each experimental spectrum is the result of approximately 20 000 transients on a 200 mg sample. In the calculations, signal contributions from the various possible molecular orientations are weighted by $-M_{1,-1}$ (see text), and effects of the ^{14}N chemical shift anisotropy are included. investigated in detail. For most quadrupolar nuclei, with non-integer spins, the ‘central transition’ (i.e. the $m = \frac{1}{2} \leftrightarrow m = -\frac{1}{2}$ transition) is already unaffected by first-order quadrupole splittings and is fully allowed. The arguments in favor of overtone spectroscopy are therefore less compelling. Nonetheless, one expects the observation of overtone signals in conjunction with single quantum signals to afford spectral simplification, contribute to the determination of quadrupole coupling parameters, and facilitate the assignment of resonances. The measurement of overtone relaxation rates may also add to the information available from relaxation measurements on the central transition.

1 INTRODUCTION

Nuclei are characterized by an atomic number Z , a mass number A , and a nuclear spin I . The value of I depends on those of A and Z (Table 1). Nuclei with spin $I > \frac{1}{2}$ are multiple energy level systems and are called quadrupolar nuclei. They represent more than 70% of those in the Periodic Table. However, they are not as frequently investigated in NMR as other elements, because of their quadrupole moments Q , which interact with the electric field gradient (EFG) generated by their surroundings. This coupling, called the quadrupolar interaction and denoted by $\mathcal{H}_Q$, may be much stronger than the amplitude of the rf excitation pulse. As a result, it affects the line intensity and alters the lineshape. These effects make the interpretation of spectra more difficult. Usually, only the first two expansion terms of $\mathcal{H}_Q$ are considered: the first-order, ($H_Q^{[1]}$), and second-order, ($H_Q^{[2]}$), quadrupolar interactions, in the vocabulary of standard perturbation theory. $H_Q^{[1]}$ splits the spectrum of a half-integer quadrupole spin system in a single crystal into $2I - 1$ satellite lines, but the central line remains at the Larmor frequency ω_0 . The additional effect of $H_Q^{[2]}$ is to shift further all the lines, including the central line.

When the sample is in powder form, as it usually is, it is mainly the central line that is observed. Moreover, its lineshape becomes nonsymmetrical when $H_Q^{[2]}$ is large. In favorable cases, the powder pattern of the satellite spinning sidebands is detected using the popular MAS technique (see *Magic Angle Spinning* and *Rotating Solids*). The powder pattern of the central line is characterized by three parameters: the quadrupolar coupling constant $\chi = e^2qQ/\hbar$, which is the product of a nuclear property (eQ) and a crystal property (eq),

the asymmetry parameter η and the center of gravity of the experimental line, δ_{CG}^{exp} (in ppm). χ is a measure of the strength of the quadrupolar interaction and η a measure of the deviation of the EFG from axial symmetry. The true chemical shift δ_{CS} of the central line is related to these three parameters:^{1,2}

$$\delta_{CS} = \delta_{CG}^{exp} + \frac{1}{30}(1 + \frac{1}{3}\eta^2)[I(I+1) - \frac{3}{4}] \left[\frac{3\chi}{2I(2I-1)\omega_0} \right]^2 \quad (1)$$

A precise determination of δ_{CS} is required if its value has to be correlated with bond lengths and bond angles. Several methods are available for determining χ and η . They can be grouped into two categories:

1. there is a series of techniques, especially the mechanical spinning of the sample,¹⁻⁵ based on the frequency domain response of the spin system (see *Variable Angle Sample Spinning*);
2. the second series deals with the time domain response of the spin system to rf excitation⁶⁻⁸ (see *Nutation Spectroscopy of Quadrupolar Nuclei*).

The experimental center of gravity δ_{CG}^{exp} is determined by spectral simulation. However, spectra acquired with DAS or DOR probes provide this value directly⁵ (see *Double Rotation* and *Dynamic Angle Spinning*). Books dealing with these modern techniques are available.⁹⁻¹¹

In the present article, we focus on the frequency domain response of half-integer quadrupolar spin larger than 1. (Jellison and co-workers¹² calculated perturbation terms up to third order for integer spins $I = 1$ and 3.) The first part is devoted to a derivation of the Hamiltonians corresponding to first- and second-order perturbations, with the emphasis on the different conventions used in the literature, namely, the asymmetry parameter, the components of spherical tensors in their principal axis system, the Larmor frequency, transitions, and the transition frequency. With this in mind, the Magnus expansion is applied instead of standard perturbation theory. For simplicity, Hamiltonians are expressed in angular velocity units and relaxation phenomena are not taken into account. In the second part, NMR parameters related to single crystal spectra (see *High-Pressure NMR*, *Incommensurate Systems*, and *Phase Transitions and Critical Phenomena in Solids*) and powder patterns in static and MAS measurements are presented (see *Amorphous Materials*, *Quadrupolar Nuclei in Glasses*, *Quadrupolar Nuclei in Solids*, and *Vanadium Catalysts: Solid State NMR*), in particular, the second-order quadrupolar shift, the critical points and the lineshapes of the powder patterns for various values of η , and the second-order quadrupolar shift for the center of gravity of a powder pattern. In the appendix, the commonly used Euler angles as well as those used by Baugher and co-workers¹³⁻¹⁵ are given in graphical form. The Wigner rotation matrix, expressing the components of the same spherical tensor in two different coordinate frames, is also given.

2 QUADRUPOLEAR HAMILTONIAN IN A UNIFORM SPACE

Slichter¹⁶ and others^{17,18} introduce the quadrupolar interaction from the classical concept of the charge density for a nucleus in a space where the three coordinate axes x , y , and z are equivalent. Then, the quantum mechanical form

Table 1 Value of Nuclear Spin I as a Function of Atomic Number Z and Mass Number A

A	Z	
	Odd	Even
Odd	Half-integer I	Half-integer I
Even	Integer I	$I = 0$

2 QUADRUPOLEAR INTERACTIONS

of this interaction is obtained using operators. Thanks to the Wigner–Eckart theorem, the Hamiltonian representing the quadrupolar interaction independently of the Cartesian coordinate frame is defined:

$$\hbar\hat{\mathcal{H}}_Q = \frac{eQ}{6I(2I-1)} \sum_{\alpha,\beta=x,y,z} V_{\alpha\beta} [\frac{3}{2}(\hat{I}_\alpha\hat{I}_\beta + \hat{I}_\beta\hat{I}_\alpha) - \delta_{\alpha\beta}I(I+1)] \quad (2a)$$

with

$$V_{\alpha\beta} = \left. \frac{\partial^2 U}{\partial\alpha\partial\beta} \right|_{r=0} \quad (2b)$$

$\delta_{\alpha\beta}$ is the Kronecker delta symbol, U is the electrostatic potential at the origin (inside the nucleus) generated by external charges, and $V_{\alpha\beta}$ are the Cartesian components of the EFG at the origin, $\mathbf{V}$, which is a second-rank symmetrical tensor (see *Deuterium NMR in Solids* and *Liquid Crystalline Samples: Deuterium NMR*). In the principal axis system Σ^{PAS} of the EFG, $\mathbf{V}$ is diagonal:

$$\mathbf{V} = \begin{bmatrix} V_{XX} & 0 & 0 \\ 0 & V_{YY} & 0 \\ 0 & 0 & V_{ZZ} \end{bmatrix} \quad (3)$$

with the convention $|V_{ZZ}| \geq |V_{YY}| \geq |V_{XX}|$. Furthermore, the Laplace equation $V_{XX} + V_{YY} + V_{ZZ} = 0$ holds for $\mathbf{V}$. Thus, only two independent parameters are required:

$$eq = V_{ZZ} \quad (4a)$$

$$\eta = \frac{V_{XX} - V_{YY}}{V_{ZZ}} \quad (4b)$$

the largest component and the asymmetry parameter, respectively, with $1 \geq \eta \geq 0$.

In the coordinate frame Σ^{PAS} , the Cartesian tensor representation of the quadrupolar interaction [equation (2a)] takes the form

$$\hbar\hat{\mathcal{H}}_Q = \frac{e^2qQ}{4I(2I-1)} [3\hat{I}_Z^2 - I(I+1) + \eta(\hat{I}_X^2 - \hat{I}_Y^2)] \quad (5a)$$

In terms of the operators

$$\hat{I}_+ = \hat{I}_X + i\hat{I}_Y, \quad \hat{I}_- = \hat{I}_X - i\hat{I}_Y \quad (5b)$$

equation (5a) becomes

$$\hbar\hat{\mathcal{H}}_Q = \frac{e^2qQ}{4I(2I-1)} [3\hat{I}_Z^2 - I(I+1) + \frac{1}{2}\eta(\hat{I}_+^2 + \hat{I}_-^2)] \quad (5c)$$

Sometimes, the opposite convention is adopted for η :

$$\eta = \frac{V_{YY} - V_{XX}}{V_{ZZ}} \quad (6)$$

which is associated with the condition $|V_{ZZ}| \geq |V_{XX}| \geq |V_{YY}|$.^{19,20} As a result, a negative sign appears in front of η in equations (5a) and (5c) and in subsequent expressions containing η .

3 SPHERICAL TENSOR REPRESENTATION FOR THE QUADRUPOLEAR HAMILTONIAN

The passage from one coordinate frame to another is more conveniently realized if the quadrupolar interaction is

expressed as a second-rank irreducible spherical tensor (see *Internal Spin Interactions and Rotations in Solids*), according to Mehring:²¹

$$\begin{aligned} \hbar\hat{\mathcal{H}}_Q &= \frac{eQ}{4I(2I-1)} \sum_{q=-2}^2 (-1)^q V^{(2,q)} T^{(2,-q)} \\ &= \frac{eQ}{4I(2I-1)} \sum_{q=-2}^2 (-1)^q V^{(2,-q)} T^{(2,q)} \end{aligned} \quad (7)$$

In any Cartesian coordinate frame Σ , the spherical tensor and Cartesian tensor components of $\mathbf{V}$ are related by

$$\left. \begin{aligned} V^{(2,0)} &\equiv V_0 = 3\sqrt{\frac{1}{6}}V_{zz} \\ V^{(2,1)} &\equiv V_1 = -V_{xz} - iV_{yz} \\ V^{(2,-1)} &\equiv V_{-1} = V_{xz} - iV_{yz} \\ V^{(2,2)} &\equiv V_2 = \frac{1}{2}(V_{xx} - V_{yy}) + iV_{xy} \\ V^{(2,-2)} &\equiv V_{-2} = \frac{1}{2}(V_{xx} - V_{yy}) - iV_{xy} \end{aligned} \right\} \quad (8)$$

and those of $\mathbf{T}$ as

$$\left. \begin{aligned} T^{(2,0)} &= \frac{1}{3}\sqrt{6}[3\hat{I}_z^2 - I(I+1)], \quad T^{(2,1)} = -\hat{I}_z\hat{I}_+ - \hat{I}_+\hat{I}_z \\ T^{(2,-1)} &= \hat{I}_z\hat{I}_- + \hat{I}_-\hat{I}_z, \quad T^{(2,2)} = \hat{I}_+\hat{I}_+, \quad T^{(2,-2)} = \hat{I}_-\hat{I}_- \end{aligned} \right\} \quad (9)$$

with $\hat{I}_+ = \hat{I}_x + i\hat{I}_y$ and $\hat{I}_- = \hat{I}_x - i\hat{I}_y$. These two operators are different from those of equation (5b) despite the same notation. It is worth noting that the numerical factors in the components of $\mathbf{V}$ and $\mathbf{T}$ [equations (8) and (9)] differ from author to author.

Using equations (7)–(9), the spherical tensor representation of the quadrupolar interaction in the coordinate frame Σ becomes

$$\begin{aligned} \hbar\hat{\mathcal{H}}_Q &= \frac{eQ}{4I(2I-1)} \{ \frac{1}{3}\sqrt{6}[3\hat{I}_z^2 - I(I+1)]V_0 + (\hat{I}_z\hat{I}_+ + \hat{I}_+\hat{I}_z)V_{-1} \\ &\quad - (\hat{I}_z\hat{I}_- + \hat{I}_-\hat{I}_z)V_1 + \hat{I}_+^2V_{-2} + \hat{I}_-^2V_2 \} \end{aligned} \quad (10)$$

Slichter¹⁶ uses nearly the same relationship, apart from a negative sign due to another choice of V_1 . From equations (4a), (4b), and (8), the spherical tensor components of $\mathbf{V}$ in Σ^{PAS} are obtained:

$$V_0^{\text{PAS}} = \sqrt{\frac{3}{2}}eq, \quad V_1^{\text{PAS}} = V_{-1}^{\text{PAS}} = 0, \quad V_2^{\text{PAS}} = V_{-2}^{\text{PAS}} = \frac{1}{2}eq\eta \quad (11a)$$

If the other convention for η , namely, equation (6) is used then the spherical tensor components of $\mathbf{V}$ in Σ^{PAS} are²⁰

$$V_0^{\text{PAS}} = \sqrt{\frac{3}{2}}eq, \quad V_1^{\text{PAS}} = V_{-1}^{\text{PAS}} = 0, \quad V_2^{\text{PAS}} = V_{-2}^{\text{PAS}} = -\frac{1}{2}eq\eta \quad (11b)$$

4 QUADRUPOLEAR INTERACTION AS A PERTURBATION OF ZEEMAN INTERACTION

A nuclear spin possesses a magnetic moment μ and an angular momentum $\hbar\mathbf{I}$, which are related by the gyromagnetic ratio γ :

$$\mu = \gamma\hbar\mathbf{I} \quad (12)$$

In the laboratory frame Σ^{lab} , the direction of the strong static magnetic field $\mathbf{B}_0$ is taken as the z axis. The coupling of the magnetic moment with $\mathbf{B}_0$ is the Zeeman interaction $\mathcal{H}_Z$:

$$\hbar\hat{\mathcal{H}}_Z = -\boldsymbol{\mu} \cdot \mathbf{B}_0 = -\hbar\omega_0\hat{I}_z \quad (13a)$$

$$\omega_0 = \gamma B_0 \quad (13b)$$

where $\omega_0/2\pi$ is the Larmor frequency. Sometimes this frequency is defined as $\omega_0/2\pi = -\gamma B_0/2\pi$. As a result, the Zeeman interaction takes the form $\hbar\hat{\mathcal{H}}_Z = \hbar\omega_0\hat{I}_z$. As with η , the choice of ω_0 changes the sign of some expressions below.

We deal with the case where $\mathcal{H}_Q$ can be treated as a weak perturbation of the Zeeman interaction. It is then more convenient to express interactions in the frame Σ^{obs} rotating relative to Σ^{lab} with an angular velocity ω_0 so that the spherical tensor representation of the quadrupolar interaction expressed by equation (10) becomes time-dependent:²²

$$\begin{aligned} \hbar\hat{\mathcal{H}}_Q(t) &= \exp(i\hat{\mathcal{H}}_Z t) \hbar\hat{\mathcal{H}}_Q \exp(-i\hat{\mathcal{H}}_Z t) \\ &= \frac{eQ}{4I(2I-1)} \left\{ \frac{1}{3}\sqrt{6}[3\hat{I}_z^2 - I(I+1)]V_0 \right. \\ &\quad + \hat{I}_+(2\hat{I}_z + 1)V_{-1} \exp(-i\omega_0 t) - \hat{I}_-(2\hat{I}_z - 1)V_1 \exp(i\omega_0 t) \\ &\quad \left. + \hat{I}_+^2 V_{-2} \exp(-i2\omega_0 t) + \hat{I}_-^2 V_2 \exp(i2\omega_0 t) \right\} \end{aligned} \quad (14)$$

However, the first term in the curly brackets (i.e., the secular term) remains time-independent. In order to make the quadrupolar interaction completely time-independent, $\hat{\mathcal{H}}_Q(t)$ is averaged over one Larmor period $2\pi/\omega_0$ up to first-order (see *Average Hamiltonian Theory*), using the Magnus expansion:²³

$$\begin{aligned} \langle \hat{\mathcal{H}}_Q(t) \rangle &= \frac{\omega_0}{2\pi} \int_0^{2\pi/\omega_0} dt \hat{\mathcal{H}}_Q(t) - \frac{i\omega_0}{4\pi} \int_0^{2\pi/\omega_0} dt \int_0^t dt' [\hat{\mathcal{H}}_Q(t), \hat{\mathcal{H}}_Q(t')] \\ &= H_Q^{(0)} + H_Q^{(1)} \end{aligned} \quad (15)$$

with

$$H_Q^{(0)} = \frac{eQ}{4I(2I-1)\hbar} \frac{\sqrt{6}}{3} [3\hat{I}_z^2 - I(I+1)]V_0 \quad (16)$$

$$\begin{aligned} H_Q^{(1)} &= -\frac{1}{\omega_0} \left[\frac{eQ}{4I(2I-1)\hbar} \right]^2 \left\{ \sqrt{6}V_0 V_{-1} \hat{I}_+ (2\hat{I}_z + 1)^2 \right. \\ &\quad - \sqrt{6}V_0 V_1 \hat{I}_- (2\hat{I}_z - 1)^2 + 2\sqrt{6}V_0 V_{-2} \hat{I}_+^2 (\hat{I}_z + 1) \\ &\quad + 2\sqrt{6}V_0 V_2 \hat{I}_-^2 (\hat{I}_z - 1) \\ &\quad + 2V_{-1} V_1 \hat{I}_z [4I(I+1) - 8\hat{I}_z^2 - 1] \\ &\quad \left. + 2V_{-2} V_2 \hat{I}_z [2I(I+1) - 2\hat{I}_z^2 - 1] \right\} \end{aligned} \quad (17)$$

Usually, only the secular terms that commute with $\hat{I}_z$ (i.e., the last two terms in the curly brackets of $H_Q^{(1)}$) are considered. With this simplification, $H_Q^{(0)}$ and $H_Q^{(1)}$ are equivalent to the first-order, $H_Q^{[1]}$, and second-order, $H_Q^{[2]}$, terms in standard perturbation theory,²⁴ i.e.,

$$H_Q^{[1]} = H_Q^{(0)} = \frac{eQ}{4I(2I-1)\hbar} \frac{\sqrt{6}}{3} [3\hat{I}_z^2 - I(I+1)]V_0 \quad (18)$$

$$\begin{aligned} H_Q^{[2]} = H_Q^{(1)} &= -\frac{1}{\omega_0} \left[\frac{eQ}{4I(2I-1)\hbar} \right]^2 \\ &\quad \times \{ 2V_{-1} V_1 \hat{I}_z [4I(I+1) - 8\hat{I}_z^2 - 1] \\ &\quad + 2V_{-2} V_2 \hat{I}_z [2I(I+1) - 2\hat{I}_z^2 - 1] \} \end{aligned} \quad (19)$$

respectively. Equations (18) and (19), derived in the rotating frame Σ^{obs} , are unchanged in the laboratory frame Σ^{lab} . This is because they commute with the Zeeman interaction. In other words, they commute with the operator $\hat{I}_z$. From now on, we shall use the language of standard perturbation theory. The first-order quadrupolar interaction $H_Q^{[1]}$ is independent of ω_0 , whereas the second-order quadrupolar interaction $H_Q^{[2]}$ is inversely proportional to ω_0 . Therefore, a strong static magnetic field is required to reduce the effects of $H_Q^{[2]}$.

5 ENERGY LEVELS AND THE SPECTRUM OF A SINGLE CRYSTAL

When a free spin I is introduced into a strong static magnetic field, the Zeeman interaction splits its $2I + 1$ energy levels $|m\rangle$, whose energy is defined by

$$\langle m | \hat{\mathcal{H}}_Z | m \rangle = -m\omega_0 \quad (20)$$

and the difference between two consecutive energy levels ($m - 1, m$), expressed in angular velocity units, is

$$\omega_{m-1,m}^{(Z)} = \langle m-1 | \hat{\mathcal{H}}_Z | m-1 \rangle - \langle m | \hat{\mathcal{H}}_Z | m \rangle = \omega_0 \quad (21a)$$

We choose the same convention as Abragam¹⁸ for the pair ($m - 1, m$) and equation (21a) to represent the transition and the transition frequency, respectively, but other authors choose ($m, m - 1$), ($m, m + 1$), ($m + 1, m$), equation (21a) or its negative

$$\omega_{m-1,m}^{(Z)} = \langle m | \hat{\mathcal{H}}_Z | m \rangle - \langle m-1 | \hat{\mathcal{H}}_Z | m-1 \rangle \quad (21b)$$

Of course, these choices affect some later relationships dealing with transitions and transition frequencies. Equation (21a) implies that the energy levels $|m\rangle$ of a free spin in a strong static magnetic field $\mathbf{B}_0$ are equally spaced. The separation between two adjacent levels is ω_0 . In the spectrum, a single line is located at ω_0 . However, these energy levels may be shifted by other interactions, including the quadrupolar interaction discussed in this article.

The first-order quadrupolar interaction $H_Q^{[1]}$ shifts the energy levels $|m\rangle$ by an amount

$$\langle m | H_Q^{[1]} | m \rangle = \frac{eQ}{4I(2I-1)\hbar} \frac{\sqrt{6}}{3} [3m^2 - I(I+1)]V_0 \quad (22)$$

and in the spectrum, its contribution to the line position, i.e., the first-order quadrupolar shift $\omega_{m-1,m}^{(1)}$ of the line position associated with the transition ($m - 1, m$), is

$$\begin{aligned} \omega_{m-1,m}^{(1)} &= \langle m-1 | H_Q^{[1]} | m-1 \rangle - \langle m | H_Q^{[1]} | m \rangle \\ &= \frac{3eQ}{4I(2I-1)\hbar} \frac{\sqrt{6}}{3} (1-2m)V_0 \end{aligned} \quad (23)$$

4 QUADROPOLAR INTERACTIONS

The spectrum consists of $2I$ lines, the central one of which, associated with the transition $(-\frac{1}{2}, \frac{1}{2})$, is still located at ω_0 . The other $2I - 1$ lines are called satellite lines.

When the second-order quadrupolar interaction $H_Q^{[2]}$ is taken into account, the energy levels $|m\rangle$ are shifted further:²⁵

$$\begin{aligned} \langle m | H_Q^{[2]} | m \rangle = & -\frac{1}{\omega_0} \left[\frac{eQ}{4I(2I-1)\hbar} \right]^2 \\ & \times \{ 2V_{-1}V_1m[4I(I+1) - 8m^2 - 1] \\ & + 2V_{-2}V_2m[2I(I+1) - 2m^2 - 1] \} \end{aligned} \quad (24)$$

and its contribution $\omega_{m-1,m}^{(2)}$ to the line position, i.e., the second-order quadrupolar shift of the line, is²⁶

$$\begin{aligned} \omega_{m-1,m}^{(2)} = & \langle m-1 | H_Q^{[2]} | m-1 \rangle - \langle m | H_Q^{[2]} | m \rangle \\ = & -\frac{2}{\omega_0} \left[\frac{eQ}{4I(2I-1)\hbar} \right]^2 \\ & \times \{ V_{-1}V_1[24m(m-1) - 4I(I+1) + 9] \\ & + \frac{1}{2}V_{-2}V_2[12m(m-1) - 4I(I+1) + 6] \} \end{aligned} \quad (25)$$

Therefore, the line associated with the transition $(m-1, m)$ is located in the spectrum at

$$\omega_{m-1,m} = \omega_0 + \omega_{m-1,m}^{(1)} + \omega_{m-1,m}^{(2)} \quad (26)$$

In the following two subsections, we apply equation (26) to two experiments, in which the single crystal is either static or is spinning at the magic angle.

5.1 Spectrum of a Static Single Crystal

We have to express V_0 in equation (23), and V_1, V_{-1}, V_2 , and V_{-2} in equation (25) in terms of the components of $\mathbf{V}$ in Σ^{PAS} , equation (11a). For this purpose, the following relationship is used:

$$V_i = \sum_{j=-2}^2 \mathcal{D}_{j,i}^{(2)}(\alpha, \beta, \gamma) V_j^{\text{PAS}} \quad (27)$$

where the Euler angles α, β , and γ describe the direction of the strong static magnetic field in Σ^{PAS} (Figure 1) and $\mathcal{D}_{j,i}^{(2)}(\alpha, \beta, \gamma)$ is the Wigner rotation matrix defined in the appendix. For example,

$$V_0 = \sqrt{\frac{3}{2}} eq \left[\frac{1}{2}(3 \cos^2 \beta - 1) + \frac{1}{2} \eta \sin^2 \beta \cos 2\alpha \right] \quad (28)$$

Its substitution into equation (18) yields

$$H_Q^{[1]} = \frac{1}{3} \omega_Q [3 \hat{I}_z^2 - I(I+1)] \quad (29)$$

with

$$\omega_Q = \frac{3\chi}{4I(2I-1)} \left[\frac{1}{2}(3 \cos^2 \beta - 1) + \frac{1}{2} \eta \sin^2 \beta \cos 2\alpha \right] \quad (30)$$

A negative sign will appear in front of η if the other convention for η , equation (6), is chosen or the Euler angles used by Baugher and co-workers¹³⁻¹⁵ are used. The definitions of $H_Q^{[1]}$ by equation (29) or of ω_Q by equation (30) are not unique.

Figure 1 Euler angles defining the direction of $\mathbf{B}_0$ in the principal axis system Σ^{PAS} of the EFG during a static experiment

Other definitions can be found in the literature. The first-order quadrupolar shift of the lines $(m-1, m)$, equation (23), becomes

$$\omega_{m-1,m}^{(1)\text{static}} = (1-2m)\omega_Q \quad (31)$$

The lines in the spectrum are separated by the same quantity $2\omega_Q$, but the central line is not shifted.

The other two factors V_1V_{-1} and V_2V_{-2} in equation (25) are

$$\begin{aligned} 2V_1V_{-1} = & -\frac{3}{2}e^2q^2 \left[\left(-\frac{1}{3}\eta^2 \cos^2 2\alpha + 2\eta \cos 2\alpha - 3 \right) \cos^4 \beta \right. \\ & + \left(\frac{2}{3}\eta^2 \cos^2 2\alpha - 2\eta \cos 2\alpha - \frac{1}{3}\eta^2 + 3 \right) \cos^2 \beta \\ & \left. + \frac{1}{3}\eta^2 (1 - \cos^2 2\alpha) \right] \end{aligned} \quad (32a)$$

$$\begin{aligned} V_2V_{-2} = & \frac{3}{2}e^2q^2 \left[\left(\frac{1}{24}\eta^2 \cos^2 2\alpha - \frac{1}{4}\eta \cos 2\alpha + \frac{3}{8} \right) \cos^4 \beta \right. \\ & + \left(-\frac{1}{12}\eta^2 \cos^2 2\alpha + \frac{1}{6}\eta^2 - \frac{3}{4} \right) \cos^2 \beta \\ & \left. + \frac{1}{24}\eta^2 \cos^2 2\alpha + \frac{1}{4}\eta \cos 2\alpha + \frac{3}{8} \right] \end{aligned} \quad (32b)$$

The second-order quadrupolar shift of the central line, using equation (25), is given by

$$\begin{aligned} \omega_{-1/2,1/2}^{(2)\text{static}} = & -\frac{1}{6\omega_0} \left[\frac{3\chi}{2I(2I-1)} \right]^2 \left[I(I+1) - \frac{3}{4} \right] \\ & \times [A(\alpha, \eta) \cos^4 \beta + B(\alpha, \eta) \cos^2 \beta + C(\alpha, \eta)] \end{aligned} \quad (33)$$

with

$$\left. \begin{aligned} A(\alpha, \eta) = & -\frac{27}{8} + \frac{9}{4}\eta \cos 2\alpha - \frac{3}{8}(\eta \cos 2\alpha)^2 \\ B(\alpha, \eta) = & \frac{30}{8} - \frac{1}{2}\eta^2 - 2\eta \cos 2\alpha + \frac{3}{4}(\eta \cos 2\alpha)^2 \\ C(\alpha, \eta) = & -\frac{3}{8} + \frac{1}{3}\eta^2 - \frac{1}{4}\eta \cos 2\alpha - \frac{3}{8}(\eta \cos 2\alpha)^2 \end{aligned} \right\} \quad (34)$$

When the EFG has axial symmetry ($\eta = 0$), equation (33) becomes simply

$$\begin{aligned} \omega_{-1/2,1/2}^{(2)\text{static}} = & -\frac{1}{16\omega_0} \left[\frac{3\chi}{2I(2I-1)} \right]^2 \left[I(I+1) - \frac{3}{4} \right] \\ & \times (1 - \cos^2 \beta)(9 \cos^2 \beta - 1) \end{aligned} \quad (35)$$

It is worth noting that the third Euler angle γ does not appear in equations (30), (33), and (34); this is because $\mathbf{B}_0$ is a symmetry axis for the spins. Our results are identical to those of Narita and co-workers²⁷ [note that their paper contains a typographical error concerning the expression of $\cos 2\alpha$ in $C(\alpha, \eta)$]. Subsequently, Baugher and co-workers¹⁵ obtained expressions similar to equation (34), except that their terms containing η have the opposite sign. Their comment 23, concerning the sign in front of all the terms in $\cos 2\alpha$,

Figure 2 Euler angles defining the direction of B_0 in the rotor coordinate frame Σ^{MAS} during a MAS experiment. In Σ^{MAS} , B_0 rotates around the rotor with the angular velocity ω_r ; θ_m is the magic angle; the third angle is $\gamma = 0$

is explained in our appendix using the Euler angles (Figure 10) defined by Goldstein.¹⁴ Another way to obtain the same results as those of Baugher and co-workers¹⁵ is to employ the usual Euler angles (Figure 9) and to replace η by $-\eta$ (the other convention for η). This point is confirmed by Hirshinger and co-workers²⁸ and by Chu and Gerstein.²⁹ Wolf and co-workers³⁰ have determined the third-order perturbation term, and shown that it is proportional to $(2m-1)/\omega_0^2$. Therefore, the position of the central line is not shifted further by this new term.

5.2 Spectrum of a Rotating Single Crystal

First of all, the expressions for V_0 , V_1 , V_{-1} , V_2 , and V_{-2} must be expressed in terms of the components of $\mathbf{V}$ in the coordinate frame Σ^{MAS} of the rotor. To do this, the Wigner rotation matrix is applied once more:

$$V_i = \sum_{j=-2}^2 \mathcal{D}_{j,i}^{(2)}(\omega_r t, \theta_m, 0) V_j^{\text{MAS}} \quad (36)$$

where ω_r is the angular velocity of the rotor and $\theta_m = 54.73^\circ$ is the magic angle (Figure 2). Then, V_j^{MAS} must be expressed in terms of the components of $\mathbf{V}$ in Σ^{PAS} :

$$V_j^{\text{MAS}} = \sum_{k=-2}^2 \mathcal{D}_{k,j}^{(2)}(\alpha, \beta, \gamma) V_k^{\text{PAS}} \quad (37)$$

where the Euler angles α , β , and γ describe the direction of the rotor in Σ^{PAS} (Figure 3).

The first step, equation (36), yields

$$\omega_{m-1,m}^{(1)\text{MAS}} = \sqrt{\frac{2}{3}}(1-2m) \frac{3eQ}{8I(2I-1)\hbar} V_0^{\text{MAS}} (3\cos^2\theta_m - 1) \quad (38)$$

The second step, equation (37), yields the first-order quadrupolar shift:

$$\omega_{m-1,m}^{(1)\text{MAS}} = \frac{1}{2}(1-2m)\omega_Q(3\cos^2\theta_m - 1) \quad (39)$$

This shift is zero when the crystal rotates at the magic angle. In other words, all the energy levels become equally spaced. Therefore, a single line instead of $2I$ lines appears in the spectrum at ω_0 .

Figure 3 Euler angles defining the direction of the rotor in the principal axis system Σ^{PAS} of the EFG during a MAS experiment. In Σ^{PAS} , the rotor containing the sample appears static

For the second-order quadrupolar shift, the first step, equation (36), yields

$$\begin{aligned} \omega_{m-1,m}^{(2)\text{MAS}} = & -\frac{2}{\omega_0} \left[\frac{eQ}{4I(2I-1)\hbar} \right]^2 \\ & \times \left\{ -\frac{1}{6} V_2^{\text{MAS}} V_{-2}^{\text{MAS}} [50m(m-1) - 6I(I+1) + 17] \right. \\ & + \frac{1}{3} V_1^{\text{MAS}} V_{-1}^{\text{MAS}} [8m(m-1) + 2] \\ & \left. - \frac{1}{2} V_0^{\text{MAS}} V_0^{\text{MAS}} [14m(m-1) - 2I(I+1) + 5] \right\} \quad (40) \end{aligned}$$

The second step, equation (37), yields, in the fast rotation regime,¹

$$\begin{aligned} \omega_{m-1,m}^{(2)\text{MAS}} = & -\frac{3}{32\omega_0} \left[\frac{\chi}{I(2I-1)} \right]^2 (1 + \frac{1}{3}\eta^2) \\ & \times [2I(I+1) - 14m(m-1) - 5] \\ & + \frac{3}{128\omega_0} \left[\frac{\chi}{I(2I-1)} \right]^2 \\ & \times [6I(I+1) - 34m(m-1) - 13]g(\alpha, \beta, \eta) \quad (41) \end{aligned}$$

with

$$\begin{aligned} g(\alpha, \beta, \eta) = & \frac{1}{2}(1 + 6\cos^2\beta - 7\cos^4\beta) \\ & + \frac{1}{3}\eta(1 - 8\cos^2\beta + 7\cos^4\beta)\cos 2\alpha \\ & + \frac{1}{18}\eta^2[-7(1 - \cos^2\beta)^2\cos^2 2\alpha + 8 - 4\cos^2\beta] \quad (42) \end{aligned}$$

For the central line, the second-order quadrupolar shift is³¹

$$\begin{aligned} \omega_{-1/2,1/2}^{(2)\text{MAS}} = & -\frac{1}{6\omega_0} \left[\frac{3\chi}{2I(2I-1)} \right]^2 [I(I+1) - \frac{3}{4}] \\ & \times [D(\alpha, \eta)\cos^4\beta + E(\alpha, \eta)\cos^2\beta + F(\alpha, \eta)] \quad (43) \end{aligned}$$

with

$$\left. \begin{aligned} D(\alpha, \eta) &= \frac{21}{16} - \frac{7}{8}\eta\cos 2\alpha + \frac{7}{48}(\eta\cos 2\alpha)^2 \\ E(\alpha, \eta) &= -\frac{9}{8} + \frac{1}{12}\eta^2 + \eta\cos 2\alpha - \frac{7}{24}(\eta\cos 2\alpha)^2 \\ F(\alpha, \eta) &= \frac{5}{16} - \frac{1}{8}\eta\cos 2\alpha + \frac{7}{48}(\eta\cos 2\alpha)^2 \end{aligned} \right\} \quad (44)$$

As in the case of a static sample, the Euler angle γ does not appear in equations (43) and (44). This is because the experimental conditions correspond to the fast rotation regime. However, this angle does appear in the intermediate regime where the angular velocity of the rotor is of the same order of magnitude as the linewidth. As a result, spinning sidebands appear in the spectrum. Samoson and co-workers²³ established

a general expression for $\Omega_{m-1,m}^{(2)\text{MAS}}$ that clearly shows the presence of modulations due to the rotation of the rotor:

$$\Omega_{m-1,m}^{(2)\text{MAS}} = \omega_{m-1,m}^{(2)\text{MAS}} + \sum_{n=1}^4 [A_n \cos(n\omega_r t) + B_n \sin(n\omega_r t)] \quad (45)$$

Two typographical errors appear in the *annexe* of their paper:²³ the expressions for A_1^λ and A_2^λ should be

$$\left. \begin{aligned} A_1^\lambda &= -\frac{1}{2}\sqrt{2} \sin 2\beta^\lambda \rho_{20}^\lambda + \frac{1}{3}\sqrt{3} \cos 2\alpha^\lambda \sin 2\beta^\lambda \rho_{22}^\lambda \\ A_2^\lambda &= \frac{1}{2} \sin^2 \beta^\lambda \rho_{20}^\lambda + \frac{1}{6}\sqrt{6} \cos 2\alpha^\lambda (1 + \cos^2 \beta^\lambda) \rho_{22}^\lambda \end{aligned} \right\} \quad (46)$$

Equation (45) allows us to investigate the spinning sidebands (see *High Speed MAS of Half-Integer Quadrupolar Nuclei in Solids* and *Sideband Analysis in Magic Angle Spinning NMR of Solids*).

6 POWDER SPECTRUM

In most cases, the sample is in powder form, because the growth of single crystals of significant size is not always possible. As a result, only the central line is detected in NMR (see *Fast Ion Conductors, Geological Applications, High Temperature Superconductors, Intercalation Compounds and Molecular Sieves: Crystalline Systems*). However, satellite lines can be detected without spinning the sample if $\chi/2\pi < 300 \text{ kHz}$; for example, for ^{23}Na ($I = \frac{3}{2}$) in NaNO_3 or ^7Li ($I = \frac{3}{2}$) in LiNbO_3 . When the MAS technique is applied, the spinning sidebands of the satellite lines are detected; for example, for iodine ^{127}I ($I = \frac{5}{2}$) in KI or the two isotopes of bromine ($I = \frac{3}{2}$) in KBr . These two compounds are used for setting the magic angle of the MAS probe in the vicinity of ^{29}Si and ^{27}Al frequencies, respectively.

In a powder sample, the principal axes of the EFG associated with each crystallite are randomly oriented with respect to $\mathbf{B}_0$. The transition frequencies are not unique, but depend on the distribution of the Euler angles α and β describing the direction of the rotor in the coordinate frame Σ^{PAS} in a MAS experiment at high spinning rate, or the direction of $\mathbf{B}_0$ in the coordinate frame Σ^{PAS} in an experiment without spinning.

The resonance condition $\omega(\alpha, \cos \beta)$ represents a surface in a three-dimensional space described by the parameters ω , α , and $\cos \beta$. The critical points of this surface define divergences and shoulders in the spectrum. They are roots of the two coupled equations^{12,13}

$$\left. \begin{aligned} \frac{\partial}{\partial \alpha} \omega(\alpha, \cos \beta) \Big|_{\alpha=r, \cos \beta=s} &= 0 \\ \frac{\partial}{\partial \cos \beta} \omega(\alpha, \cos \beta) \Big|_{\alpha=r, \cos \beta=s} &= 0 \end{aligned} \right\} \quad (47)$$

The nature of the critical point (r, s) is related to the sign of the Wronskian determinant D_W :

$$D_W = \left[\left(\frac{\partial^2 \omega}{\partial \alpha \partial \cos \beta} \right)^2 - \left(\frac{\partial^2 \omega}{\partial \alpha^2} \right) \left(\frac{\partial^2 \omega}{\partial^2 \cos \beta} \right) \right]_{\alpha=r, \cos \beta=s} \quad (48)$$

If D_W is positive then the critical point (r, s) represents a divergence; if D_W is negative then the critical point represents a shoulder. Unfortunately, this method does not allow us to determine the lineshape. Therefore, numerical calculations are required.

Figure 4 Critical points¹³ of a satellite powder pattern associated with the transition $(m-1, m)$; $b = 3\chi(1-2m)/8I(2I-1)$

6.1 Powder Pattern for a Pair of Satellite Lines

For static samples,²⁷ numerical calculations are based on the summation of signals for the direction of each crystallite. The two Euler angles are redefined by $\alpha = 2\pi p/300$ and $\cos \beta = p/300$, where $p = 0, \dots, 300$. For each value of η , the summation is performed on

$$\omega_{m-1,m}^{(1)\text{static}} \Big/ \frac{3\chi(1-2m)}{8I(2I-1)} = 3 \cos^2 \beta - 1 + \eta \sin^2 \beta \cos 2\alpha \quad (49)$$

A satellite lineshape is shown in Figure 4. The positions of the shoulder and divergence¹³ are derived from equations (47) and (48). The powder pattern of a pair of satellite lines for several values of η is plotted in Figure 5.

Figure 5 Simulated powder pattern of a pair of satellite lines for increasing values of the asymmetry parameter η from 0 to 1 in steps of 0.1

Figure 6 Critical points determined by Stauss.³² They are associated with the powder pattern of the central line in a static experiment;

$$a = -\frac{1}{6\omega_0} \left[\frac{3\chi}{2I(2I-1)} \right]^2 \left[I(I+1) - \frac{3}{4} \right]$$

6.2 Powder Pattern for the Central Line

The critical points in the powder pattern of the central line have been determined for the two experiments. For a static sample, they have been determined by Stauss.³² Two patterns (Figure 6) appear according to the value of η compared with $\frac{1}{3}$; for example, for ^{39}K in inorganic potassium salts³³ or ^{139}La in lanthanum salts.³⁴ It is worth noting that these critical points depend neither on the convention for η nor on the choice of Euler angles: changing η to $-\eta$ yields the same set of critical points. For a rotating sample, these points have been determined by Müller.³¹ As previously, two powder patterns (Figure 7) appear, depending on the value of η compared with $\frac{3}{7}$. These patterns are clearly observed in ^{27}Al compounds.³⁵

The powder pattern of the central line is obtained as in the previous case using equation (33) for a static sample or equation (43) for a rapidly rotating sample. To facilitate the comparison, the two sets of spectra are superposed as shown in Figure 8. We can see that the linewidth is reduced by a factor ranging from 2 to 4, depending on the value of η when a MAS experiment is performed (see **Line Narrowing Methods in Solids**). From a practical point of view, the asymmetry parameter of an experimental spectrum can be estimated by comparing the lineshape with those in Figure 8. Then the quadrupolar coupling constant can be calculated using the positions of the experimental critical points and those represented in Figures 6 and 7. Other simple procedures are also defined for extracting quadrupolar parameters from the spectra of static³⁶ or rotating³⁷ samples.

The second-order quadrupolar shift of the center of gravity $\omega_{\text{iso}}(m = 1, m)$ of the powder pattern is determined as

Table 2 Wigner Rotation Matrix $\mathcal{D}_{p,q}^{(2)}(\alpha, \beta, \gamma)$, Identical to That Used by Spiess,²⁰ Mehring,²¹ and Doane,³⁸ but the Transposed and Complex Conjugate of That Used by Haeblerlen,¹⁹ Equal to $\mathcal{D}_{p,q}^{(2)}(-\alpha, -\beta, -\gamma)$ Used by Freude and Haase⁹

p	q	-2	-1	0	1	2
2		$\frac{1}{4}(1 + \cos \beta)^2 e^{-2i(\alpha+\gamma)}$	$-\frac{1}{2}(1 + \cos \beta) \sin \beta e^{-i(2\alpha+\gamma)}$	$\frac{3}{8} \sin^2 \beta e^{-2i\alpha}$	$-\frac{1}{2}(1 + \cos \beta) \sin \beta e^{-i(\alpha+\gamma)}$	$\frac{1}{4}(1 + \cos \beta)^2 e^{-2i(\alpha+\gamma)}$
1		$\frac{1}{2}(1 + \cos \beta) \sin \beta e^{-i(\alpha+2\gamma)}$	$[\cos^2 \beta - \frac{1}{2}(1 - \cos \beta)] e^{-i(\alpha+\gamma)}$	$-\frac{3}{8} \sin^2 \beta e^{-i\alpha}$	$[\cos^2 \beta - \frac{1}{2}(1 - \cos \beta)] e^{-i(\alpha+\gamma)}$	$-\frac{1}{2}(1 + \cos \beta) \sin \beta e^{-i(\alpha-2\gamma)}$
0		$\frac{3}{8} \sin^2 \beta e^{-2i\gamma}$	$-\frac{3}{8} \sin^2 \beta e^{i\gamma}$	$\frac{1}{2}(3 \cos^2 \beta - 1)$	$\frac{3}{8} \sin^2 \beta e^{i\gamma}$	$\frac{3}{8} \sin^2 \beta e^{2i\gamma}$
-1		$\frac{1}{2}(1 - \cos \beta) \sin \beta e^{i(\alpha-2\gamma)}$	$[\cos^2 \beta - \frac{1}{2}(1 + \cos \beta)] e^{i(\alpha+\gamma)}$	$\frac{3}{8} \sin^2 \beta e^{i\alpha}$	$[\cos^2 \beta - \frac{1}{2}(1 + \cos \beta)] e^{i(\alpha+\gamma)}$	$-\frac{1}{2}(1 - \cos \beta) \sin \beta e^{i(\alpha+2\gamma)}$
-2		$\frac{1}{4}(1 - \cos \beta)^2 e^{2i(\alpha+\gamma)}$	$-\frac{1}{2}(1 - \cos \beta) \sin \beta e^{i(2\alpha+\gamma)}$	$\frac{3}{8} \sin^2 \beta e^{2i\alpha}$	$-\frac{1}{2}(1 - \cos \beta) \sin \beta e^{i(\alpha+\gamma)}$	$\frac{1}{4}(1 - \cos \beta)^2 e^{2i(\alpha+\gamma)}$

Figure 7 Corrected critical points^{9,11} determined by Müller.³¹ They are associated with the powder pattern of the central line in a MAS experiment;

$$a = -\frac{1}{6\omega_0} \left[\frac{3\chi}{2I(2I-1)} \right]^2 \left[I(I+1) - \frac{3}{4} \right]$$

follows:¹

$$\begin{aligned} \omega_{\text{iso}}(m-1, m) &= \frac{1}{4\pi} \int_0^\pi d\beta \sin \beta \int_0^{2\pi} d\alpha \omega_{m-1, m}^{(2)\text{MAS}} \\ &= -\frac{3}{40\omega_0} \left[\frac{\chi}{I(2I-1)} \right]^2 \left(1 + \frac{1}{3}\eta^2 \right) \\ &\quad \times [I(I+1) - 9m(m-1) - 3] \end{aligned} \quad (50)$$

From a practical point of view, the experimental chemical shift of the center of gravity associated with the transition $(m-1, m)$, $\delta_{\text{CG}}^{\text{exp}}(m-1, m)$, consists of two terms: the true chemical shift $\delta_{\text{CS}}(m-1, m)$ and the contribution from the second-order quadrupolar shift $\omega_{\text{iso}}(m-1, m)/\omega_0$. Thus,

$$\delta_{\text{CS}}(m-1, m) = \delta_{\text{CG}}^{\text{exp}}(m-1, m) - \omega_{\text{iso}}(m-1, m)/\omega_0 \quad (51)$$

For the central line, equation (51) becomes equation (1).

7 APPENDIX

The Euler angles are extensively used in the study of the quadrupolar interaction, especially in MAS, VAS, DAS, and DOR. They are defined as three successive positive angles of rotation for the coordinate frame (c.f.) as described in Figure 9. First [(Figure 9a)], the starting c.f. (x, y, z) , called the old c.f., in which we know the components V_k^{OLD} of the

Figure 8 Superposition of simulated powder patterns of the central line during static and MAS (shaded spectra) experiments for increasing values of the asymmetry parameter η from 0 to 1 in steps of 0.1

spherical tensor $\mathbf{V}$, is rotated counterclockwise around the z axis by an angle α . This rotation generates a new c.f. (X, Y, z) . Then [(Figure 9b)] the counterclockwise rotation of this intermediate c.f. around the Y axis by an angle β generates a second intermediate c.f. (X', Y, z') . Finally [(Figure 9c)], this second intermediate c.f. is rotated counterclockwise by an angle γ around the z' axis, resulting in a c.f. (x', y', z') , called the new c.f., in which we wish to know the components V_j^{NEW} of the spherical tensor $\mathbf{V}$. It is worth noting that, in this definition of the Euler angles, β and α also represent the polar angles of the z' axis in the old coordinate frame.

As explained by Spiess,²⁰ the mathematical tool for expressing the components of the same spherical tensor $\mathbf{V}$ in two different coordinate frames, where the new c.f. is obtained by three positive angles of rotation (α, β, γ) of the old one, is the Wigner rotation matrix $\mathcal{D}_{p,q}^{(2)}(\alpha, \beta, \gamma)$ reported in Table 2. This matrix relates the components V_j^{NEW} of the spherical tensor in the new c.f. to the known components V_k^{OLD} of the same tensor in the old one by the relationships^{20,21,38,39}

$$V_j^{\text{NEW}} = \sum_{k=-2}^2 \mathcal{D}_{k,j}^{(2)}(\alpha, \beta, \gamma) V_k^{\text{OLD}} \quad (52)$$

with the summation over the first subscript.

Figure 10 shows the Euler angles used by Baugher and co-workers.^{13,15} First [(Figure 10a)], as in the previous definition,

Figure 9 Euler angles defining positive rotation of the coordinate frame (x, y, z) . They are used by Narita and co-workers,²⁷ Spiess,²⁰ Doane,³⁸ and Freude and Haase.⁹ The angles β and α are the polar angles of the z' axis in (x, y, z)

the old c.f. (x, y, z) is rotated counterclockwise by an angle ϕ around the z axis, generating an intermediate c.f. (X, Y, z) . Then [(Figure 10b)] this intermediate c.f. is rotated counterclockwise, this time around the X axis, by an angle θ , generating a second intermediate c.f. (X, Y', z') . Finally [(Figure 10c)], a counterclockwise rotation of this second intermediate c.f. around the z' axis by an angle ψ produces the new c.f. (x', y', z') . In contrast to the previous definition, θ and ϕ are not the polar angles of the z' axis in the old coordinate frame. In Figure 9, α is the angle relating the y axis and the line of nodes Y , whereas in Figure 10, ϕ is the angle relating the x axis and the line of nodes X . These two angles are related by $\alpha + \frac{1}{2}\pi = \phi$. In other words, $\alpha + \frac{1}{2}\pi$ and ϕ correspond to the angle connecting the x axis with the line of nodes. As a result, $\cos 2\phi = -\cos 2\alpha$. This explains the change of sign for the terms containing η in equations (30) and (34), as in the paper of Baugher and co-workers.¹⁵

1 INTRODUCTION

The first use of nuclear magnetic resonance (NMR) to study glass structure using nuclei having electric quadrupole moments was reported by Silver and Bray in 1958.¹ In that work, the interaction between the nuclear electrical quadrupole moment (possessed by all nuclei having a spin $I > \frac{1}{2}$) and the electric field gradient at the nuclear site is small in comparison with the Zeeman interaction of the nuclear magnetic dipole moment with an externally applied magnetic field. The energy levels and transition frequencies can be calculated² using the quadrupolar interaction as a perturbation of the Zeeman interaction.

It is this case that is discussed and illustrated with specific examples in the following section. Extensive studies of this type have been summarized and referenced in a number of reviews of NMR studies of glasses.^{3–7} (Note that the review by Eckert³ contains, on p. 163, a table of 39 earlier reviews, listing their main topics.) Succeeding sections of this article contain discussions of the cases in which the magnetic field is absent [i.e., pure nuclear quadrupole resonance (NQR) studies], and cases in which the Zeeman interaction is present but sufficiently small to be treated as a perturbation of the quadrupolar interaction.

There will necessarily be some overlap between the material presented in this article and in other portions of the Encyclopedia. Cross references to pertinent subjects are given at the end of the article.

2 NMR WITH A QUADRUPOLEAR PERTURBATION

Figure 1 displays the energy levels for the case of the pure Zeeman interaction (i.e. no quadrupolar interaction present), and the shifting of those levels when a relatively small quadrupolar interaction is present. The shifts depend on the coupling of the nuclear electrical quadrupole moment eQ with the components of the electric field gradient (EFG) tensor at the nuclear site. These are V_{xx} , V_{yy} , and V_{zz} in the system of principal axes for the EFG. Here V is the electrical potential at the nuclear site arising from charges outside the nucleus, and $V_{xx} = \partial^2 V / \partial x^2$, etc. The shifts also depend on the angles θ

Figure 1 Energy levels arising from the interaction of the nuclear magnetic dipole moment with a magnetic field: (a) no electrical quadrupolar interaction; (b) small quadrupolar interaction present (the levels shown are appropriate for the ^{11}B nucleus)

and ϕ that specify the orientation of the magnetic field $\mathbf{B}$ with respect to the principal axes of the EFG. Since all angles θ and ϕ are equally probable in a finely divided polycrystalline powder or a glass, the NMR spectra for those cases will be the envelope of responses observed for a single crystal as it is placed in all possible orientations in the magnetic field. The resulting theoretical ‘powder pattern’ for a quadrupolar interaction that is sufficiently small to be treated with first-order perturbation theory is displayed in Figure 2 for the case of a nuclear spin $I = \frac{3}{2}$. (No dipolar or other broadening mechanisms have been taken into account.) Here $\chi = e^2 q Q = e^2 V_{zz} Q$ is the quadrupole coupling constant that measures the strength of the quadrupolar interaction, and $\eta = (V_{xx} - V_{yy})/V_{zz}$ is the asymmetry parameter that measures the departure of the EFG from axial symmetry. (With $|V_{zz}| \geq |V_{yy}| \geq |V_{xx}|$, one finds that $0 \leq \eta \leq 1$.) Note that the ‘central’ transition ($m = +\frac{1}{2} \leftrightarrow -\frac{1}{2}$) is unaffected at first-order, and remains at the Larmor frequency ν_0 , while the ‘satellite’ transitions ($m = +\frac{3}{2} \leftrightarrow +\frac{1}{2}$ and $m = -\frac{3}{2} \leftrightarrow -\frac{1}{2}$) are spread out into the ‘powder patterns’.

Broadening mechanisms (e.g., dipolar interactions, and distributions in the EFG components) smooth the divergences in the theoretical powder pattern, and give breadth to the central transition peak. This is exemplified in Figure 3 for the particular case of $\eta = 0$. When use is made of older

Figure 2 First-order quadrupolar spectrum for $I = \frac{3}{2}$ nuclei in a powder or glass. Here $\nu_Q = 3\chi/2I(2I - 1)$

Figure 3 Resonance lineshape (solid curve) predicted for a nucleus such as ^{11}B with a small quadrupolar interaction in a glass or polycrystalline powder. This is the $\eta = 0$ case

CW NMR spectrometers, the recorded resonance is usually the first derivative of the absorption curve. This is displayed in Figure 4 for the ^{11}B ($I = \frac{3}{2}$) response in polycrystalline boron phosphate (BPO_4), for which the value of $\chi = 50.4 \text{ kHz}$ if η is assumed to be zero.⁸ (The boron atom is at the center of a BO_4 tetrahedron that is only slightly distorted, so the components of the EFG are quite small. The EFG vanishes for perfect tetrahedral and octahedral symmetry.)

Figure 5 displays⁹ the derivative response for ^7Li ($I = \frac{3}{2}$) in a glass containing 25 mol% Li_2O and 75 mol% B_2O_3 . If $\eta = 0$ then $\chi \approx 185 \text{ kHz}$. (The electrical quadrupole moment Q for ^7Li is relatively small.) The partial ‘smearing’ of the divergences in the powder pattern arises from the distribution in the EFG components caused by the disorder of the vitreous state. See Krämer et al.¹⁰ for other examples of ^7Li NMR spectra for glasses.

When the quadrupolar interaction is larger (but still treatable as a perturbation of the Zeeman interaction), the central ($m = \frac{1}{2} \leftrightarrow -\frac{1}{2}$) transition is affected at second order. Figure 6 displays the theoretical pattern for this case, both for $\eta < \frac{1}{3}$ and $\eta > \frac{1}{3}$. The particular case of small or zero η is illustrated in Figure 7

Figure 4 ^{11}B NMR spectrum in boron phosphate (BPO_4); $\nu_0 = 7.177 \text{ MHz}$

Figure 5 ^7Li NMR spectrum of glass of composition $\text{Li}_2\text{O} \cdot 3\text{B}_2\text{O}_3$

where the dashed lines indicate the theoretical pattern without broadening and the solid line indicates the expected lineshape when broadening is included.

This transition^{11a} for ^{11}B in vitreous boron oxide (B_2O_3) is displayed in Figure 8. In this case, in which all of the boron atoms are at the center of planar triangles of oxygens (i.e., BO_3 units) and all of the oxygens are bridging (i.e., bonded to two borons), one finds $\chi = 2.76 \text{ MHz}$ and $\eta = 0.10$. The departure from perfect trigonal symmetry about the axis perpendicular to the BO_3 units and passing through the boron is small or moderate. One finds for such BO_3 units

Figure 6 Powder patterns for the central transition ($m = -\frac{1}{2} \leftrightarrow m = +\frac{1}{2}$) of half-integer spin nuclei in the presence of second-order quadrupolar interactions for two regimes: $\eta < \frac{1}{3}$ and $\eta > \frac{1}{3}$. Here $\nu_Q = 3\chi/2I(2I - 1)$ and ν_0 is the Larmor frequency

Figure 7 Resonance lineshape (solid curve) for a nucleus with a large quadrupole interaction in a glass or polycrystalline powder. This is the $\eta = 0$ case

that $2.4 \text{ MHz} \leq \chi \leq 2.9 \text{ MHz}$ and $0 \leq \eta \leq 0.2$. (In the case of vitreous B_2O_3 , the BO_3 units are portions of the boroxol structural groupings depicted in Figure 9, but they occur also in other borate structural groupings shown there.)

In alkali borate compounds of 50 mol% or more of alkali oxide, one finds BO_3 units that have one or more nonbridging oxygens (NBO) (i.e., the oxygen is bonded to only one boron and is negatively charged). If the BO_3 unit has one or two of these, the trigonal symmetry noted above is lost, and the asymmetry parameter has been found from NMR spectra to rise into the range $0.4 \leq \eta \leq 0.9$. An example is calcium metaborate ($\text{CaO} \cdot \text{B}_2\text{O}_3$), whose chain structure is depicted in Figure 9. The NMR spectrum^{11a} of this material is displayed in Figure 10. These asymmetric BO_3 units, and the BO_4 and symmetric BO_3 units, are all present in many borate glasses. Responses from all three units are present in the ^{11}B NMR spectrum^{11a} displayed in Figure 11, where the narrow structureless line from BO_4 units is off scale and the symmetric BO_3 units give rise to the middle positive peak on the left and part of one of the negative peaks on the right. The fraction of each type of unit present in the glass can be obtained from the intensity of the corresponding NMR responses, as illustrated in Figure 12 for a low-alkali glass where N_4 is the fraction of four-coordinated borons (i.e. in BO_4 tetrahedra). Figure 13 displays N_4 as a function of the molar fraction x of alkali

Figure 8 ^{11}B NMR spectrum of vitreous B_2O_3 at 16 MHz ^{11b}

Figure 9 Structural groupings found in alkali borate compounds and glasses

oxide in alkali borate glasses.¹² With the composition $x\text{Na}_2\text{O}(1-x)\text{B}_2\text{O}_3$, N_4 is $x/(1-x)$ if each oxygen added as Na_2O converts two borons from three- to four-coordination.

Kirkpatrick and Oldfield and co-workers¹³ have demonstrated that the ^{11}B NMR responses from BO_3 and BO_4 configurations can be separated using magic angle sample spinning (MAS) with high spinning speeds at high magnetic fields. Figure 14 displays the BO_3 and BO_4 responses for polycrystalline $\text{Li}_2\text{O} \cdot 2\text{B}_2\text{O}_3$ and Pyrex glass. (For the Pyrex glass, they conclude that two BO_3 and two BO_4 sites are present. χ for the BO_3 units can be determined to perhaps two significant figures if η is assumed to be zero.)

Quadrupolar effects, then, clearly identify the various boron-oxygen bonding configurations in glasses. That information makes possible the development and validation of structural models for binary,¹⁴ ternary,¹⁵ and more complex glasses containing boron oxide.

Figure 10 (a) Theoretical powder pattern for the transition ($m = +\frac{1}{2} \leftrightarrow m = -\frac{1}{2}$), with $I = \frac{3}{2}$, $\nu_0 = 16 \text{ MHz}$, $\chi = 2.56 \text{ MHz}$, and $\eta = 0.54$. (b) First derivative of the theoretical powder pattern after convolution with a Gaussian curve of linewidth $2\sigma = 5 \text{ kHz}$. (c) Superposition of four experimental traces for ^{11}B in polycrystalline calcium metaborate, at a resonant frequency of 16 MHz ^{11b}

Figure 11 ^{11}B NMR spectrum of (a) a BO_4 unit, (b) a BO_3 unit, (c) a BO_3^- unit (with one NBO), and (d) a sample containing all three units^{11b}

Müller-Warmuth and colleagues¹⁶ have improved the resolution and accuracy, and obtained values of χ for the BO_4 units, using very high speed (e.g. 15 kHz) spinning rates and satellite transition spectroscopy (SATRAS). Very short excitation pulses (e.g., 0.5 μs) are used to excite large spectral ranges. Figure 15 displays ^{11}B spectra for a glass of composition (mol%) 33 Li_2O –67 B_2O_3 . Values of χ can be determined from the extent of the spinning sidebands or locations of the centers of gravity of the central and satellite transitions, and (for BO_3) computer simulation of the central transition line-shape as narrowed by the MAS procedure.¹⁷ For the glass of Figure 15, the values of quadrupolar parameters found are 2.6 MHz and 0.3 for BO_3 , and 0.80 MHz for BO_4 . (The isotropic chemical shifts for BO_3 and BO_4 can also be determined.)

^{27}Al NMR has been extensively employed to study glass structure. Static NMR investigations have generally revealed only structureless, but asymmetric, lines. But utilization of MAS MMR spectroscopy by D. Müller,¹⁸ Samoson and Lippmaa,¹⁹ Kirkpatrick,²⁰ and Dupree²¹ and their colleagues has yielded separation of Al responses from different sites in glasses due to different chemical shifts (and quadrupolar parameters). Kirkpatrick and co-workers²⁰ clearly identified four-, five-, and six-coordinated aluminum sites in SiO_2 – Al_2O_3 glasses. Those studies have generally been focused on the chemical shifts, but Müller-Warmuth

Figure 12 Method for determining N_4 in a ^{11}B NMR spectrum. The experimental spectrum at the top is the first derivative of the absorption curve

The frequency of rotation is 15 kHz (see van Wüllen and Müller-Warmuth¹⁶)

and associates²² have used the high-field, high-spinning-rate SATRAS procedure to obtain both the isotropic chemical shifts and the values of χ for a number of ternary glasses. The value of η was not determined, and χ values are therefore limited to an accuracy of about 14%.

Oxygen bonding in vitreous SiO_2 ²³ and B_2O_3 ²⁴ has been studied using samples substantially enriched in the ^{17}O ($I = \frac{5}{2}$) isotope from the natural abundance of 0.037%. The ^{17}O spectrum in SiO_2 was simulated by only one oxygen site using the parameters $\chi = 5.17$ MHz and $\eta = 0.2$. Changing the value of η or the width of the distributions in χ and η by as much as 30% still yielded an acceptable fit to the experimental spectrum, but the central value (5.17 MHz) of χ could be changed by only 1%. These results can be related to a distribution in the Si–O–Si bond angle between 130° and 180° , which is consistent with an earlier X-ray investigation of SiO_2 glass.

The ^{17}O NMR spectrum for vitreous B_2O_3 , shown in Figure 16, required a two-site fit. Quadrupolar parameters for the two sites are $\chi = 4.69$ MHz, $\eta = 0.58$ and 5.75 MHz, 0.40 . The first site has only small distributions in χ and η , and is assigned to an oxygen in the boroxol ring (see Figure 9). The second site also has a small distribution of χ but a broad distribution in η , and arises from the oxygens connecting boroxol rings. About 83% of the borons in the glass are in boroxol rings. Kirkpatrick and co-workers²⁵ have extended ^{17}O NMR studies to high fields, and have succeeded in assigning features of the quadrupolar induced structure

Figure 16 Two superimposed ^{17}O spectra from B_2O_3 glass and a computer simulation using the quadrupolar parameters given in the text

to oxygens in various bonding arrangements (e.g., Si–O–Si, Na–O–Si, and B–O–B).

Segel and Creel²⁶ prepared vitreous potassium metavanadate and found that the ^{51}V NMR response is the typical ($m = +\frac{1}{2} \leftrightarrow -\frac{1}{2}$) transition displaying second-order quadrupolar effects. The quadrupolar parameters at 300 K are approximately 3.35 MHz and 0.47. These values are in line with those for the crystalline metavanadates,^{26,27} in which each vanadium is enclosed in a tetrahedron of oxygens. In vanadium phosphate glasses²⁸ and crystalline V_2O_5 ,²⁹ in which the vanadiums are five-coordinated to oxygens in VO_5 units, the values of χ are found by NMR to be lower. The value²⁹ in crystalline V_2O_5 is 805 kHz (with $\eta = 0.04$), and rough estimates of χ for the vanadium phosphate glasses are in the 1.0–1.5 MHz range.²⁸

The reader is directed to the review by Eckert³ for summaries of, and references for, similar works on boron-doped amorphous silicon, boron in metal–metalloid glasses, gallium and arsenic studies of GaAs and GaP amorphous semiconductors, deuteron studies of ‘water’ in glasses, glasses based on B_2S_3 , B_2Se_3 , Ga_2O_3 , and BeF_2 , glasses containing Na_2O and Cs_2O , and other quadrupolar nuclei in glasses.

3 PURE NUCLEAR QUADRUPOLE RESONANCE (NQR) STUDIES

Since the quadrupolar interaction generates a set of energy levels in the absence of a magnetic field, transitions between these levels will yield resonance spectra if the spectrometers employed are sufficiently sensitive in the relevant frequency regions. These zero field NMR studies are labeled pure nuclear quadrupole resonance (NQR) spectroscopy.

Pure NQR spectra in solids were first detected by Dehmelt and Kruger in 1950.³⁰ A large body of NQR studies of chemical bonding and atomic arrangements in crystalline solids, using quadrupolar nuclei, has followed from that discovery and continues to expand (see, e.g., the summaries by Lucken,³¹ Schempp and Bray,³² Semin et al.,³³ and Rubenstein and Taylor^{34,35}). The following sections summarize the application of NQR to glass studies employing particular nuclei.

3.1 ^{75}As NQR

The first detection of NQR in a glass was reported by Rubenstein and Taylor in 1972³⁴ and extended by Taylor and colleagues.^{35,36} Rubenstein and Taylor³⁴ employed the spin $I = \frac{3}{2}$ nucleus ^{75}As in vitreous arsenic trisulfide (As_2S_3). The extended studies^{35,36} also encompassed vitreous arsenic telluride and elemental arsenic.

The Hamiltonian for the pure quadrupolar interaction is³⁷

$$\hat{\mathcal{H}} = \frac{\chi}{4I(2I-1)}[3\hat{I}_z^2 - I(I+1) + \frac{1}{2}\eta(\hat{I}_+^2 + \hat{I}_-^2)] \quad (1)$$

where $\hat{I}_\pm = \hat{I}_x \pm i\hat{I}_y$. When $I = \frac{3}{2}$, the secular equation (with E in units of $\frac{1}{4}\chi$) is

$$E^2 - (1 + \frac{1}{3}\eta^2) = 0 \quad (2)$$

and the frequency ν_0 of the single allowed transition between the $m = \pm\frac{3}{2}$ and $m = \pm\frac{1}{2}$ states, both of which are degenerate in the absence of a magnetic field, is

$$\nu_0 = \frac{1}{2}\chi\sqrt{1 + \frac{1}{3}\eta^2} \quad (3)$$

(Clearly, the values of χ and η cannot be independently extracted from this one transition. Methods to determine η , and thus χ , independently are discussed later in this article.)

The transition at frequency ν_0 given in equation (3) was observed by Rubenstein and Taylor³⁴ for crystalline (orpiment) and vitreous As_2S_3 at 4.2 K using a variable frequency pulsed NQR/NMR spectrometer and observing the frequency dependence of the spin echo amplitude. Figure 17 displays the data points and fitted Gaussian curve for the glass; the two narrower lines in the 70–73 MHz region are data for crystalline As_2S_3 . The latter resonances occur at 70.38 and 72.86 MHz with respective halfwidths at half-maximum amplitude (HWHM) of 87 and 44 kHz. (There are two inequivalent As sites in the known structure of orpiment.)

Figure 17 ^{75}As NQR in glassy and crystalline As_2S_3 at 4.2 K. The solid circles are experimental points for the glass through which a Gaussian curve has been drawn. The two narrow lines are data for crystalline As_2S_3 (see Rubenstein and Taylor³⁴)

But the glass yields only one very broad response centered at 71.6 MHz and having an HWHM of 3.5 MHz.

Orpiment has a layer structure in which each As atom is bonded to three S atoms in a triangular pyramidal arrangement with an As atom at the apex and three S atoms at the base. Rubenstein and Taylor³⁴ assumed that the large breadth of the lineshape in the As_2S_3 glasses arises from a distribution of distortions in the apex angles α . Since a difference of 1.3° between the α values for the two sites in orpiment produces a difference of 3.48 MHz between the NQR responses, a distribution of apex bonding angles α with a halfwidth of 2° will produce a distribution of frequencies with the observed halfwidth of 3.5 MHz for the glass. (The analysis assumes that the sites present in orpiment, and yielding the observed NQR frequencies, are present in the As_2S_3 glass. This has been placed in question by the work of Szeftel and Alloul that is discussed later in this article.)

In a later study, Rubenstein and Taylor³⁵ detected and analyzed the pure NQR spectra for crystalline and vitreous As_2Se_3 and obtained a better-resolved spectrum for vitreous As_2S_3 . They also measured the spin–lattice relaxation time T_1 at various temperatures. From the near equality of the As_2S_3 crystalline and amorphous initial relaxation behavior, they concluded that the near-neighbor environments of As atoms in the crystal and the glass are quite similar (i.e., the two sites in orpiment, and two-dimensional correlations between As_2S_3 pyramidal units in the layer-structured crystalline phase, are retained in the glass).

Application of a small magnetic field at a series of orientations of an orpiment single crystal yielded data that, based on calculations by Bersohn³⁷ and Dean,³⁸ yielded values of the asymmetry parameter for the two sites in the crystal that Rubenstein and Taylor concluded are also present in the glass. This case of a Zeeman perturbation of an NQR spectrum is discussed in the next section. The values of η for the two sites are 0.343 and 0.374.

Jellison, Petersen, and Taylor³⁶ reported in 1980 an NQR study of amorphous, orthorhombic, and rhombohedral arsenic. Figure 18 displays the highly asymmetric response for the arsenic glass, and the much narrower line for orthorhombic arsenic. Jellison et al. found that the asymmetric pattern obtained for the glass could be reproduced in a calculation by varying the dihedral angle using distributions in the angle

Figure 18 NQR absorption in amorphous As (circles and solid line) and orthorhombic As (dashed line) at 4.2 K (see Jellison et al.³⁶)

suggested in the literature. (The dihedral angle is the angle of rotation along the As–As bond required to bring the pair into an eclipsed position.) The temperature dependence of the NQR frequencies for the crystalline forms of arsenic were obtained, and could be well fitted by the customary Bayer model,³⁹ but the NQR lineshape for the arsenic glass is too broad for observation of shifts in the peak frequency with temperature.

In more recent studies,⁴⁰ Taylor and colleagues have used ⁷⁵As NQR and ⁶³Cu NMR spectroscopy to study chalcogenide glasses in the systems Cu–As–S and Cu–As–Se.

3.2 ¹¹B and ¹⁰B NQR

The NQR resonance frequencies, predicted from the quadrupolar effects observed in NMR studies, for many other quadrupolar nuclei in glasses (e.g., ⁷Li, ¹⁰B, ¹¹B, ¹⁴N, ¹⁷O, ²³Na, ²⁷Al, ³⁹K, and ⁵¹V) lie below 10 MHz and even below 1 MHz. Sufficient signal-to-noise (S/N) values for detection of those responses can be very difficult to achieve. However, a modified Robinson circuit,⁴¹ placing the entire inductive-capacitive tank circuit at 77 K and utilizing state-of-the-art solid state components and Zeeman modulation, has achieved high S/N at low frequencies. Figure 19 from Gravina and Bray,⁴² displays the ¹¹B NQR spectrum for crystalline boron oxide (B₂O₃). (¹¹B has spin $I = \frac{3}{2}$, and equation (3) predicts the NQR frequency.) A S/N value between 100 and 200 is easily obtained at this frequency of 1.358 MHz. Figure 20 displays a vertically expanded version of Figure 19 in which the highest frequency of 13 allowed ¹⁰B transitions is seen in full detail. (¹⁰B is 18.8% and ¹¹B 81.2% abundant in nature.)

In light of the extreme width of the ⁷⁵As NQR spectra in amorphous As and vitreous As₂S₃ and As₂Se₃, one might anticipate failure in seeking the ¹¹B NQR spectrum in borate glasses near 1.35 MHz. But, if those widths of some megahertz are caused by distributions in the EFG components, they will scale with the resonance frequency. Figure 21 displays the ¹¹B NQR spectrum for vitreous B₂O₃. The full width at half-maximum (FWHM) is 21 kHz. This is only a moderate increase in width from the FWHM of 15 kHz, arising from

Figure 19 Boron NQR spectrum of crystalline B₂O₃

Figure 20 The features of Figure 19 displayed with a greatly expanded vertical scale

Figure 21 ¹¹B responses from vitreous B₂O₃

dipolar broadening, in crystalline B₂O₃. The larger response in Figure 21 must arise from borons in the boroxol groups that predominate²⁴ in the glass (see Figure 9). The site for the borons yielding the lower-frequency response in Figure 21 has not yet been identified.

Some work has been completed in ¹¹B NQR studies of structural arrangements and chemical bondings in alkali borate glasses. According to the model proposed by Krogh-Moe⁴³ and supported (but not proved) by the ¹¹B and ¹⁰B NMR studies of Bray and co-workers,⁴⁴ those glasses should be composed of mixtures of the structural groupings presented in Figure 9. As an indication of the sensitivity of the ¹¹B NQR resonance frequency to the particular structural grouping in which the BO₃ or BO₄ units are located, it is instructive to study Figure 22. The sample under study was prepared as polycrystalline sodium tetraborate (Na₂O·4B₂O₃), but X-ray diffraction showed the material to be a mixture of sodium borate compounds. ¹¹B NQR responses from at least six sites are resolved in the spectrum displayed in Figure 22, and they span a range of some 150 kHz. There is hope, then, of identifying the particular structural groupings present in any

Figure 22 ^{11}B responses from a polycrystalline sample having the sodium tetraborate composition ($\text{Na}_2\text{O}\cdot 4\text{B}_2\text{O}_3$)

borate glass, and even gaining a measure of the amount of each grouping present.

An example of the degree of correspondence between the ^{11}B NQR spectra for crystal and glass is displayed in Figure 23. The spectrum in (a) is for polycrystalline sodium diborate ($\text{Na}_2\text{O}\cdot 2\text{B}_2\text{O}_3$), and the spectrum for the glass is in (b). The crystal is known from X-ray diffraction studies to consist of sodium ions and diborate groupings (see Figure 9). Figure 24 shows the ^{11}B NQR spectrum for a glass of molar composition $0.15\text{Na}_2\text{O}-0.85\text{B}_2\text{O}_3$, with the spectrum for vitreous B_2O_3 superposed. It is clear that there are at least three different structural groupings present in the sodium borate glass, and that one of them is probably the boroxol unit found in vitreous B_2O_3 . On the basis that the structural groupings from the crystalline compounds nearest in composition to the glass should predominate, the other responses may arise from the tetraborate group or the pentaborate and triborate groups that can join to form the tetraborate structural grouping (see Figure 9).

3.3 ^{27}Al NQR

The Robinson-type CW spectrometer has been used successfully⁴⁵ to detect ^{27}Al NQR spectra in polycrystalline powders and glasses at relatively low frequencies. ^{27}Al has spin $I = \frac{5}{2}$, and the secular equation for the energy values E (with E in units of $\frac{1}{20}\chi$) is

$$E^3 - 7(3 + \eta^2)E - 20(1 - \eta^2) = 0 \quad (4)$$

Numerical solution via a computer program yields the values of E and the transition frequencies for any set of values of χ and η .

Figure 25 displays the two NQR responses for ^{27}Al in a glass of composition (mol%) of $16.8\text{Al}_2\text{O}_3-83.2\text{TeO}_2$ at 77 K. The frequencies are 490.1 and 853.3 kHz and the widths (FWHM) are approximately 15 kHz. Values of $\chi = 2.909 \pm 0.014\text{ MHz}$ and $\eta = 0.346 \pm 0.014$ were obtained from the

Figure 23 ^{11}B NQR spectra of (a) crystalline and (b) vitreous $\text{Na}_2\text{O}\cdot 2\text{B}_2\text{O}_3$

data. An NMR measurement yielded an isotropic chemical shift of 36.7 ppm, which identifies a pentahedrally coordinated aluminum site.

It is clear that NQR studies of aluminum in four-, five-, and six-coordination in glasses are feasible and very accurate in measurements of the quadrupolar parameters.

4 NQR WITH A ZEEMAN PERTURBATION

We now survey the case in which a small magnetic field is present during the NQR experiment. This Zeeman splitting of a pure NQR spectrum was first treated by Bersohn³⁷ using a perturbation procedure. Dean³⁸ subsequently treated the theory of Zeeman splitting rigorously, and discussed the case of nuclear spin $I = \frac{3}{2}$ in detail. The applied field lifts the degeneracy of the $m = \pm\frac{3}{2}$ and $m = \pm\frac{1}{2}$ states, yielding the energies⁴⁶ and transition frequencies displayed in Figure 26.

Rubenstein and Taylor³⁵ applied the expressions for the four transition frequencies $\omega_i = \nu_i$, $i = 1, \dots, 4$ to rotations about the a , b , and c axes of a single crystal (orpiment) of As_2S_3 , using a magnetic field of about 87.5 mT. (The Zeeman interaction in this field would be 638 kHz, whereas the NQR frequencies are in the 70–72 MHz range. A first-order perturbation treatment of the Zeeman interaction is adequate.)

Figure 24 ^{11}B NQR spectrum of a glass of composition $0.15\text{Na}_2\text{O}-0.85\text{B}_2\text{O}_3$ referenced to vitreous B_2O_3

Figure 25 The two ^{27}Al NQR responses for vitreous $16.8\text{Al}_2\text{O}_3-83.2\text{TeO}_2$ (mol%)

The values of η extracted for the two inequivalent As sites in orpiment are 0.343 and 0.374.

Szeftel and Alloul⁴⁷ employed the frequency Ω_1 in Figure 26 to determine the value of the asymmetry parameter for ^{75}As in several vitreous chalcogenides. (In theory, Ω_3 could also be used, but the transition probability is lower than for Ω_1 . No response was detected⁴⁷ at Ω_3 .) The frequency Ω_1 is given by

$$\Omega_1 = \Omega \left[\left(1 - \frac{2}{\rho} \right)^2 \cos^2 \theta + \left[\left(1 + \frac{1}{\rho} \right)^2 + \frac{\eta^2}{\rho^2} - 2 \frac{\eta}{\rho} \left(1 + \frac{1}{\rho} \right) \cos 2\phi \right] \sin^2 \theta \right]^{1/2} \quad (5)$$

where $\Omega = \gamma B$, γ is the gyromagnetic ratio, and $\rho = 1 + \frac{1}{3}\eta^2$. Since equation (4) does not include the quadrupolar coupling constant χ , this transition can be used to obtain the value of η quite decoupled from that of χ .

Figure 26 Energy level diagram for a nuclear spin $I = \frac{3}{2}$ in the presence of a strong quadrupolar coupling and, respectively, zero and nonzero Zeeman perturbation (see Szeftel and Alloul⁴⁷)

Prediction of the observable lineshape for a polycrystalline powder or glass requires averaging over all θ and ϕ , including the dependence of the state functions and transition probabilities on those angles. Figure 27 displays the calculated lineshapes for two values of η . The parameter $r = \Omega/\nu = \gamma H_0/\nu$, where ν is the frequency of the spectrometer, has the limits $r_m \leq r \leq r_M$, and a logarithmic divergence occurs at r_p , where

$$\left. \begin{aligned} r_m &= \left[1 + \frac{1+\eta}{\rho} \right]^{-1}, & r_M &= \left(\frac{2}{\rho} - 1 \right)^{-1} \\ r_p &= \left[1 + \frac{1-\eta}{\rho} \right]^{-1} \end{aligned} \right\} \quad (6)$$

The ^{75}As spectra obtained at 4.2 K for four vitreous chalcogenides are displayed in Figure 28. Analysis of the spectra was carried out using Gaussian distributions in η about the value determined at the logarithmic divergence (τ_p). For vitreous As_2S_3 and As_2Se_3 , it was found necessary to include the contributions from two As sites with distinctly different values of η . These were determined as 0.12 and 0.36 for vitreous As_2S_3 , whereas the values for crystalline orpiment found by Rubenstein and Taylor³⁵ using a single crystal are 0.343 and 0.374. The site with $\eta = 0.12$ is clearly not present in orpiment, and is a site not considered by Rubenstein and Taylor³⁵ in their discussions of the ^{75}As NQR spectrum for vitreous As_2S_3 . For vitreous As_2Se_3 , the values of η were determined by Szeftel and Alloul⁴⁷ to be 0.14 ± 0.02 and 0.45.

Figure 27 Spectra (solid lines) calculated for two values of η (see Szeftel and Alloul⁴⁷)

Figure 28 ^{75}As spectra recorded in four vitreous chalcogenides at 5.9 MHz (circles) and 10.3 MHz (crosses). The powder spectrum calculated with the η values of orpiment is plotted as dash-dotted lines. Solid lines indicate the best fit. When two Gaussian distributions are needed to obtain the best fit, the contribution of the distribution of higher weight is plotted as a dashed line (see Szeftel and Alloul⁴⁷)

1 INTRODUCTION

Nuclei with a spin quantum number equal to or greater than unity have an electric quadrupole moment Q , prolate or oblate. The quadrupolar coupling is the interaction between such an electric quadrupole—stemming from the nonspherical distribution of the proton charges within the nucleus—and the electric field gradient due to the rest of the molecule. This field arises entirely from charges external to the nucleus: the other nuclei and the electrons both contribute. Thus, the electrostatic field gradient (EFG) is a traceless tensor. In its principal axis system (α, β, γ), it is represented by two observables, for example,

$$eq = V_{\alpha\alpha}, \quad \eta = \frac{V_{\beta\beta} - V_{\gamma\gamma}}{V_{\alpha\alpha}} \quad (1)$$

The axes are chosen so as to rank the components of the EFG in the alphabetical sequence $|V_{\alpha\alpha}| > |V_{\beta\beta}| > |V_{\gamma\gamma}|$. η is called the asymmetry parameter, and $\chi = e^2qQ/h$ is known as the quadrupolar coupling constant. In general, quadrupolar coupling constants range between a few tens of kilohertz and a few megahertz.

A majority of the nuclides in the Periodic Table are quadrupolar. Yet, so far, the historical development of NMR has given a privileged position to spin- $\frac{1}{2}$ nuclei such as ^1H , ^{13}C , ^{15}N , ^{19}F , ^{29}Si , ^{31}P , and ^{131}Xe . The objective reasons are the very high sensitivity of protons, the fact that the composition of organic molecules is predominantly carbon, hydrogen, oxygen, and nitrogen, and the ease with which both scalar and dipolar couplings can be used to provide rich structural information. The former reveal coupling patterns (multiplets) uniquely diagnostic of the number and type of neighboring nuclei, and thus indicate the local

connectivity. The latter, as manifested especially through nuclear Overhauser effects, gives complementary information about internuclear distances.

The efficiency of quadrupolar relaxation makes it, in general, rather difficult to extract these two types of structural information from the magnetic resonance of a quadrupolar nucleus. One should perhaps add to these objective reasons the innate conservatism of chemists—and indeed of paradigmatic science in general.

Yet quadrupolar nuclei have themselves so much to give to their observer. Even though chemists have tended to neglect it, the quadrupolar coupling constant holds comparable intrinsic interest to the electric dipole moment. It is one of the few measures we have of the electronic distribution in molecules, which in turn determines so many of their ground state properties, and can also be astutely used to make predictions of reactivity.

As is well known, any NMR relaxation mechanism gives a relaxation rate proportional to the square of the relevant interaction energy, multiplied by a spectral density. In the extreme narrowing limit, the spectral density at zero frequency is a correlation time, as defined from the appropriate correlation function. With the quadrupolar interaction energy into the megahertz range, this means that its fluctuations on a picosecond timescale, i.e., one characteristic of reorientation of organic molecules in solution, will be readily amenable to measurement. The attendant relaxation rates will be of the order of a few hertz. Thus, another major application of quadrupolar NMR is to the study of dynamics and microdynamics.

It is impossible within the space available here to give a thorough overview of the field. Probably, even a list of references for the past decade would more than fill the available space. Thus, a decision has been made not even to attempt comprehensiveness—because this would actually lead to its very opposite, superficiality. This is the reason why we have opted for a personal selection.

What are the main characteristics of this selection? It will emphasize contributions to science rather than technology. Good science is something like a convolution product between an important problem, a good idea to solve it, and an adequate technique—probably in that order. This review will also attempt to lay the groundwork for future historians by backtracking to the original seminal contributions. Scientists tend to downplay their predecessors in order to put their own contributions in the best possible light—sometimes even at the extent of mutilating their bibliography of highly relevant references. Perhaps, the length of time that this reviewer has invested in NMR will give a more balanced overview.

Yet another characteristic is the limitation to isotropic environments. This is apparently a severe limitation drastically curtailing applications of quadrupolar NMR: the transitions being made degenerate, the spectra are apparently devoid of the quadrupolar interaction, in the form of an observed splitting. Nevertheless, as already stated, even though there may be a single resonance to record, its relaxation behavior is determined by the magnitude of the quadrupolar interaction. Hence, while other articles are devoted to quadrupolar nuclei in the presence of local order, as in solids or liquid crystals (see *Liquid Crystals: General Considerations*), this review confines itself to quadrupolar nuclei in isotropic media.

Two more constraints on this article should be mentioned briefly. Obviously, the author's own work will not be mentioned. More cruel yet is the taboo on individual areas that could have had their natural niche within this review—such as the lovely ^{43}Ca study of calceins by the Lund group—but which are covered elsewhere in the Encyclopedia.

2 MICRODYNAMICS FROM DEUTERONS

Deuterium is rather easy to substitute for hydrogen in organic molecules. Such a move is attractive for NMR studies. Since scalar couplings are reduced by the ratio of the gyromagnetic ratios, the spectrum is simplified—and the chemical shifts in ppm to first approximation remain the same. Furthermore, replacement of a proton with a deuteron makes interpretation of relaxation measurements much simpler. In the absence of electronic relaxation by paramagnetic species, deuteron relaxation is exclusively quadrupolar.

The electrostatic field gradient at deuterium arises from imperfect (but near-perfect) cancellation of nuclear and electronic contributions. Accordingly, the quadrupolar coupling constant χ associated with a carbon–deuterium $\text{C}-^2\text{H}$ bond usually has values of about 160–180 kHz, depending upon carbon hybridization and substitution.¹ Deuterium quadrupolar coupling constants have been obtained from ab initio SCF calculations. These yield coupling constants accurate to about 5% (10 kHz). A plot of the calculated versus the experimental values has unit slope, a standard deviation of 10 kHz and a correlation coefficient of 0.989 for 24 data points. The confidence limits ($P = 0.95$) of the slope and the intercept include 1 and 0, respectively. Examination of the calculated values reveals an empirical proportionality to one another of the electronic and nuclear parts of the quadrupolar coupling constant. This observation is turned into a model that yields electrostatic field gradients at deuterium, q , of equal quality to the SCF calculations.²

The history of chemistry shows an empirical law not unlike Haeckel's Law ('ontogeny recapitulates phylogeny'), namely, whatever organic chemistry has achieved, organometallic chemistry strives to emulate. An instance is the quadrupolar coupling constant of deuterium in metal hydrides. It ranges from 55 to 158 kHz, as obtained from T_1 relaxation data in solution, and provides useful information on the ionicity of the metal–deuterium bond.³

After this aside, we return to deuterium-labeled organic molecules. Under extreme narrowing conditions, the longitudinal and transverse relaxation rates are equal and given by $R_{1,2} = \frac{3}{2}\pi^2\chi^2(1 + \frac{1}{3}\eta^2)\tau_c$, where η is the asymmetry parameter, which vanishes only when the C–D bond is coaxial, with a threefold or higher molecular symmetry axis. Thus, longitudinal relaxation times in the range of 17 ms to 17 s are measured under these conditions. Knowledge of both the quadrupolar coupling constant χ and the asymmetry parameter η , combined with measurement of the relaxation rates, thus yields the effective reorientational correlation time τ_c . For instance, methylenepheneanthrene tumbles about in deuteriochloroform solution with $\tau_c = 13.6$ ps. The anisotropy of the reorientation can be probed simply by monitoring C–D bonds variously located with respect to the inertial axes around which the molecule rotates: the fastest reorientational motion is associated with the highest symmetry axis.

Whenever the C–D bond, instead of being attached to a rigid skeleton, is part of a rotor, at least two correlation times are needed for the description of its motion: τ_i for the internal rotation and τ_M for the overall motion. For instance, a $-\text{CH}_2\text{D}$ group in an isotropically reorienting molecule corresponds to

$$\tau_\chi = 0.11\tau_M + 0.89(\tau_M^{-1} + \tau_i^{-1}) \quad (2)$$

A number of substituted aromatic molecules have been examined in this way.⁴

Consider now a molecule A that incorporates the telltale C–D bond and that is involved in a dynamic equilibrium process $\text{A} + \text{B} = \text{AB}$. Let us denote by k_a and k_d the rate constants for association and dissociation. Since the system bears its own internal clocks ('To choose time is to save time'—Francis Bacon⁵), with τ_f and τ_g the correlation times of the free A molecule and of the complex AB, it becomes possible to measure k_a and k_d .⁶ Brevard and Lehn achieved such a truly lovely application. They studied the charge-transfer complexes between trinitrobenzene as the electron acceptor and fluorene, methylfluorene, and methylenepheneanthrene as the electron donors. The results showed that each of the CT complexes amounted to a collision complex.⁷ During the last two decades, there have been numerous applications of deuterium nuclear relaxation to organic and biomolecules.⁸

To give but one example of the sophistication that has been achieved, a study has examined the intercalates formed by dimethyl sulfoxide in the interstitial space of a kaolinite clay, using $\text{DMSO}-d_6$. The results show the coexistence of two DMSO sites. In one of these sites, with $\chi = 67$ kHz, the methyl group rotors hop through angular steps of 140° . In the other site, with $\chi = 59$ kHz, the methyl groups hop through 110° . The former is a site in which one methyl group is anchored in a hexagonal hole within the honeycombed silicate layer, and the DMSO molecule is able to rotate around this sulfur–carbon axis. The latter has the DMSO pyramid with its symmetry plane, through the S–O bond and bisecting the C–S–C angle, orthogonal to the parallel layers of the clay.⁹

3 ORGANOLITHIUM COMPOUNDS: ELECTRONIC STRUCTURE, GEOMETRY, AND DEGREE OF AGGREGATION

The two lithium nuclides are ^6Li and ^7Li , with natural abundances of 7.42% and 92.58%, respectively. The spin quantum numbers are 1 and $\frac{3}{2}$, respectively. Nevertheless, ^6Li has a tiny quadrupole moment of $-0.0008 \times 10^{-28} \text{ m}^2$ making it an honorary spin- $\frac{1}{2}$ nucleus.¹⁰

An elegant use of the two isotopes is Jackman's study of the structure of phenyllithium in diethyl ether–cyclohexane (1:2) and in tetramethylethylenediamine (TMEDA)–cyclohexane (1:9) stable solutions. The idea stems from the contrasted abilities of the two lithium nuclides at dipole–dipole relaxation. Lithium-7 has 70% of the ^1H effectiveness while ^6Li has only 8%.^{11,12} In the solid state, the diethyl ether solvate is a tetramer by X-ray evidence. Hence, if this cubic tetramer endures in solution, it should undergo isotropic reorientation. Describing its motion with a single correlation time is thus legitimate. This correlation time is obtained independently from the T_1 of C-4,

which arises from exclusive dipolar relaxation by the proton attached 110.7 pm away. The difference in relaxation rate R_1 of the neighboring ^{13}C nucleus at C-1 with the two lithium isotopes provides the carbon–lithium distance, with excellent accuracy. Use of $[2,3,5,6\text{-}^2\text{H}_4]$ phenyllithium eliminates contributions to T_1 of C-1 from the *ortho* protons. It is necessary to measure T_1 values at 2.35 T to make relaxation by chemical shift anisotropy negligible. In this manner, the Li–C-1 distance is measured as 227 ± 5 pm in diethyl ether–cyclohexane (tetramer) and as 218.8 ± 2.2 pm in TMEDA–cyclohexane (dimer). Confirmation of the two oligomers comes from monitoring relaxation of H-2 by its two adjacent lithium nuclei in both the dimer and the tetramer. The observed values are 262 ± 2 pm in ether–cyclohexane, uniquely consistent with the tetrameric structure.¹³

Brown pioneered the use of lithium NMR to elucidate structures of alkyllithiums. The first lithium NMR showed ethyllithium to consist of a single hexameric species,¹⁴ bound strongly enough for the exchange rate constant to be less than 10 s^{-1} .¹⁵ In 1965, Lucken showed the quadrupolar coupling constant in methylolithium to be smaller than 16 kHz.¹⁶ Brown translated the absence of ^6Li – ^7Li scalar coupling in the methylolithium tetramer into a negligible metal–metal bond order.¹⁷ A group at Dow Chemical made the first observation of ^7Li – ^{13}C scalar coupling in methylolithium,¹⁸ in various solvents.¹⁹ The finding of a statistical distribution in ^{13}C -enriched methylolithium was consistent only with a cubic tetramer in which each lithium had three adjacent methyl groups, in accord with the local environment hypothesis of Seitz and Brown,²⁰ which had enabled Brown not only to confirm a cubic tetrameric structure in solution but also to measure an activation energy of approximately 100 kJ mol^{-1} for dissociation.^{21,22} Subsequent work showed that the degree of oligomerization of alkyllithiums is solvent-dependent, *n*-butyllithium going from the tetramer in ether to the hexamer in hydrocarbon solutions,²³ and that, furthermore, the bonding changes from an ion pair to a covalent carbon–lithium bond as a function of the solvent.²⁴ Several alkyllithium compounds are converted by small amounts of bases from hexamers to solvated tetramers.²⁵

The stylistic feature characteristic of the school of Brown is the use of scalar couplings to ^6Li as structural evidence. Lithium diisopropylamide (LDA) generates kinetic enolates from carbonyls. Its use in organic synthesis has become widespread in recent years.²⁶ The solution structure of lithium enolates is therefore of central importance. It determines their solubility, the effect of cosolvents, and addition to aldehydes and acid chlorides. Mixed aggregates determine the diastereo- and enantioselectivities.^{27,28} X-ray structures in the solid state do not necessarily extend to solution structures, and the latter determine the chemistry. Hence NMR has unique value in ascertaining those. A pioneering study is that by Grutzner of the solution in tetrahydrofuran of the simplest enolate, namely, that from acetaldehyde. Carbon-13 relaxation rates indicate aggregation—the cluster is significantly bigger than a THF molecule. These data also indicate anisotropic reorientation, with fast (slow) rotation of the C-1–H (C-2–H) dipole. With an effective radius of 580 pm, the aggregated species is identified as the cubic $(\text{CH}_2=\text{CHOLi})_4$ tetramer. It includes lithiums with a quadrupolar coupling constant of 65 kHz. The enolate rotates more rapidly about its C–O axis than the aggregate reorients in solution.²⁹ Such cubic tetramers are

involved in highly selective formation of such products as result from alkylation of the lithium enolate of norbornenone, whose structure³⁰ was established at the same time as others of the same ilk.³¹

The solution structure of lithium isopropylcyclohexylamide (LICA) was characterized by Collum at Cornell, as an equimolar mixture of the *cis* and *trans* lithium-bridged dimers: ^6Li – ^{15}N double labeling^{32–34} shows N–Li–N and Li–N–Li connectivity. LDA exists also as the cyclic dimer. In THF solution, each lithium is coordinated to the two amide nitrogens and to a single THF. This conclusion results unambiguously from ^6Li detection of ^{15}N homonuclear zero quantum coherence³⁵—the technique devised by Müller³⁶ and Bodenhausen and Ruben.³⁷ As hexamethylphosphoric triamide (HMPA) is added, HMPA sequentially displaces each of the two THF solvates in the dimer, as proved by both ^6Li – ^{15}N and ^6Li – ^{31}P coupling patterns.³⁸ Mixed dimers can form in the presence of other enolates; for instance, one LDA is replaced in the cyclic dimer by one pinacolate, as shown by the ^6Li coupled to a single ^{15}N .³⁹ In hydrocarbon (hexane) solution, LDA exists as an equilibrium mixture of at least three cyclic oligomers.⁴⁰

It is worth making explicit the above statement about the virtue of inverse-detected ^{15}N homonuclear zero quantum spectroscopy, and reproduce here Collum's explanation. It provides a rigorous distinction of D_{2h} cyclic dimers from D_{nh} higher oligomers. In the ^{15}N zero quantum experiment, homonuclear ^{15}N two-spin coherence is prepared from the two ^{15}N spins neighboring a ^6Li atom in a ^6Li – ^{15}N doubly labeled lithium dialkylamide cyclic oligomer. During the evolution period, the zero quantum coherence will evolve under scalar coupling only to ^6Li spins that couple to one, but not both, ^{15}N spins. For a lithium amide dimer, all ^6Li spins coupled to ^{15}N spins involved in the two-spin coherence couple to both ^{15}N spins. Consequently, the coupling pattern will be a singlet along the f_1 dimension of the 2D spectrum. In higher cyclic oligomers, there exist two ^6Li spins that couple to one, but not both, ^{15}N spins. The zero quantum coherence will develop scalar coupling to the two nonshared ^6Li spins, resulting in a 1:2:3:2:1 pattern along the f_1 dimension. As a result of a refocusing delay employed prior to detection, all oligomers will show a 1:2:1 pattern along the f_2 dimension.⁴¹

4 NITROGEN-14

With an isotopic abundance of 99.7% and a spin quantum number I of unity, ^{14}N suffers from a low gyromagnetic ratio and from long longitudinal relaxation times (see *Nitrogen NMR*). Its relaxation is dominated by the quadrupolar mechanism—even in the most unfavorable situations. The tiny ammonium ion NH_4^+ relaxes exclusively by the quadrupolar mechanism, despite the zero electrostatic field gradient at nitrogen in the full T_d symmetry.⁴² Even in the paramagnetic hexacyanide complexes of chromium, manganese, and iron, the ^{14}N linewidths are determined solely by quadrupolar relaxation.⁴³ Resonances are usually very broad, with linewidths greater than 500 Hz. Bypassing these experimental difficulties calls either for astute experiments or for a cop-out. Many have chosen the latter, resorting to ^{15}N enrichment, in particular for investigating biomolecules such as proteins

and nucleic acids. Nevertheless, there have been a few studies of the ^{14}N chemical shift in relation to structure. For instance, the extent of $d_{\pi}-p_{\pi}$ bonding has been determined in *N*-trimethylsilylaminoboranes⁴⁴ and in trimethylsilylamines.⁴⁵ Likewise, σ and π contributions from fluorine are sorted out in fluoronitrogen cations.⁴⁶ The nitrogen chemical shift gives a rather direct estimate of the atomic charge.⁴⁷ But there have been some rather smart solutions to circumvent the ^{14}N limitations. Indirect measurement of ^{14}N relaxation rates is feasible through attached protons in amino groups by measurement of the ^1H longitudinal rate in the rotating frame. In this manner, ^{14}N relaxation has been studied in a variety of biomolecules, such as nucleotide bases.^{48,49} Another elegant experiment—also indirect and also taking advantage of the sensitivity of ^1H NMR—is observation of ^{14}N double quantum (DQ) coherence in isotropic solution. The usual recipe with two $\frac{1}{2}\pi$ pulses on the *S* spins (^{14}N) during the preparation sequence fails. Augmentation of this sequence by spin tickling of *I* spins ($I = \frac{1}{2}$) mixes *S*-spin DQ coherence into the *S*-spin magnetization.⁵⁰ An alternative solution is to excite and detect the *S* DQ coherence by using only the *I* magnetization and applying single hard pulses at both *I* and *S* frequencies. This is an example of heteronuclear coherence transfer taking advantage of the signal enhancement accruing from using only proton magnetization for both the initial and the final conditions. The method was tested on ammonium nitrate 8 M (!) in water acidified to pH 1 to slow down proton exchange. The DQ ^{14}N coherence is observed, with a splitting $2J = 105$ Hz. The multiplet resonance is a quintet with a vanishing central line. Using the composite particle method and replacing the two *I* = 1 spins with four *I* = $\frac{1}{2}$ spins and evaluating the matrix elements does indeed give the line amplitudes for the five transitions $m^I = \pm 2, \pm 1$, and 0: this last one has zero amplitude.⁵¹ Determination of the quadrupolar coupling constant and of the asymmetry parameter for ^{15}N even approximately and for some general category such as cyano group, nitro group, or secondary amine, would seem to demand recourse to a method such as microwave spectroscopy, or NMR in a single crystal, or even pure quadrupole resonance. A smart manner of obtaining these required parameters in the liquid state is applicable to polar groups: alignment by a strong external electric field. Thus, the principal components of the quadrupolar coupling tensors were determined in the ^{14}N NMR of nitrobenzene.⁵²

Nitrogen-14 NMR gives a handle onto relaxation, especially of highly symmetrical nitrogen-containing solutes having a vanishingly small electrostatic field gradient at nitrogen. The azide anion N_3^- shows a strong dependence of the T_1 values for both nitrogen types upon concentration. The ratio $T_1(\text{end})/T_1(\text{central})$ is 0.25, reflecting a ratio of the corresponding χ values of 0.50.⁵³ The transverse relaxation rates for the azide ion nitrogens are extremely sensitive to the presence of an associating counterion. Observed values in aqueous solution are 500 Hz with Zn(II) , 1000 Hz with Cd(II) , 5×10^6 Hz with Cu(II) , 2.5×10^6 Hz with Mn(II) , and 6×10^5 Hz with Fe(III) .⁵⁴ In an early piece of work, as handsome as it turned out to be useful, Pople had calculated the lineshapes for a spin $I = 1$ (^{14}N) resonance scalar-coupled with a spin $I = \frac{1}{2}$ (^1H) for various values of the ^{14}N relaxation rate. In this manner, one may obtain the ^{14}N relaxation rate indirectly from the proton resonance lineshape.⁵⁵ More than 30 years later, the method is still very useful. For instance, the ^{14}N linewidth in methyl-substituted ammonium ions increases from

less than 0.2 Hz in NH_4^+ to 32.1, 80.7, and 96.4 Hz with the successive introduction of one, two, and three methyl groups; the activation energy for molecular reorientation remains relatively invariant at about 10.6 kJ mol^{-1} .⁵⁶

5 OXYGEN-17

Townes and Dailey pioneered the interpretation of quadrupolar coupling constants to analyze chemical bonding. They did it on bonds involving halogens.⁵⁷ Brown made use of similar tactics to gain insight into the details of the carbonyl group, using ^{17}O NMR. A representative carbonyl has the α , β , and γ axes of the quadrupolar interaction tensor (see Section 1) oriented along the carbon–oxygen internuclear axis, perpendicular to the carbonyl plane, and in that plane, respectively. In 28 carbonyl-containing compounds, Cheng and Brown found a π population ranging from 1.366 for *p*-benzoquinone to 1.742 for sodium bicarbonate. The less polarizable σ bond has a narrower range, as expected. The formal electronic charge on oxygen is rather large, of the order of one electron.^{58,59} Following the pioneering work of Kintzinger,^{60,61} numerous authors have obtained chemical shifts and quadrupolar coupling constants in organic molecules.⁶² Likewise, after Lauterwein gave a similar impulse for applications to biomolecules,^{63,64} these have thrived, and have presently reached studies of hemoglobin and myoglobin.⁶⁵ Also, ^{17}O NMR is a nice biochemical labeling technique.⁶⁶ Organometallic applications have developed in parallel, to the structures of species such as metal carbonyls⁶⁷ and oxo–peroxo complexes,⁶⁸ and to mechanistic studies.⁶⁹ With the new techniques of dynamic angle spinning and double rotation,⁷⁰ ^{17}O NMR has penetrated into the solid state, and is helping to elucidate the structure of silicates.⁷¹

To end this section, we single out studies of molecular microdynamics based on ^{17}O relaxation to a large extent. They include, of course, water, for which the isotropic motional model was shown to be an adequate description in the picosecond timescale.⁷² The motion of tetrahedral oxo anions is a natural for the technique,⁷³ and correlation times in heavy water at 28 °C are 0.80 ps for perchlorate, 2.8 ps for sulfate, and 14–16 ps for phosphate, reduced to 0.73 ps (perchlorate) and 1.1 ps (sulfate) in methanol- d_4 .⁷⁴

6 THE SODIUM ANION

The preamble to this story took place in London, at the Royal Institution in 1808, when Humphry Davy, after he had isolated sodium and potassium, heated the latter in ammonia and obtained potassamide.^{75,76} Weyl proceeded to study the blue solutions formed when alkali metals dissolve in dry ammonia.⁷⁷ Mendeleev pointed out the quantitative resemblance between the alkali metals and the halogens.⁷⁸ Thus, alkali metal anions ought to be capable of existence. In the early 1960s, Dye used optical spectra in support of the postulated existence of alkali metal anions when the alkali metals are dissolved in primary amines and in some polyethers.⁷⁹

In 1974, Ceraso and Dye obtained a ^{23}Na NMR spectrum with distinct, well-separated resonances for the cryptated

sodium cation and the sodium anion, after they had co-dissolved metallic sodium and the [2.2.2]cryptand in an organic solvent, ethylamine. The signal of the sodium anion is found 63 ppm to low frequency of the aqueous sodium chloride reference, and is solvent-independent when measured in THF, methylamine, and ethylamine.^{80,81} Clearly, Dye had been following very carefully the new developments in polyether and cryptate chemistry, and realized the versatility of their utilizations.

The NMR spectrum published in 1974 truly demonstrated the structure of the sodium anion, Na^- . The paramagnetic part of the shielding constant of the sodium nucleus in the sodium cation arises from the introduction of orbital angular momentum by interaction of the filled outer p shell with electron pairs from neighboring solvent donor molecules.⁸² The sodium anion, with a more diffuse electronic distribution, and with only a weaker interaction with external electronic pairs, should have much less of a paramagnetic shift. The two spin-paired electrons in the 3s orbital shield the 2p electrons from the influence of the solvent. Indeed, its chemical shift, with reference to external saturated aqueous NaCl, is invariant at -57 to -63 ppm^{83,84} and the same within experimental error as that of -63.8 ppm calculated for the isolated anion in a gas.⁸⁵ Thus, the system studied consisted of $\text{Na}^+\text{C222.Na}^-$, where C222 denotes the cryptand.

Edwards's group in Cambridge then showed that it was not mandatory to hide away the sodium cation in a crown ether or cryptand in order to dismutate sodium metal into the +1 and -1 oxidation states. When they dissolved sodium in anhydrous hexamethylphosphoric triamide (HMPA), they recorded the ^{23}Na spectrum of the naked anion at -62 ppm with a linewidth of 10 Hz.⁸⁶ They were unable to observe any resonance from the sodium cation, presumably because of its extreme width in the paramagnetic (solvated electrons) solution. The Cambridge group proceeded to make a similar series of observations in 12-crown-4⁸⁷ and in various amide solutions, *N,N*-diethylacetamide, *N,N*-di-*n*-propylacetamide, *N,N*-dimethylpropanamide, and tetramethylurea: the chemical shift of the sodide ion is both solvent- and temperature-independent, at -62.3 ± 0.3 ppm. The linewidth is very narrow, 8–13 Hz from 233 to 200 K, in contrast to Na^+ , for which the linewidth trebles in going from 279 to 250 K, in diethylacetamide solution.⁸⁸ Again, Edwards and co-workers were unable to detect the signals of the solvated cations. Direct measurements of the longitudinal relaxation rate for Na^- in solutions containing an alkali counteranion in 12-crown-4 showed independence with respect to the nature of the alkali counterion. Relaxation occurs by a predominant, although rather inefficient, quadrupolar relaxation mechanism via the reorientational–vibrational motion of the surrounding 12-crown-4 molecules in the liquid. Furthermore, solvation of the sodium anion by the crown ether is very weak: there is neither a preferential orientation of the crown ether nor a clearly identifiable first solvation shell around the sodide anion. An RMS value of 0.03 MHz is deduced for the quadrupolar coupling constant χ in 12-crown-4 solutions: Na^- is a gas-like entity in solution.^{89,90}

The ^{23}Na NMR of both $\text{Na}^+\text{C222}$ and Na^- in polycrystalline $\text{Na}^+\text{C222.Na}^-$ was monitored from the $(+\frac{1}{2}, -\frac{1}{2})$ transition, as a function of the Larmor frequency (at 4.7, 8.5, and 11.7 T): second-order perturbation theory gives the shift of this

central transition with frequency as

$$\nu - \nu_L = -\chi^2[I(I+1) - \frac{3}{4}](1 + \frac{1}{3}\eta^2)/30\nu_L \quad (3)$$

where ν_L is the Larmor frequency and η the asymmetry parameter. For the cryptated sodium cation, the authors determined $\chi = 1.2$ MHz and an isotropic chemical shift of -6.5 ppm, essentially the same as that for $\text{Na}^+\text{C222}$ in solution in various solvents. The quadrupolar contribution to the static linewidth of the complexed cation in $\text{Na}^+\text{C222.Na}^-$ is 320 Hz whereas the observed linewidth is 3700 ± 300 Hz—a difference ascribable to dipolar couplings with the protons in the methylene groups of the [2.2.2] cryptand. Conversely, the sodium anion has a quadrupolar coupling constant χ of 0.26 MHz and a calculated (van Vleck expression) dipolar broadening from $^1\text{H} \cdots \text{Na}^-$ interactions of 2860 Hz in excellent agreement with the observed linewidth of 2800 Hz.⁹¹ More recently, Dye has provided a more accurate determination of the quadrupolar coupling constant for the sodium anion from a single crystal ^{23}Na NMR study of the same $\text{Na}^+\text{C222.Na}^-$ system. Values for χ of 1.268 and 0.1763 MHz were determined for Na^+ and Na^- , respectively. Isotropic chemical shifts of -5.5 and -61.8 ppm were obtained for the cation and the anion, respectively.⁹² At the time of writing (December 1993), Dye is studying mixed systems such as $\text{Cs}^+(\text{18C6})_2\text{Na}^-$, in which the ^{23}Na chemical shift of about -61 ppm is diagnostic of the sodium anion.⁹³

7 COORDINATION OF ALUMINUM-27

Many applications reflect the natural state of aluminum, which constitutes 9% of the Earth's crust. They concern aluminates and aluminosilicates. In the latter category, it is not so much layered clays (phyllosilicates), but rather microporous aluminosilicates, zeolites, that have been extensively studied as industrially important catalysts. Especially since the discovery of the Mobil process for conversion of methanol into gasoline on the HZSM-5 zeolites, there has been a flurry of high-resolution ^{27}Al NMR studies of these solids. Nevertheless, the field of ^{27}Al NMR is wider. At the time when Delpuech wrote his useful review, most data pertained to tetra- or hexacoordinate compounds.⁹⁴ A fuller picture can now be given. Benn pointed out that the chemical shift characterized organoaluminum compounds in classes, depending on coordination of the metal. Tricoordinate aluminum has a chemical shift of about 250 ppm, tetracoordinate aluminum about 150 ppm, pentacoordinate aluminum about 120 ppm, and hexacoordinate aluminum 0 ppm with respect to an external reference of $\text{Al}(\text{acac})_3$.⁹⁵ A word is in order here about the ^{27}Al reference. Usually, the hexaquoaluminum(III) cation, $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$, is chosen.⁹⁶ It is sensitive to second-sphere effects.⁹⁷ Another candidate, with the merit of better invariance to solvation and concentration, is the AlH_4^- anion, with $\delta = 101$ ppm with respect to the aluminum(III) hydrate.⁹⁸ A caveat on the use of ^{27}Al NMR for characterization of organometallics was issued.⁹⁹ Distinction between tricoordinate and tetracoordinate aluminum in alkylaluminum phenoxides was made.¹⁰⁰ In the gauge-independent decomposition,¹⁰¹ the diamagnetic part of the shielding constant is invariant within a few ppm. Variations arise from the paramagnetic contribution, itself dominated by

the HOMO–LUMO gap. Low-valent aluminum compounds have been made in recent years. The chemical shift of aluminum(I) compounds has been studied experimentally and theoretically.¹⁰² The latter are SCF calculations^{103–105} using the gauge-including atomic orbital (GIAO) method.¹⁰⁶ The surprise is that, rather than settling into a niche of their own next to the others for aluminum(III) compounds, aluminum(I) compounds are anarchists, roaming through the whole range of ^{27}Al chemical shifts. The calculated values include one of the most shielded (AlCp , -170 ppm) and one of the most deshielded ($\text{AlSi}(t\text{-Bu})_3$, 854 ppm). The actual, quite different, chemical shifts, are -111 and 64.5 ppm, respectively. They point to the existence of AlCp as the tetramer Al_4Cp_4 and to the importance of solvation effects in determining the chemical shift of $\text{AlSi}(t\text{-Bu})_3$. The calculations confirm the correlation between the calculated shielding constants and the HOMO–LUMO energy gap.

A seminal finding for solid state studies of aluminosilicates has been the sensitivity of the ^{27}Al chemical shift to the composition of the second coordination sphere. Thus, studies of aluminosilicate solutions showing that the chemical shift for Si–O–Al units depended on the structural unit (Q^0 , Q^1 , Q^2 , or Q^3) with incremental changes¹⁰⁷ launched this very active field. Aluminum-27 NMR can serve to characterize synthetic and natural zeolites.¹⁰⁸ Owing to the strong industrial interest already referred to, increased technical sophistication was brought to bear on structural studies of zeolites. Klinowski in Cambridge resorted to quadrupolar nutation ^{27}Al NMR to study isomorphous substitutions in the zeolite Y framework.¹⁰⁹ Already in 1988, one could start reading reviews of MAS studies in zeolites.¹¹⁰ The advantages of very high fields B_0 and ultrafast spinning became clear,¹¹¹ and were applied to samples such as USY zeolites¹¹² or dealuminate Y zeolite.¹¹³ Another big experimental breakthrough was the development of double rotation and of dynamic angle spinning to average out both the first- and second-order anisotropic broadenings in solids. In this manner, it has been possible to characterize both tetrahedral environments and heavily distorted pentacoordinate aluminum in zeolites of the $\text{AlPO}_4\text{-21}$ and $\text{AlPO}_4\text{-25}$ types.¹¹⁴ The ^{27}Al longitudinal relaxation was related to the organic molecules and exchangeable cations present within the channels and supercages of the zeolites.¹¹⁵ A fine multinuclear study paid attention to satellite transitions,¹¹⁶ which have been receiving increased attention.¹¹⁷ The analytical aspects were not neglected, and quantitation of aluminum in zeolites was perfected.¹¹⁸ A study was made of β -zeolites in relation to their catalytic prowess.¹¹⁹ Of course, the acidic HZSM-5 received star treatment.¹²⁰ Aluminophosphate zeolites¹²¹ such as VPI-5¹²² and $\text{AlPO}_4\text{-11}$ ^{123,124} were also studied. Aluminum-27 NMR was the test used to distinguish between various models of ionic solvation.¹²⁵ The quadrupolar coupling constant was determined for aqueous Al(III) in solutions of perchloric acid.¹²⁶ Other aluminosilicates got the studies that they deserved. The mechanism of kaolinite dehydroxylation was scrutinized,¹²⁷ and likewise its thermal transformation¹²⁸ and activated layered aluminosilicates were examined.¹²⁹ Adsorption of chlorine on γ -alumina was monitored.¹³⁰ Cross polarization focused on surface aluminum atoms on alumina.¹³¹ Iron-bearing montmorillonites—outstanding catalysts for quite a few organic reactions—were examined.¹³² A related study examined Friedel–Crafts catalysts formed by adsorption of

divalent fluorides on the K-10 montmorillonite, a partly amorphized 2:1 clay used as a cracking catalyst in the petrochemical industry.¹³³ The structure of pumice was examined.¹³⁴ In the bio-inorganic realm, aluminum porphyrins were studied.¹³⁵ Dimerization of tricoordinate aluminum(III) Lewis acids such as trimethylaluminum deserved some attention.¹³⁶ Preferential solvation of aluminum(III) perchlorate in binary mixtures of urea and DMF was studied.¹³⁷

8 MICROENVIRONMENT OF THE CHLORIDE ION

Chlorine-35 NMR was given an early and outstanding review, which continues to be extremely valuable.¹³⁸ We shall focus here on a few more recent contributions that in various guises examine the immediate environment of the chloride anion, probed by ^{35}Cl NMR. An interesting question is that of the proximity of the counteraction, in the presence of a complexant that encapsulates this cation. Thus, the ^{35}Cl linewidths were determined for the KCl-18-crown-6 complex in various solvents. The chloride anion exists in acetonitrile in a completely dissociated state, approximating the proverbial and elusive ‘naked anion’. The ^{35}Cl linewidth due to the Cl-ion-paired with the crown ether is 90 ± 20 Hz in aqueous solutions. The contact ion pair is that in which Cl^- and K^+ are nearest neighbors. It would have a significantly greater linewidth, of about 550 Hz. Thus, because the crown ether grabs the potassium cation with a pseudoequatorial arrangement of its coordinated oxygens, while the apical positions are occupied by water molecules, the chloride anion is unable to coordinate the potassium cation. What is observed instead is a loose, solvent-separated ion pair.¹³⁹ Another interesting question is competition between two different counterions. For instance, lithium chloride and lithium perchlorate were studied in acetone solution in the presence of various phosphates. The ^{35}Cl linewidth is monitored as a function of concentration. It shoots up in the presence of triphenyl phosphate $\text{O=P(OC}_6\text{H}_5)_3$. The observation is consistent only with dissymmetric penetration of the perchlorate anion coordination shell by the Li–O–P fragment, with this particular phosphate only.¹⁴⁰ Conceptually similar experiments can be carried out in yet more exotic environments. Sodalites are aluminosilicates with a nanoporous structure that makes them of interest in quantum electronics, nonlinear optics, information storage and processing, and so on. A recent study focused on sodalite semiconductors. The chloride anions are distributed within the cavities of $\text{Na}_{8-n-p}\text{Ag}_n\text{X}_{2-p}$ lattices. Narrow ^{35}Cl resonances are, nevertheless, observed. They stem from the presence of highly symmetrical species. A sharp peak at -122 ppm (0.1 M NaCl external reference) is ascribed to Na_4Cl tetrahedra encapsulated within the sodalite cavities. A substantially low-frequency-shifted peak at -310 ppm in the fully Ag^+ -exchanged system corresponds likewise to encapsulated Ag_4Cl clusters. These symmetrical environments around the halide anion give rise to narrow resonances in the ^{35}Cl MAS spectra.¹⁴¹

Hydrophobic effects leading to asymmetric solvation and/or aggregation have been reported by many authors. Let us start with water–dimethyl sulfoxide binary mixtures. The relaxation rates at intermediate solvent compositions are higher than those in either pure solvent by more than one order of magnitude. This pronounced deviation from ideality contrasts with that of

the chemical shift: the ^{35}Cl chemical shift varies linearly with composition.^{142, 143} Useful applications from such observations need not resort to sophisticated analyses. Even at an empirical level, they can be turned into extremely useful consequences. A case at hand is the study by the Martins in Nantes of chloride ion reactivity. They examined the variation in the transverse relaxation of ^{35}Cl as a function of temperature for 13 chloride salts in acetonitrile solutions. When two ammonium species, such as tetrabutyl- and benzyltributylammonium chlorides, are mixed at a fixed concentration, the ^{35}Cl linewidths do not vary linearly between the values characteristic of each species. A broadening occurs, and the maximum linewidth is reached at equimolar concentrations of the two salts. From its magnitude, both types of ammonium cations must coexist in the chloride ion coordination shell. Likewise, the ^{35}Cl linewidth is very sensitive to the presence of phenols in the solution, and depends in a simple way on the $\text{p}K_{\text{a}}$ of the phenol added. This behavior makes it feasible to define a linewidth $\Delta\nu_{\frac{1}{2}}^0$ characteristic of the chloride anion in various organic salts. This parameter, with an observed range of 45–450 Hz, appears to measure the reactivity of the chloride anion as displayed in reactions under phase transfer catalysis, or in the catalytic phosgenation of phenol.¹⁴⁴

Paradoxically, we have kept for the end of this section the apparently much simpler behavior of a chloride salt in aqueous solution. Consider magnesium chloride. The limiting behavior at infinite dilution has been described with a so-called dynamically oriented solvation model, specifying both the structure and the internal dynamics of the hydration spheres of Mg^{2+} and Cl^- . The ^{35}Cl relaxation rate gives a value of 0.43 for water–water correlation effects, i.e., the influence of water from outer hydration layers on the hydration water molecules.¹⁴⁵ Turning to chloride ion relaxation for MgCl_2 at finite concentrations, this shows contributions from ion–ion interaction, ion–hydration water, and in-bulk water. At low salt concentrations, below 1 M, the main contribution (75%) arises from bulk water. With increasing MgCl_2 concentration, the contribution from the magnesium hydration water molecules becomes more important, and at 5.5 M is responsible in turn for about 75% of the total ion–water contribution. This is very likely due to encounter between the chloride anions and the hexaaquamagnesium(II) cations, with temporary distortion of the hydration shell during the encounter.¹⁴⁶

9 HOW DOES COBALT-59 RELAX IN OCTAHEDRAL COMPLEXES?

Cobalt-59 NMR has the attraction of 100% isotopic abundance, high sensitivity, and an enormous range of chemical shifts. In hexacoordinate octahedral cobalt(III) complexes, the chemical shifts are correlated to electronic excitation energies, owing to magnetic-field-induced mixing of the $^1T_{1g}$ excited state with the $^1A_{1g}$ ground state, leading to a paramagnetic contribution to the ^{59}Co shielding. A quadrupolar mechanism appears to serve as the dominant mode of relaxation in cobalt(III) complexes devoid of full octahedral symmetry. Indeed, linewidths become very large in the presence of permanent electrostatic field gradients at cobalt.¹⁴⁷ The quadrupolar coupling constant has a value of 2.7 MHz in $[\text{Co}(\text{NH}_3)_6]^{3+}$, is multiplied about 20-fold on replacement of one ammonia by

one water ligand (inner sphere perturbation),¹⁴⁸ but increases only slightly to 3.5 MHz in the $[\text{Co}(\text{NH}_3)_6]^{3+}-\text{ClO}_4^-$ ion pair (outer sphere perturbation).¹⁴⁹

The question remains of the origin of the linewidth in fully symmetric octahedral cobalt(III) complexes. Spin–rotation relaxation has been invoked. For hexamminecobalt(III), $[\text{Co}(\text{NH}_3)_6]^{3+}$, the longitudinal relaxation rate extrapolated to infinite dilution shows a temperature invariance suggestive of operation of a spin–rotation mechanism with the opposite temperature dependence to that of quadrupolar relaxation. The results were consistent with a quadrupolar coupling constant of about 3 MHz and a spin–rotation coupling constant of 72 kHz.¹⁴⁹ Scalar relaxation of the second kind¹⁵⁰ is another potential contributor. Take the same example of hexamminecobalt: the cobalt nucleus is scalar-coupled to the ^{14}N nucleus, which relaxes efficiently by a nucleus–electric quadrupole mechanism. Such an interaction makes the transverse ^{59}Co relaxation rate proportional to the product of the square of the interaction energy J and the correlation time τ_{N} descriptive of reorientation of the nitrogen spin. Thus, differences between T_1 and T_2 in some CoN_6 complexes have been ascribed to unresolved scalar couplings with nitrogen, of the order of magnitude of 50 Hz.^{151, 152} And, of course, there is the problem of explaining the intervention of quadrupolar relaxation in a complex with strict O_h symmetry, in which the electrostatic field gradient at the central nucleus has to vanish. The origin of the fluctuating EFG must be found either in instantaneous distortions with respect to the ideal O_h geometry or in deviations from this perfect symmetry due, for instance, to the proximity of a counterion. When, indeed, a charged anion was placed in the outer sphere of $[\text{Co}(\text{en})_3]^{3+}$ and $[\text{Co}(\text{pn})_3]^{3+}$ complexes, its contribution was reported as insignificant.¹⁵¹ The remaining explanation—that of excitation of the vibrational modes of the octahedron¹⁵³—was scrutinized in the case of tris(tropolonato)cobalt(III), and appears as a likely candidate.¹⁵²

Potassium hexacyanocobaltate(III) $\text{K}_3\text{Co}(\text{CN})_6$ was examined by monitoring the relaxation rates of all the nuclei in the anion. Although the ^{59}Co relaxation rate decreases with increasing temperature, the slope is half that for ^{13}C . Again, this uncoupling of ^{59}Co relaxation from rotational reorientation is suggestive of modulation of the EFG by solvent-assisted molecular vibrations.¹⁵⁴

In order to proceed further the ^{59}Co chemical shift and its relationship to the linewidth enters as another piece of evidence. The context is Deverell's electronic distortion theory.^{155, 156} The valence atomic orbitals distort upon each collision with a solvent molecule. A paramagnetic contribution to shielding σ_{p} stems from injection of electrons into atomic orbitals with the appropriate symmetry. This also sets up a fluctuating electrostatic field gradient at the nucleus monitored. The relaxation rate R_1 is predicted to be proportional to the product of the reorientational correlation time with the square of a term $\sigma_{\text{p}} \Delta E$, where ΔE is the average electron excitation energy. Thus, the square root of the linewidth is predicted to be proportional to the chemical shift. After normalization to unit viscosity, the ^{23}Na linewidths for a series of sodium cation solvates¹⁵⁷ and for sodium cryptates¹⁵⁸ obey this prediction with impressive discipline. In like manner, three octahedral cobalt(III) complexes were studied in a number of solvents: $\text{Co}(\text{en})_3\text{Cl}_3$ and *cis*- and *trans*- $\text{Co}(\text{en})_2(\text{N}_3)_2\text{NO}_3$. Attempts to correlate linewidths and viscosity-normalized linewidths with

the solvent electric dipole moment failed to provide convincing support for the Hertz electrostatic model.^{159–162} The square root of the viscosity-normalized linewidths, after correction for scalar relaxation of the second kind [a 45 Hz contribution to the linewidth for $\text{Co(en)}_3\text{Cl}_3$], produces excellent linear correlations with the ^{59}Co chemical shift.¹⁶³ A related study examined cobalt(III) porphyrin complexes—cobalt(III) is an excellent isomorphous substituent for iron(III), and ^{59}Co NMR is more amenable than ^{57}Fe NMR. The contribution of scalar relaxation of the second kind amounted to about 5% of the excess linewidth only. Arbitrary subtraction from the linewidth of a 100 Hz increment led to a quite decent linear relationship between the square root of the linewidth and the chemical shift.¹⁶⁴ This makes for an incisive tool, as an example will show. Two types of cobalt(III) tetraphenylporphyrin complexes are studied: unhindered or hindered, the latter bearing *ortho*-chloro or methyl substituents sterically interfering with the *meso* phenyl rings. A corrected linewidth F is defined by subtraction of a 81 Hz contribution for relaxation by scalar coupling, and by normalization to unit viscosity. Then $F^{1/2}$ correlates handsomely with the chemical shift only if the electrostatic field gradient q changes sign for the hindered complexes compared with the unhindered ones. This is a unique piece of information. It means that the electron density in the hindered complexes migrates from the axial d orbitals d_{xz} , d_{yz} , and d_{z^2} to the equatorial d orbitals $d_{x^2-y^2}$ and d_{xy} . This amounts, for the molecule as a whole, to a build-up of σ electron density at the expense of π electron density, due to steric inhibition of resonance.¹⁶⁵ Once again, quadrupolar NMR shows its mettle in matters of electronic distribution!

10 A NOTE ON THE STERNHEIMER ANTISHIELDING FACTOR

This is a magnifying factor that increases the effective interaction between an electrostatic field gradient q at the nucleus, and the quadrupole moment of the nucleus Q .^{166–168} The reason is that the mere presence of an electrostatic quadrupole (the nucleus) distorts (slightly) the spherical electronic distribution around it, consisting of the core electrons. There is a radial part in which electrons close to the positive (negative) poles of the quadrupole are pulled in (out). There is an angular part in which s electrons acquire a d-orbital-like polarization: these distortions are conveniently referred to as, for example, $2s \rightarrow d$ excitations. Shielding corresponds to values of the Sternheimer factor γ between 0 and 1, and antishielding corresponds to negative values of γ . Access to γ is, in general, by calculation. For instance, while the sodium cation has a Sternheimer γ of -5.073 computed at the Hartree–Fock level, the sodium anion has values of -14.98 and -15.69 , depending on the method used for incorporating electron correlation.¹⁶⁹

The problem is more severe yet: which value to choose from those available in the literature? For instance, in the series of halide anions, the spread between the lowest and the highest value of γ is a factor of about 2.^{170–172}

11 CONCLUSIONS

In closing, this reviewer begs to be allowed the privilege of editorializing—of expressing a few sincere opinions,

and submitting a few concluding observations. At the risk of belaboring the obvious, we cannot help stating that quadrupolar nuclei, at the time of writing, remain outside the mainstream of NMR studies. There are objective reasons: experimental difficulty first and foremost. For instance, ^{57}Fe is a rather discouraging nucleus, in spite of the importance of iron as an element. However, now that indirect methods of detection—we did mention earlier the example of ^{14}N —are becoming routine, we may hope for more and more forays into the quadrupolar jungle.

It became clear while preparing this survey that there are shockingly few studies of molecular electronic distributions from NMR of quadrupolar nuclei. The weak explanation is the need for determination of the full shielding tensor and of the full quadrupolar interaction tensor from high-resolution solid state studies. But here again technical solutions exist. One must conclude that the main problem is the sociological (or psychological?) issue of the necessary collaboration between theoreticians and experimentalists.

Relaxation studies are another underdeveloped area. Scientists shy away from it for a basic reason: they are being confronted with only one observable, namely the linewidth or the transverse relaxation rate. And this single observable is determined by the product of at least two parameters: the correlation time and the quadrupolar coupling constant. The obvious solution is to get at the correlation time (or the spectral density) with other nuclei—which a number of people have done, to splendid avail unflinching.

Quite a few very handsome physicochemical studies have addressed themselves to ionic relaxation, in order to probe solutions of electrolytes. In that area, electrostatic models have been perhaps unduly popular. They have served as a red rag, to lure physical chemists into their intricacies, their (too) large number of (in fact) adjustable parameters. The relevance of electrostatic models to the systems studied from hindsight does not strike one as self-evident.

My last point is that the science-historical law asserting that the real advances to significant progress are contributed by outsiders to a field is once again vindicated. Brilliant work by Jean-Marie Lehn (^2H , ^{14}N), Jim Dye (^{23}Na), and Ted Brown (^6Li , ^{17}O) has thus been at the forefront of both chemical science and NMR science.

1 INTRODUCTION

Inasmuch as three-fourths of all NMR-receptive nuclei have measurable quadrupole moments, the electric quadrupolar interaction, and its ability to effect nuclear spin relaxation, necessarily plays a central role in both the theory and practice of nuclear magnetic resonance. Furthermore, in addition to the importance on relaxing high-spin nuclei, quadrupolar interactions impact upon the relaxation features of scalar-coupled spin- $\frac{1}{2}$ nuclei.

Except for nuclei occupying molecular sites of cubic electronic symmetry, the interaction strength of the quadrupolar coupling typically is on the order of 10^6 – 10^8 s $^{-1}$, whereas comparable dipolar, spin rotation and anisotropic shielding interaction strengths are on the order of 10^4 – 10^5 s $^{-1}$. Hence, electric quadrupolar interactions usually result in extremely efficient *dissipation* of nuclear spin coherence and restoration of thermal polarization for all $I > 1$ (quadrupolar and multipolar) nuclei. However, weaker relaxation pathways, often neglected in the discussion of the relaxation of quadrupolar nuclei, are responsible for relaxation-induced polarization and coherence *transfer*.

In the context of high-resolution and multidimensional NMR, homogeneous line broadenings associated with the efficiency of quadrupolar relaxation present a number of challenging obstacles. In contrast, the general dominance of quadrupolar relaxation generally facilitates its application in the study of molecular dynamics. For applications involving spin- $\frac{1}{2}$ nuclei, it often proves difficult to isolate and identify competitive relaxation pathways. Furthermore, for spin- $\frac{1}{2}$ nuclei, inter- and intramolecular effects must be differentiated, whereas quadrupolar relaxation is purely intramolecular in nature.

Finally, from a theoretical vantage, a discussion of quadrupolar relaxation can be utilized to illustrate numerous symmetries and characteristics common to spin relaxation in any multistate system.

2 THE ELECTRIC QUADRUPOLE INTERACTION

The electric quadrupolar interaction between a nuclear spin $\hat{I}$ and a nonzero electric field gradient can be written compactly in tensor notation, $\hat{\mathcal{F}}^{QI} \propto \hat{I} \cdot \mathbf{Q} \cdot \hat{I}$. When written in this manner, the functional similarity between a quadrupolar interaction and an electron zero field splitting or a dipole–dipole coupling between equivalent nuclei is apparent. Since the coupling tensor $\mathbf{Q}$ is both symmetric and traceless, only two of the three principal components are independent. Although various conventions exist, this coupling is usually characterized by a principal value $q_{zz} \sum q_I$ and asymmetry $\eta = (q_{yy} - q_{xx})/q_{zz}$, with $|q_{zz}| > |q_{xx}| > |q_{yy}|$.

Application of the Wigner–Eckart theorem demonstrates that the quadrupolar interaction vanishes unless $I \geq 1$. Some of the more important members of the set of nuclei subject to the quadrupolar interaction are ^2H and ^{14}N ($I = 1$), ^7Li and ^{23}Na ($I = \frac{3}{2}$), ^{17}O and ^{27}Al ($I = \frac{5}{2}$), and ^{43}Ca and ^{59}Co ($I = \frac{7}{2}$).

If the electric field gradient tensor is axially symmetric ($\eta = 0$), the quadrupolar coupling can be written simply as

$$\hat{\mathcal{F}}^{QI} = \frac{e^2 q_I Q_I}{4I(2I-1)\hbar} (3\hat{I}_{z\text{mol}}^2 - \hat{I}^2) \quad (1)$$

Additional parameters appearing in equation (1) include the charge q_I and the nuclear electric quadrupole moment eQ_I . Occasionally, the quadrupolar coupling is written in terms of a gradient anisotropy $\Delta Q = \frac{3}{2}q_I = \frac{3}{2}q_{zz} = q_{zz} - \frac{1}{2}(q_{xx} + q_{yy})$. A subscript is attached to the operator $\hat{I}_z$ to emphasize that this interaction is defined in the molecular frame. In the presence of an applied external magnetic field $\mathbf{B}_0$, where $|\gamma_I B_0 \sum \omega_I| \gg |e^2 q_I Q_I / \hbar|$, the spins are effectively quantized in the laboratory frame. In all subsequent discussion, this form of the high-field approximation will be implicit. For arbitrary relative orientations of these two frames, $\hat{\mathcal{F}}^{QI}$ can be written as a scalar product of spin and spatial coordinates:

$$\hat{\mathcal{F}}^{QI} = \xi_{QI} \sum_n (-1)^n \hat{T}_Q^n(I) V_Q^{-n}(\theta, \phi) \quad (2a)$$

The spin operators are defined as

$$T_Q^{\pm 2} = \frac{\hat{I}_{\pm}^2}{I(2I-1)}, \quad \hat{T}_Q^{\pm 1} = \mp \frac{\hat{I}_{\pm}(2\hat{I}_z + 1)}{I(2I-1)} \quad (2b)$$

$$\hat{T}_Q^0 = \left(\frac{2}{3}\right)^{1/2} \frac{3\hat{I}_z^2 - \hat{I}^2}{I(2I-1)}$$

The lattice or orientation functions $V_Q^n(\theta, \phi)$ are normalized rank-2 spherical harmonics. The angular arguments position the unique axis of the diagonalized electric field gradient tensor in the laboratory frame. The interaction constant is defined as $\xi_{QI} = (\frac{3}{40}\pi)^{1/2} e^2 q_I Q_I / \hbar$.

Hence, in a rigid system such as a solid, the energy level spacings for quadrupolar nuclei depend on the molecular orientation relative to the direction of the external field. These

2 RELAXATION THEORY FOR QUADRUPOLEAR NUCLEI

levels do not vary in time, and a rigid lattice powder pattern results. However, in the presence of molecular motions, the energy levels appear time-dependent and act as a source of magnetic relaxation.

For a nonaxially symmetric field gradient, the electric quadrupolar interaction takes the form

$$\hat{\mathcal{H}}^{QI} = \frac{e^2 q_I Q_I}{4I(2I-1)\hbar} [(3\hat{I}_{z\text{mol}}^2 - \hat{I}^2) + \frac{1}{2}\eta(\hat{I}_+^2 + \hat{I}_-^2)] \quad (3)$$

Unfortunately, the analog of equation (2a) is cumbersome, and the separation of spin and spatial coordinates from the interaction constants proves impossible. However, it is possible to rewrite any traceless rank-2 tensor $\mathbf{Q}$ as the sum of two, axially symmetric composites:

$$\begin{bmatrix} q_{xx} & \vdots & \vdots \\ \vdots & \ddots & \vdots \\ \vdots & \vdots & q_{yy} \\ \vdots & \vdots & \vdots \\ \vdots & \vdots & q_{zz} \end{bmatrix} = \Delta Q^+ \begin{bmatrix} \frac{2}{3} & \vdots & \vdots \\ \vdots & \ddots & \vdots \\ \vdots & \vdots & -\frac{1}{3} \\ \vdots & \vdots & \vdots \\ \vdots & \vdots & -\frac{1}{3} \end{bmatrix} + \Delta Q^- \begin{bmatrix} -\frac{1}{3} & \vdots & \vdots \\ \vdots & \ddots & \vdots \\ \vdots & \vdots & \frac{2}{3} \\ \vdots & \vdots & \vdots \\ \vdots & \vdots & -\frac{1}{3} \end{bmatrix} \quad (4a)$$

where

$$\left. \begin{aligned} \Delta Q^+ &= q_{xx} - q_{zz} = -\Delta Q(1 + \frac{1}{3}\eta) \\ \Delta Q^- &= q_{yy} - q_{zz} = -\Delta Q(1 - \frac{1}{3}\eta) \\ \Delta Q &= q_{zz} - \frac{1}{2}(q_{xx} + q_{yy}) \\ \eta &= \frac{3(q_{yy} - q_{xx})}{2\Delta Q} \end{aligned} \right\} \quad (4b)$$

An important equivalence between the $(\Delta Q, \eta)$ and the $(\Delta Q^+, \Delta Q^-)$ representations is

$$\begin{aligned} & \frac{1}{2}[(q_{xx} - q_{yy})^2 + (q_{xx} - q_{zz})^2 + (q_{yy} - q_{zz})^2] \\ &= (\Delta Q)^2 (1 + \frac{1}{3}\eta^2) \\ &= (\Delta Q^+)^2 + (\Delta Q^-)^2 - (\Delta Q^+)(\Delta Q^-) \end{aligned} \quad (5)$$

The two resultant anisotropies $\Delta Q^\pm$ are axially symmetric and mutually orthogonal. This alternative description enables the separation of the interaction constants from the lattice variables as implied by equation (2a). However, with respect to relaxation considerations, these two composite interactions are temporally correlated, and this correlation must not be neglected.

3 ELECTRIC QUADRUPOLEAR RELAXATION OF ATHERMAL SPIN POLARIZATIONS

Spin-lattice or longitudinal relaxation in the $(2I + 1)$ -level system associated with a collection of isolated spin- I nuclei can be described in master equation form:¹

$$-\frac{d}{dt}P_n = \sum_{m \neq n} W_{nm}(\Delta P_m - \Delta P_n) \quad (6)$$

P_n is the population of the n th state, ΔP_n denotes the deviation of this population from the associated thermal equilibrium value, $\Delta P_n = P_n - P_n(\text{eq})$, and $W_{nm} (=W_{mn})$ is the appropriate transition probability per unit time. Because of the nature of the quadrupolar interaction, W_{nm} vanishes unless $m = n \pm 1$ or $m = n \pm 2$. Values for these two transition probabilities can be written in concise form as

$$\begin{aligned} W_{n,n-1} &= W_{-n+1,-n} \\ &= \frac{2(2n-1)^2(I-n+1)(I+n)}{I^2(2I-1)^2} J_1^Q(\omega_I) \end{aligned} \quad (7)$$

$$\begin{aligned} W_{n,n-2} &= W_{-n+2,-n} \\ &= \frac{2(I-n+2)(I-n+1)(I+n-1)(I+n)}{I^2(2I-1)^2} J_2^Q(2\omega_I) \end{aligned} \quad (8)$$

The spectral density function² for an *axially symmetric quadrupolar* coupling is defined as

$$\begin{aligned} J_k^Q(\omega) &= (4\pi)^{-1}(\xi_{QI})^2 \\ &\times \text{Re} \left[\int_0^\infty \langle Y_2^k(\theta(t), \phi(t)) Y_2^{-k}(\theta(0), \phi(0)) \rangle \right. \\ &\quad \left. \times \exp(-i\omega t) dt \right] \end{aligned} \quad (9)$$

For isotropic media ($\langle \hat{\mathcal{H}}^{QI}(t) \rangle = 0$), the k dependence of the spectral density is superfluous.³ In subsequent developments, *unless this index is explicitly shown*, the limit $J_k^Q(\omega) = J_{k'}^Q(\omega) \sum J^Q(\omega)$ is assumed.

For *isotropic, diffusional reorientation* of the molecular frame relative to the laboratory frame, equation (9) reduces to

$$J^Q(\omega) = \frac{3}{160} \left(\frac{e^2 q_I Q_I}{\hbar} \right)^2 \frac{\tau_2}{1 + \omega^2 \tau_2^2} \quad (10)$$

The correlation time $\tau_2 = \frac{1}{6}D$, where D is the rotational diffusion constant.

For *symmetric-top reorientation* characterized by an axially symmetric diffusion tensor with principal components D_{zz} and $D_{xx} = D_{yy}$,

$$\begin{aligned} J^Q(\omega) &= \frac{3}{640} \left(\frac{e^2 q_I Q_I}{\hbar} \right)^2 \left[\frac{(3\cos^2\theta - 1)^2 \tau_{20}}{1 + (\omega\tau_{20})^2} \right. \\ &\quad \left. + \frac{12\cos^2\theta \sin^2\theta \tau_{21}}{1 + (\omega\tau_{21})^2} + \frac{3\sin^4\theta \tau_{22}}{1 + (\omega\tau_{22})^2} \right] \end{aligned} \quad (11)$$

Here θ is the angle between the principal axes of the diffusion and electric quadrupole tensors. The three correlation times are defined as $1/\tau_{2n} = 6D_{zz} + n^2(D_{zz} - D_{xx})$. In general, the molecular coordinate frames that diagonalize the diffusion and the electric field gradient tensors are not coincident.

The spectral density function, for an *asymmetric quadrupolar* coupling, assuming symmetric-top diffusional reorientation, can be described with either one of the two alternative

representations discussed earlier:

$$J^Q(\omega) = (16\pi)^{-1} \left\{ \frac{[\xi_{QIx}(3\cos^2\theta_x - 1)^2 + \xi_{QIy}(3\cos^2\theta_y - 1)]^2\tau_{20}}{1 + (\omega\tau_{20})^2} + 3(\xi_{QIx})^2 \left[\frac{4\cos^2\theta_x \sin^2\theta_x \tau_{21}}{1 + (\omega\tau_{21})^2} + \frac{\sin^4\theta_x \tau_{22}}{1 + (\omega\tau_{22})^2} \right] + 3(\xi_{QIy})^2 \left[\frac{4\cos^2\theta_y \sin^2\theta_y \tau_{21}}{1 + (\omega\tau_{21})^2} + \frac{\sin^4\theta_y \tau_{22}}{1 + (\omega\tau_{22})^2} \right] + 6\xi_{QIx}\xi_{QIy} \left[\frac{4\cos\theta_x \cos\theta_y \sin\theta_x \sin\theta_y \cos(\phi_x - \phi_y)\tau_{21}}{1 + (\omega\tau_{21})^2} + \frac{\sin^2\theta_x \sin^2\theta_y \cos(2\phi_x - 2\phi_y)\tau_{22}}{1 + (\omega\tau_{22})^2} \right] \right\} \quad (12)$$

or

$$J^Q(\omega) = \frac{3}{640} \left(\frac{e^2 q_I Q_I}{\hbar} \right)^2 \left\{ \frac{(3\cos^2\theta - 1 - \eta \sin^2\theta \cos 2\phi)^2 \tau_{20}}{1 + (\omega\tau_{20})^2} + [12\sin^2\theta [\cos^2\theta (1 + 2\eta \cos 2\phi) + (\frac{1}{3}\eta)^2 (1 - \cos^2 2\phi \sin^2\theta)] \tau_{21}] [1 + (\omega\tau_{21})^2]^{-1} + [3\sin^4\theta - 2\eta \sin^2\theta (\cos^2\theta + 1) \cos 2\phi + \frac{1}{3}\eta^2 (\cos^2 2\phi \sin^4\theta + 4\cos^2\theta)] \frac{\tau_{22}}{1 + (\omega\tau_{22})^2} \right\} \quad (13)$$

The parameters ξ_{QIx} and ξ_{QIy} are defined as $(q_{xx} - q_{zz})(\frac{1}{30}\pi)^{1/2} e^2 Q_I / \hbar$ and $(q_{yy} - q_{zz})(\frac{1}{30}\pi)^{1/2} e^2 Q_I / \hbar$, respectively. Utilizing equation (5), it can be seen that for isotropic reorientation, equation (12) or equation (13) reduces to

$$J^Q(\omega) = (1 + \frac{1}{3}\eta^2) \frac{3}{160} \left(\frac{e^2 q_I Q_I}{\hbar} \right)^2 \frac{\tau_2}{1 + \omega^2 \tau_2^2} = [(q_{xx} - q_{yy})^2 + (q_{xx} - q_{zz})^2 + (q_{yy} - q_{zz})^2] \times \frac{1}{240} \left(\frac{e^2 Q_I}{\hbar} \right)^2 \frac{\tau_2}{1 + \omega^2 \tau_2^2} \quad (14)$$

Although equation (6) implies that the spin-lattice relaxation is described by $2I + 1$ coupled equations, transformation to an appropriate operator basis, which results in both a conceptual and mathematical simplification, proves otherwise. Using the irreducible spherical tensor basis consisting of the operators

$$\left. \begin{aligned} \hat{T}_1^0 &\propto \langle \hat{I}_z \rangle \\ \hat{T}_2^0 &\propto \langle 3\hat{I}_z^2 - \hat{I}^2 \rangle \\ \hat{T}_3^0 &\propto \langle 5\hat{I}_z^3 - \hat{I}_z(3\hat{I}^2 - 1) \rangle \\ \hat{T}_4^0 &\propto \langle 35\hat{I}_z^4 - 5\hat{I}_z^2(6\hat{I}^2 - 5) + 3\hat{I}^2(\hat{I}^2 - 2) \rangle \\ \hat{T}_5^0 &\propto \langle 63\hat{I}_z^5 - 35\hat{I}_z^3(2\hat{I}^2 - 3) + (15\hat{I}^4 - 50\hat{I}^2 + 12)\hat{I}_z \rangle \\ \hat{T}_6^0 &\propto \langle 231\hat{I}_z^6 - 105\hat{I}_z^4(3\hat{I}^2 - 7) + 21\hat{I}_z^2(5\hat{I}^4 - 25\hat{I}^2 + 14) \\ &\quad - 5(\hat{I}^6 - 8\hat{I}^4 + 12\hat{I}^2) \rangle \\ &\vdots \end{aligned} \right\} \quad (15)$$

the longitudinal relaxation is described by the concise expression

$$-\frac{d}{dt} \hat{T}_L^0 = \sum_{L'} R_{L,L'}^{0,I} (\Delta \hat{T}_{L'}^0) \quad (16)$$

If extreme narrowing [$J_k^Q(0) = J_k^Q(\omega_0) = J_k^Q(2\omega_0) \sum J_k^Q$] and spatial isotropy [$J_k^Q(\omega) = J_k^Q(\omega_0)$] obtain then⁴

$$R_{L,L'}^{0,I} = \delta_{L,L'} \{2L(L+1)[4I(I+1) - L(L+1) - 1](2I^2 - I)^{-2}\} J^Q \quad (17)$$

For various situations of practical importance, the spectral density J^Q is given by equations (10)–(13). Table 1 provides a listing of $R_{L,L'}^{0,I} J^Q$ for various ranks L and spins I .

If conditions of extreme narrowing and spatial isotropy are not realized, additional couplings of the form $R_{L,L'}^{0,I} = \delta_{L,L\pm 2} C_{L,L\mp 2}^{0,I} [J_1^Q(\omega_I) - J_2^Q(2\omega_I)]$ arise. Specific values of the proportionality constant $C_{L,L\mp 2}^{0,I}$ for various spins I and ranks L can be found in the literature.^{5,6} Thus, monoexponential relaxation of the Zeeman magnetization ($\propto \hat{T}_1^0$) quantified by a well-defined spin-lattice relaxation rate $R_{11}^{0,I} = 1/T_1$ occurs for arbitrary I if and only if extreme narrowing and spatial isotropy obtain. In this limit, $1/T_1 = 4(2I+3)(2I^3 - I^2)^{-1} J^Q$.

The parity of each member of the operator basis introduced in equation (15) with respect to spin inversion is defined by

$$\exp(-i\pi \hat{I}_y) \hat{T}_L^0 \exp(+i\pi \hat{I}_y) = (-1)^L \hat{T}_L^0 \quad (18)$$

Relaxation effected via the quadrupolar interaction does not couple operators of different parity.⁷ If I is an integer then $\hat{T}_1^0$ couples into $I - 1$ additional polarizations of similar parity. An additional manifold comprising I polarizations, including ‘quadrupolar order’ ($\hat{T}_2^0$), also couple together. These latter polarizations are consequential only in anisotropic environments, where residual quadrupolar couplings lift the spectral degeneracy of various transitions. Similarly, if I is a half-integer then $\hat{T}_1^0$ couples into $\frac{1}{2}(2I+1)$ additional polarizations of similar parity. The remaining $\frac{1}{2}(2I-1)$ polarizations of opposite parity also couple together. Obviously, if $I = 1$ then there is monoexponential relaxation of the Zeeman polarization $\hat{T}_1^0$, characterized by the relaxation rate

$$R_{1,1}^{0,1} = 1/T_1 = 4[J_1^Q(\omega_I) + 4J_2^Q(2\omega_I)] \quad (19)$$

and quadrupolar order, characterized by the relaxation rate

$$R_{2,2}^{0,1} = 12J_1^Q(\omega_I) \quad (20)$$

regardless of whether or not extreme narrowing obtains.

Although the relaxation characteristics of $I = 1$ are exceptionally simple, the behavior of $I = \frac{3}{2}$ is only slightly more complex.⁸ Quadrupolar polarization or alignment decays exponentially with rate

$$R_{2,2}^{0,3/2} = \frac{16}{3} [J_1^Q(\omega_I) + J_2^Q(2\omega_I)] \quad (21)$$

Zeeman and octupolar ($\hat{T}_3^0$) order each evolve biexponentially. For an initial spin preparation (perturbation) that only disturbs Zeeman order, it can be shown that

$$\left. \begin{aligned} \frac{\Delta \langle \hat{I}_z(t) \rangle}{\Delta \langle \hat{I}_z(0) \rangle} &= \frac{1}{5} \exp[-\frac{16}{3} t J_1^Q(\omega_I)] \\ &\quad + \frac{4}{5} \exp[-\frac{16}{3} t J_2^Q(2\omega_I)] \\ \frac{\langle \hat{I}_z(0) \rangle - \langle \hat{I}_z(t \rightarrow 0) \rangle}{\Delta \langle \hat{I}_z(0) \rangle} &\approx R_{1,1}^{0,3/2} t \\ &= \frac{16}{15} t [J_1^Q(\omega_I) + 4J_2^Q(2\omega_I)] \end{aligned} \right\} \quad (22)$$

4 RELAXATION THEORY FOR QUADRUPOLEAR NUCLEI

Table 1 The Electric Quadrupolar Relaxation Rates $R_{L,L}^{0,I}$ for Various Spins I and Spin Orders L

	$I = 1$	$I = \frac{3}{2}$	$I = 2$	$I = \frac{5}{2}$	$I = 3$	$I = \frac{7}{2}$	$I = 4$	$I = \frac{9}{2}$

$L = 6$					$\frac{28}{15}J^Q$	$\frac{80}{147}J^Q$	$\frac{111}{28}J^Q$	$\frac{98}{27}J^Q$
$L = 7$						$\frac{32}{21}J^Q$	$\frac{23}{7}J^Q$	$\frac{98}{27}J^Q$
$L = 8$							$\frac{9}{7}J^Q$	$\frac{26}{9}J^Q$
$L = 9$								$\frac{10}{9}J^Q$

$$\left. \begin{aligned} \frac{\langle 5\hat{I}_z^3 - \hat{I}_z(3\hat{I}^2 - 1)(t) \rangle}{\Delta\langle \hat{I}_z(0) \rangle} &= \frac{6}{5} \{ \exp[-\frac{16}{3}tJ_1^Q(\omega_I)] \\ &\quad - \exp[-\frac{16}{3}tJ_2^Q(2\omega_I)] \} \\ \frac{\langle 5\hat{I}_z^3 - \hat{I}_z(3\hat{I}^2 - 1)(t \rightarrow 0) \rangle}{\Delta\langle \hat{I}_z(0) \rangle} &\approx -R_{3,1}^{0,3/2}t \\ &= -\frac{32}{5}t[J_1^Q(\omega_I) - J_2^Q(2\omega_I)] \end{aligned} \right\} \quad (23)$$

For spin $I = \frac{3}{2}$, it is illustrative to define two fictitious spin operators,⁹ $\langle \hat{I}_z^b \rangle = \frac{3}{2}[(P_{3/2} - P_{1/2}) + (P_{-1/2} - P_{-3/2})]$ and $\langle \hat{I}_z^n \rangle = 2(P_{1/2} - P_{-1/2})$. Thus, $\langle \hat{I}_z \rangle = \langle \hat{I}_z^b \rangle + \langle \hat{I}_z^n \rangle$ and $\langle 5\hat{I}_z^3 - \hat{I}_z(3\hat{I}^2 - 1) \rangle = \langle \hat{I}_z^b \rangle - \frac{3}{2}\langle \hat{I}_z^n \rangle$. These identifications permit the following transformation of the kinetic equations for $I = \frac{3}{2}$:

$$\frac{5}{2} \frac{\langle \hat{I}_z^b(t) \rangle - \frac{3}{5}\langle \hat{I}_z^b(\text{eq}) \rangle}{\Delta\langle \hat{I}_z(0) \rangle} = 2 \exp[-\frac{16}{3}tJ_2^Q(2\omega_I)] - \exp[-\frac{16}{3}tJ_1^Q(\omega_I)] \quad (24)$$

$$\frac{5}{3} \frac{\langle \hat{I}_z^n(t) \rangle - \frac{3}{5}\langle \hat{I}_z^n(\text{eq}) \rangle}{\Delta\langle \hat{I}_z(0) \rangle} = \exp[-\frac{16}{3}tJ_1^Q(\omega_I)] \quad (25)$$

For $I = \frac{3}{2}$, one has the highly unusual situation where a specific population difference ($P_{3/2} - P_{1/2}$ or $P_{-1/2} - P_{-3/2}$) is characterized by simple exponential relaxation. Furthermore, if $J_2^Q(2\omega_I) < \frac{1}{2}J_1^Q(\omega_I)$, the deviation population difference $\Delta(P_{1/2} - P_{-1/2})$ initially grows rather than decays!

Although integrated forms of equation (16) cannot be written in tractable form, for higher spin nuclei, the *initial* response to any perturbation of $\hat{I}_z$ is always described by

$$\frac{\langle \hat{I}_z(0) \rangle - \langle \hat{I}_z(t \rightarrow 0) \rangle}{\Delta\langle \hat{I}_z(0) \rangle} \approx R_{1,1}^{0,I}t \quad (26)$$

where

$$R_{1,1}^{0,I} = 1/T_1 = \frac{4}{5}(2I+3)I^{-2}(2I-1)^{-1}[J_1^Q(\omega_I) + 4J_2^Q(2\omega_I)] \quad (27)$$

4 ELECTRIC QUADRUPOLEAR RELAXATION OF NUCLEAR SPIN COHERENCE

Because of the efficiency of the quadrupolar interaction in effecting nuclear spin relaxation, usually inhomogeneous

line broadening can be assumed negligible, and spin-spin or transverse relaxation rates can be abstracted directly from measurement of linewidths.

In addition to the aforementioned $2I + 1$ populations, a collection of isolated spin- I nuclei is characterized by $2I$ single quantum coherences (1QCs), $2I - 1$ double quantum coherences (2QCs), ..., two $(2I - 1)$ QCs and one $(2I)$ QC. At thermal equilibrium, all coherence vanishes. Generalized 'spin-spin' relaxation in a multilevel system can be described in a manner analogous to equation (6):

$$\begin{aligned} -\frac{d}{dt}\chi_{nn'} &= i(\omega_{nn'} + \Omega_{nn'})\chi_{nn'} \\ &\quad + \left[Z_{nn'} + \frac{1}{2} \sum_j (W_{nj} + W_{n'j}) \right] \chi_{nn'} \\ &\quad + \sum_{m,m'} \delta(\omega_{nn'} - \omega_{mm'}) (W_{nm} W_{n'm'})^{1/2} \chi_{mm'} \end{aligned} \quad (28)$$

In the absence of applied rf fields, the evolution of coherence between states $|n\rangle$ and $|n'\rangle$, $\chi_{nn'}$, is characterized by an intrinsic frequency $\omega_{nn'}$, a dynamic frequency shift, $\Omega_{nn'}$, an adiabatic term or zero frequency contribution $Z_{nn'}$, lifetime terms $W_{nn'}$, which were defined earlier, and a secular coupling term $(W_{nm} W_{n'm'})^{1/2}$, which vanishes unless the coherences $\chi_{nn'}$ and $\chi_{mm'}$ are degenerate or overlapping (the secular approximation). The validity of equation (28) is restricted to the motionally narrowed, perturbative regime, $1/\tau_2 \gg Z_{nn'}, |\hat{\mathcal{F}}^{QI}|$.

In the absence of multiplet structure attributed to a residual quadrupolar interaction, each set of $2I + 1 - n$, n QCs are degenerate. With the additional stipulation of extreme narrowing, the perturbation-response characteristics of these coherences are remarkably simple. Once again, this is revealed by transformation to an irreducible spherical tensor operator basis:

$$\left. \begin{aligned} \hat{T}_1^{\pm 1} &\propto \langle \hat{I}_{\pm} \rangle \\ \hat{T}_2^{\pm 1} &\propto \langle \hat{I}_{\pm}(2\hat{I}_z \pm 1) \rangle \\ \hat{T}_2^{\pm 2} &\propto \langle \hat{I}_{\pm}^2 \rangle \\ \hat{T}_3^{\pm 1} &\propto \langle \hat{I}_{\pm}[5\hat{I}_z^2 \pm 5\hat{I}_z + (2 - \hat{I}^2)] \rangle \\ \hat{T}_3^{\pm 2} &\propto \langle \hat{I}_{\pm}^2(\hat{I}_z \pm 1) \rangle \\ \hat{T}_3^{\pm 3} &\propto \langle \hat{I}_{\pm}^3 \rangle \\ &\vdots \\ \hat{T}_{2I}^{\pm(2I-1)} &\propto \langle \hat{I}_{\pm}^{(2I-1)}[2\hat{I}_z \pm (2I-1)] \rangle \\ \hat{T}_{2I}^{\pm 2I} &\propto \langle \hat{I}_{\pm}^{2I} \rangle \end{aligned} \right\} \quad (29)$$

The relaxation behavior of these coherences can be cast in a form identical to equation (16):

$$-\frac{d}{dt}\hat{T}_L^{\pm k} = \pm ik\omega_I + \sum_{L'} R_{L,L'}^{k,I} \hat{T}_L^{\pm k} \quad (30)$$

For the moment, the dynamic frequency shift is ignored.

The validity of the secular approximation ensures that only coherences of similar precessional frequency couple together. In the limit of extreme narrowing,

$$R_{L,L'}^{k,I} = R_{L,L'}^{0,I} = \delta_{LL'} [2L(L+1) \times [4I(I+1) - L(L+1) - 1](2I^2 - I)^{-2}] J^Q \quad (31)$$

When extreme narrowing fails, additional couplings of the form $R_{L,L'}^{k,I} = \delta_{LL\pm 2} \sum_{n=0}^2 C_{L,L\mp 2}^{k,n,I} J_n^Q(n\omega_I)$ arise. Selected values of $C_{L,L\mp 2}^{1,n,I}$ for various spins I and ranks L can be found in the literature.⁶ Again, monoexponential relaxation of single quantum coherence or ‘transverse’ magnetization ($\propto \hat{T}_1^{\pm 1}$), quantified by a well-defined spin–spin relaxation rate $R_{1,1}^{1,I} = 1/T_2$, results for arbitrary I if and only if extreme narrowing obtains: $1/T_2 = 1/T_1 = 4(2I+3)(2I^3 - I^2)^{-1} J^Q$.

However, there are other interesting decay rates that can be expressed in closed analytic form. For example, the dissipation of $(2I)QC$ ($\hat{T}_{2I}^{2I}$) and in-phase ($\hat{T}_{2I-1}^{2I-1}$) and antiphase ($\hat{T}_{2I}^{2I-1}$) $2I - 1$ multiple quantum coherences are determined by the respective rates

$$R_{2I,2I}^{2I,I} = (4I^{-1})J_1^Q(\omega_I) + 8I^{-1}(2I-1)^{-1}J_2^Q(2\omega_I) \quad (32)$$

$$R_{2I-1,2I-1}^{2I-1,I} = 2I^{-2}(2I-1)^{-1}\{3(2I-1)J_0^Q(0) + [4I(2I-1) + (2I-3)^2]J_1^Q(\omega_I) + 2(4I-3)J_2^Q(2\omega_I)\} \quad (33)$$

$$R_{2I,2I}^{2I-1,I} = 2I^{-2}(2I-1)^{-1}\{3(2I-1)J_0^Q(0) + (2I-3)^2J_1^Q(\omega_I) + 2(4I-3)J_2^Q(2\omega_I)\} \quad (34)$$

These expressions demonstrate that for $I = 1$, not only do Zeeman and quadrupolar polarizations relax exponentially, so do both forms of single quantum coherence and the unique double quantum coherence:

$$R_{2,2}^{1,1} = 2[3J_0^Q(0) + J_1^Q(\omega_I) + 2J_2^Q(2\omega_I)] \quad (35)$$

$$R_{1,1}^{1,1} = 1/T_2 = 2[3J_0^Q(0) + 5J_1^Q(\omega_I) + 2J_2^Q(2\omega_I)] \quad (36)$$

$$R_{2,2}^{2,1} = 4J_1^Q(\omega_I) + 8J_2^Q(2\omega_I) \quad (37)$$

Equations (19), (20), and (35)–(37) summarize completely the relaxation characteristics for $I = 1$. Similarly, the description for $I = \frac{3}{2}$, initiated with equations (21)–(25), can now be completed. For $I = \frac{3}{2}$, forms of spin order associated with $\hat{T}_3^{\pm 3}$, $\hat{T}_3^{\pm 2}$, $\hat{T}_2^{\pm 2}$, and $\hat{T}_2^{\pm 1}$ dissipate in time exponentially with the following relaxation rates:

$$R_{3,3}^{3,3/2} = \frac{8}{3}J_1^Q(\omega_I) + \frac{8}{3}J_2^Q(2\omega_I) \quad (38)$$

$$R_{3,3}^{2,3/2} = \frac{8}{3}J_0^Q(0) + \frac{8}{3}J_2^Q(2\omega_I) \quad (39)$$

$$R_{2,2}^{2,3/2} = \frac{8}{3}J_0^Q(0) + \frac{16}{3}J_1^Q(\omega_I) + \frac{8}{3}J_2^Q(2\omega_I) \quad (40)$$

$$R_{2,2}^{1,3/2} = \frac{8}{3}J_0^Q(0) + \frac{8}{3}J_1^Q(\omega_I) + \frac{16}{3}J_2^Q(2\omega_I) \quad (41)$$

In-phase and doubly antiphase $1QC$, $\hat{T}_1^{\pm 1}$ and $\hat{T}_3^{\pm 1}$, couple together, and each evolves biexponentially. For an initial spin preparation (perturbation) that selectively disturbs one-spin order, $\langle \hat{I}_{\pm}(0) \rangle \neq 0$, it can be shown that

$$\left. \begin{aligned} \frac{\langle \hat{I}_{\pm}(t) \rangle}{\langle \hat{I}_{\pm}(0) \rangle} &= \frac{1}{3} \exp[-\frac{8}{3}tJ_1^Q(\omega_I)] \\ &\times \{3 \exp[-\frac{8}{3}tJ_0^Q(0)] + 2 \exp[-\frac{8}{3}tJ_2^Q(2\omega_I)]\} \\ - \frac{\langle I_{\pm}(t \rightarrow 0) \rangle - \langle \hat{I}_{\pm}(0) \rangle}{\langle \hat{I}_{\pm}(0) \rangle t} &\approx R_{1,1}^{1,3/2} = 1/T_2 \\ &= \frac{8}{15}[3J_0^Q(0) + 5J_1^Q(\omega_I) + 2J_2^Q(2\omega_I)] \end{aligned} \right\} \quad (42)$$

$$\left. \begin{aligned} \frac{\langle \hat{I}_{\pm}[5\hat{I}_z^2 \pm 5\hat{I}_z(2 - \hat{I}^2)](t) \rangle}{\langle \hat{I}_{\pm}(0) \rangle} &= \frac{6}{5} \exp[-\frac{8}{3}tJ_1^Q(\omega_I)] \{ \exp[-\frac{8}{3}tJ_0^Q(0)] \\ &- \exp[-\frac{8}{3}tJ_2^Q(2\omega_I)] \} \\ - \frac{\langle \hat{I}_{\pm}[5\hat{I}_z^2 \pm 5\hat{I}_z(2 - \hat{I}^2)](t \rightarrow 0) \rangle}{\langle \hat{I}_{\pm}(0) \rangle t} &\approx R_{3,1}^{1,3/2} \\ &= \frac{16}{5}[J_0^Q(0) - J_2^Q(2\omega_I)] \end{aligned} \right\} \quad (43)$$

Introducing two fictitious spin operators $\langle \hat{I}_{\pm}^b \rangle = \sqrt{3}$ ($\chi_{3/2, 1/2} + \chi_{-1/2, -3/2}$) and $\langle \hat{I}_{\pm}^n \rangle = 2\chi_{1/2, -1/2}$ {with $\langle \hat{I}_{\pm} \rangle = \langle \hat{I}_{\pm}^b \rangle + \langle \hat{I}_{\pm}^n \rangle$ and $\langle \hat{I}_{\pm}[5\hat{I}_z^2 \pm 5\hat{I}_z(2 - \hat{I}^2)] \rangle$ } results in the following transformation of the kinetic equations for $I = \frac{3}{2}$:

$$\frac{5}{2} \frac{\langle \hat{I}_{\pm}^b(t) \rangle}{\langle \hat{I}_{\pm}^b(0) \rangle} = \exp[-\frac{8}{3}tJ_2^Q(2\omega_I) - \frac{8}{3}tJ_1^Q(\omega_I)] \quad (44)$$

$$\frac{5}{3} \frac{\langle \hat{I}_{\pm}^n(t) \rangle}{\langle \hat{I}_{\pm}^n(0) \rangle} = \exp[-\frac{8}{3}tJ_0^Q(0) - \frac{8}{3}tJ_1^Q(\omega_I)] \quad (45)$$

For $I = \frac{3}{2}$ both of the coherences $\langle \hat{I}_{\pm}^b \rangle$ and $\langle \hat{I}_{\pm}^n \rangle$ are characterized by simple exponential relaxation. This representation clearly illustrates one of the most interesting and useful feature of electric quadrupolar relaxation. The decay of coherence between the states $|\frac{1}{2}\rangle$ and $|- \frac{1}{2}\rangle$ is determined by a rate free from adiabatic contributions.

In numerous practical situations, a partially averaged quadrupole coupling of residual amplitude $\langle \hat{\mathcal{F}}^{QI}(t) \rangle = \omega_Q (3\hat{I}_z^2 - \hat{I}^2)$ removes spectral degeneracies and eliminates all secular couplings from equation (28). In this limit, the free decay of nQC between states $|m\rangle$ and $|m-n\rangle$ is characterized by a unique, well-defined relaxation rate, which can be written in closed form as

$$\begin{aligned} (1/T_2)_{m,m-n} &= [I(2I-1)]^{-2} \{ [6n^2(2m-n)^2]J_0^Q(0) \\ &+ [4(4m^2+1)[I(I+1)-m^2]-16m^2 \\ &- 2n(2m-n)[4I(I+1)-8m^2-5 \\ &+ 4n(2m-n)]J_1^Q(\omega_I) \\ &+ [4(I^2-m^2-1)[I(I+2)-m^2]+16m^2 \\ &+ 2n(2m-n)[2I(I+1)-2m^2-5 \\ &+ n(2m-n)]J_2^Q(2\omega_I) \} \end{aligned} \quad (46)$$

Once again, it is emphasized that the coherence between states $|m\rangle$ and $|-m\rangle$ has no adiabatic $[J_0^Q(0)]$ contribution. In the slow motion limit $[\omega_0\tau_2 \gg 1]$, or, equivalently, $J_0^Q(0) \gg J_1^Q(\omega_I), J_2^Q(2\omega_I)$, all transitions except the $|m\rangle \leftrightarrow |-m\rangle$ n -quantum transition are dramatically broadened leaving behind a solitary, narrowed component, which contributes a fractional intensity

$$\left[\prod_{i=1}^{n+1} (2i-1) \right] \left[\prod_{i=1}^n (2I+2i-n) \right] \left[\prod_{i=1}^n (2i) \right]^{-1} \left[\prod_{i=1}^{n+1} (2I+2i-n-1) \right]^{-1} \quad (47)$$

to the overall intensity of the n QC. For half-integral spin, the 1QC is the transition that attracts most interest. The relaxation rate for this unique 1QC is defined as

$$(1/T_2)_{1/2,-1/2} = (2I+3)I^{-2}(2I-1)^{-1} \{ 2J_1^Q(\omega_I) + [(I+\frac{3}{2})(I-\frac{1}{2})-1]J_2^Q(2\omega_I) \} \quad (48)$$

Equation (48) is more general than suggested, and obtains in isotropic media for those situations where $J^Q(0)$ dominates, thereby quenching the secular coupling. Equations (46) and (48) assume that $J_k^Q(k\omega_I \pm 3k(2I-k)\omega_Q) = J_k^Q(k\omega_I)$. In the unlikely situation where this assumption fails, equation (46) becomes much more complex. For example, the specific relaxation rate $(1/T_2)_{1/2,-1/2}$ is given by

$$\begin{aligned} (1/T_2)_{1/2,-1/2} = [I(2I-1)]^{-2} \{ & [4I(I+1)-3][J_1^Q(\omega_I+6\omega_Q) \\ & + J_1^Q(\omega_I-6\omega_Q)] \\ & + (I+\frac{3}{2})(I-\frac{1}{2})\{(I-\frac{3}{2})(I+\frac{5}{2}) \\ & \times [J_2^Q(2\omega_I+18\omega_Q) + J_2^Q(2\omega_I-18\omega_Q)] \\ & + (I+\frac{1}{2})^2[J_2^Q(2\omega_I+6\omega_Q) + J_2^Q(2\omega_I-6\omega_Q)]\} \} \quad (49) \end{aligned}$$

5 ELECTRIC QUADRUPOLEAR RELAXATION IN THE ROTATING FRAME

The preceding sections have summarized nuclear spin relaxation induced by the electric quadrupolar interaction in the absence of applied rf fields. However, sometimes it is advantageous and more informative to perform relaxation studies in the presence of a resonant or ‘spin locking’ field. The resultant measurement of relaxation in ‘the rotating frame’, provides the researcher with the opportunity to examine certain spectral densities while selectively suppressing other contributions.

It has been shown that expressions for rotating frame relaxation can be obtained very simply by replacing spectral density functions in the laboratory frame by new linear combinations of spectral density functions J_{kp}^Q .¹⁰ If it is assumed that a spin lock field of amplitude B_{sl} ($\gamma IB_{sl} = \omega_{sl} \ll \omega_I/\gamma_I$) is applied on resonance then

$$J_{0\rho}^Q(0) = \frac{1}{4}J_0^Q(0) + \frac{3}{4}J_2^Q(2\omega_I) \quad (50)$$

$$J_{1\rho}^Q(\omega_I) = \frac{1}{2}J_1^Q(\omega_I) + \frac{1}{2}J_2^Q(2\omega_I) \quad (51)$$

$$J_{2\rho}^Q(2\omega_I) = \frac{3}{8}J_0^Q(2\omega_{sl}) + \frac{1}{2}J_1^Q(\omega_I) + \frac{1}{8}J_2^Q(2\omega_I) \quad (52)$$

Thus, equation (27) becomes

$$R_{1,1}^{0,I\rho} = 1/T_{1\rho} = \frac{2}{5}(2I+3)I^{-2}(2I-1)^{-1} \times [3J_0^Q(2\omega_{sl}) + 5J_1^Q(\omega_I) + 2J_2^Q(2\omega_I)] \quad (53)$$

and the analogous expression for $R_{1,1}^{1,I}$,

$$R_{1,1}^{1,I} = 1/T_2 = \frac{2}{5}(2I+3)I^{-2}(2I-1)^{-1} \times [3J_0^Q(0) + 5J_1^Q(\omega_I) + 2J_2^Q(2\omega_I)] \quad (54)$$

reduces to

$$\begin{aligned} R_{1,1}^{1,I\rho} = 1/T_{2\rho} = \frac{1}{10}(2I+3)I^{-2}(2I-1)^{-1} \\ \times [3J_0^Q(2\omega_{sl}) + 3J_0^Q(0) \\ + 14J_1^Q(\omega_I) + 20J_2^Q(2\omega_I)] \quad (55) \end{aligned}$$

All expressions previously introduced can be transcribed in a similar fashion.

6 THE ELECTRIC QUADRUPOLEAR INTERACTION AND DYNAMIC FREQUENCY SHIFTS

The dynamic frequency shift is associated with the imaginary part of the spectral density function introduced in equation (9):

$$\begin{aligned} L_k^Q(\omega) = (\xi_{QI})^2 \text{Im} \left[\int_0^\infty \langle Y_2^k(\theta(t), \phi(t)) Y_2^{-k}(\theta(0), \phi(0)) \rangle \right. \\ \left. \times \exp(-i\omega t) dt \right] \quad (56) \end{aligned}$$

For isotropic, diffusional reorientation of the molecular frame relative to the laboratory frame, equation (56) reduces to

$$L^Q(\omega) = \frac{3}{160} \left(\frac{e^2 q_I Q_I}{\hbar} \right)^2 \frac{\omega \tau_2^2}{1 + \omega^2 \tau_2^2} = \omega \tau_2 J^Q(\omega) \quad (57)$$

Because the dynamic frequency shift is negligible in extreme narrowing and has no adiabatic component, often this term is dismissed. However, it has been shown previously that the relaxations of numerous coherences also have no adiabatic contribution, and, in the slow motion regime, the dynamic shift can be a dominating effect.¹¹ The maximum dynamic frequency shift is on the order of $|\hat{\mathcal{F}}^{QI}|^2/\omega_I$ and can easily exceed several kilohertz.

To illustrate the effect of the dynamic shift, consider the coherence between states $|m\rangle$ and $|m-n\rangle$ in the limit where each transition is well resolved. The dynamic frequency shift of this coherence is described by the expression

$$\begin{aligned} \Omega_{m,m-n} = 2n[I(2I-1)]^{-2} \{ [-4I(I+1) + 24m(m-n) \\ + 8n^2 + 1]L_1^Q(\omega_I) + [4I(I+1) - 12m(m-n) \\ - 4n^2 - 2]L_2^Q(2\omega_I) \} \quad (58) \end{aligned}$$

Of special importance are expressions for those coherences where the adiabatic contribution to the linewidth vanishes:

$$\begin{aligned} \Omega_{m,-m} = 4m[I(2I-1)]^{-2} \{ [-4I(I+1) + 8m^2 + 1]L_1^Q(\omega_I) \\ + [4I(I+1) - 4m^2 - 2]L_2^Q(2\omega_I) \} \quad (59) \end{aligned}$$

The relative shift of any two components of the n QC is given by the expression

$$\Omega_{m,m-n} - \Omega_{m',m'-n} = 24n[I(2I-1)]^{-2}(m-m')(m+m'-n) \times [2L_1^Q(\omega_I) - L_2^Q(2\omega_I)] \quad (60)$$

Except for the case where $m = I$ and $n = 2I$, equation (58) differs dramatically from equation (46). Consequently, there is no simple relationship between the dynamic shift and linewidth (relaxation rate) for any given spectral component.

The effects of the dynamic frequency shift on the various forms of spin order, $\hat{T}_L^{\pm k}$, can be written in a manner analogous to equation (30):

$$-\frac{d}{dt}\hat{T}_L^{\pm k} = \sum_{L'} S_{L,L'}^{k,I} \hat{T}_{L'}^{\pm k} \quad (61)$$

Like other relaxation parameters introduced previously, $S_{L,L'}^{k,I}$ vanishes unless $L = L'$, $L' \pm 2$. In extreme narrowing, the term $S_{1,3}^{1,I}$ is proportional to $2L_1^Q(\omega_I) - L_2^Q(2\omega_I)$ and scales as $(\omega_I\tau_2)^3 J^Q(\omega_I)$, thus ensuring the insignificance of the dynamic frequency shift in this limit. The intrinsic shift of the transverse 'magnetization', $S_{1,1}^{1,I}$, can be written as

$$S_{1,1}^{1,I} = -\frac{2}{3}(2I+3)I^{-2}(2I-1)^{-1}[L_1^Q(\omega_I) + 2L_2^Q(2\omega_I)] \quad (62)$$

Figure 1 summarizes the frequency dependence of the various relaxation rates introduced thus far. Rates applicable for $I = 1$ are shown explicitly. Note that the second-order dynamic frequency shift associated with the 2QC exceeds the relaxation rate in the slow motion limit ($\omega_I\tau_2 \gg 1$).

Figure 1 A plot of the various quadrupolar relaxation rates for an $I = 1$ nuclear spin versus isotropic rotational correlation time, measured in units of the reciprocal Larmor frequency. Conventional rates, $1/T_1$, $1/T_2$ ($= 1/T_{1\rho}$ in the limit shown), and $1/T_{2\rho}$ are represented by the heavy full curves. Rates associated with relaxation of the three forms of two-spin order are shown as lighter full curves. The dynamic frequency shift of the double quantum coherence is shown as a dotted curve

7 EFFECTS OF ALTERNATIVE SOURCES OF RELAXATION FOR QUADROPOLAR NUCLEI

Although $I \geq 1$ nuclei generally are driven towards equilibrium by electric quadrupolar relaxation, other sources of relaxation play important roles in relaxation-induced polarization and coherence transfer.¹² For example, as resonance experiments are performed at higher and higher magnetic field strengths, anisotropic shielding will continue to play an increasingly important role in magnetic relaxation of quadrupolar nuclei.

Utilizing the spin operators and notation introduced earlier, the relaxation of a nuclear spin I by an axially symmetric anisotropic shielding ($\Delta\sigma = \sigma_{zz} - \sigma_{xx} = \sigma_{zz} - \sigma_{yy}$) is described by the concise, general expression:

$$R_{L,L'}^{k,I} = R_{L,L'}^{k,I'} = \delta_{LL'} \{2L(L+1)J_1^{\text{SA}}(\omega_I) + k^2 [\frac{8}{3}J_0^{\text{SA}}(0) - 2J_1^{\text{SA}}(\omega_I)]\} \quad (63)$$

For isotropic reorientation,

$$J^{\text{SA}}(\omega) = \frac{1}{30} \frac{(\gamma_I B_0 \Delta\sigma_I)^2 \tau_2}{1 + \omega^2 \tau_2^2} \quad (64)$$

This expression, when compared with equation (31), indicates that higher forms of spin order are relaxed with increasing efficiency by shielding anisotropy.

Of special interest are the adiabatic contributions, which dominate the decay of coherence when extreme narrowing fails. In the limit where residual couplings result in well-resolved structure, the adiabatic contribution associated with the coherence between states $|m\rangle$ and $|m-n\rangle$ is simply $\frac{8}{3}n^2 J_0^{\text{SA}}(0)$. This result is independent of I or m , and only depends on the coherence order n . Meanwhile, the quadrupolar adiabatic contribution, given by equation (46), is $[I(2I-1)]^{-2}6n^2(2m-n)^2 J_0^Q(0)$. Once again, it is noted that this contribution vanishes when $n = 2m$. It should be clear that there are numerous situations where the electric quadrupolar contribution will be selectively suppressed and the relaxation characteristics of high-spin nuclei can be determined by alternative, intrinsically less efficient, relaxation pathways.

The preceding arguments implicitly presume that relaxation rates for quadrupolar and anisotropic shieldings are additive. Since both interactions are molecule-fixed and transform identically under molecular reorientation, these interactions are temporally correlated, and interference effects between these interactions must be considered. The contribution of this interference to the adiabatic portion of $(1/T_2)_{m,m-n}$ is given by the expression

$$(1/T_2)_{m,m-n}^{\text{adiabatic}} = \frac{1}{5}\zeta n^2(2m-n)(2I^2-I)^{-1} \times (e^2 q_I Q_I / \hbar) \gamma_I B_0 \Delta\sigma_I \tau_2 \quad (65)$$

where ζ is the relevant correlation factor. Unlike other relaxation parameters mentioned thus far, this interference distinguishes between the decay rates of the spin-inverted coherences, $\chi_{m'}$ and $\chi_{-n'-n}$.

To illustrate the significance of equation (65), consider the situation where the unique axis of the quadrupole and anisotropic shielding interactions are coincident ($\zeta = 1$) and the slow motion limit obtains. Assuming the quadrupole interaction is significantly stronger than the anisotropic

shielding interaction, the differential linebroadening can be written as

$$\frac{(1/T_2)_{m,m-n} - (1/T_2)_{-m,n-m}}{(1/T_2)_{m,m-n} + (1/T_2)_{-m,n-m}} = \frac{\frac{16}{9}I(2I-1)(2m-n)\xi}{[\frac{8}{9}I(2I-1)\xi]^2 + (2m-n)^2} \approx \frac{16I(2I-1)}{9(2m-n)}\xi \quad (66)$$

where $\xi = \gamma_I B_0 \Delta\sigma_I / (e^2 q_I Q_I / \hbar)$. For example, if $I = \frac{5}{2}$, the asymmetry in the relaxation rates (linewidths) of the two 1QCs, $\chi_{3/2,1/2}$ and $\chi_{-1/2,-3/2}$, is $\frac{80}{9}\xi$. Assuming that ξ^{-1} is on the order of 100, the anisotropic shielding interaction is 1000 times less effective than the quadrupolar interaction at relaxing 1QC directly [$\frac{8}{3}J_0^{SA}(0) : \frac{6}{25}J_0^Q(0)$]. However, this same set of parameters will result in a 10% relaxation asymmetry between these two components!

Another source of relaxation that may play an increasingly important role in the relaxation of quadrupolar nuclei is the electron–nuclear anisotropic hyperfine interaction. Although the hyperfine interaction can effect nuclear spin relaxation in numerous ways, in this discussion, only relaxation effects attributed to the coupling of a nuclear spin to the thermal average of electron spin, $\langle \hat{S}_z(\text{eq}) \rangle = g_e \beta S(S+1)B_0/3kT$, modulated by molecular reorientation, are considered. In appropriate limits, this interaction, which is formally equivalent to an anisotropic shielding, results in ‘Curie’ relaxation of nuclear spin.¹³ The effect of ‘Curie’ relaxation on the various spin operators introduced earlier can be summarized by the expression

$$R_{L,L'}^{k,I} = R_{L,L'}^{k,I'} = \delta_{L,L'} \{ 2L(L+1)J_1^{\text{CR}}(\omega_I) + k^2 [\frac{8}{3}J_0^{\text{CR}}(0) - 2J_1^{\text{CR}}(\omega_I)] \} \quad (67)$$

For isotropic reorientation,

$$J^{\text{CR}}(\omega) = \frac{3}{10} \left(\frac{g_e \beta S(S+1)B_0}{3kT} \right)^2 (\gamma_I g_e \beta (r^{-3}))^2 \frac{\tau_2}{1 + \omega^2 \tau_2^2} \quad (68)$$

Like anisotropic chemical shielding, this interaction can interfere with the quadrupolar interaction. The contribution of this interference to the adiabatic portion of $(1/T_2)_{m,m-n}$ is given by

$$(1/T_2)_{m,m-n}^{\text{adiabatic}} = \frac{3}{5}\zeta n^2(2m-n)(2I^2 - I)^{-1} \frac{e^2 q_I Q_I}{\hbar} \times \left[\frac{g_e \beta S(S+1)B_0}{3kT} \right]^2 (\gamma_I g_e \beta (r^{-3}))^2 \tau_2 \quad (69)$$

where ζ is the relevant correlation factor.

In general, interference (dipole–quadrupole, anisotropic shielding–quadrupole, ‘Curie spin’–quadrupole, or quadrupole–quadrupole) retards the relaxation process and results

in polarization/coherence transfer. In a spherical tensor description of relaxation, interference (cross correlation) between anisotropic shieldings or ‘Curie spin’ and the electric quadrupolar interaction results in terms such as $R_{L,L\mp 1}^{k,I}$ being nonzero. Hence, various forms of spin order of differing parity are coupled together by these interference terms. This coupling persists in all motional limits. As noted earlier, the magnitudes of these couplings scale as the geometric mean of the two competitive interactions, and can be significant even in the limit where one interaction dominates conventional relaxation parameters.¹⁴

8 IMPACT OF QUADRPOLAR RELAXATION ON SPIN- $\frac{1}{2}$ NUCLEI

In multispin systems containing both quadrupolar ($I \geq 1$) and dipolar ($I = \frac{1}{2}$) nuclei, the high-spin nuclei generally are relaxed efficiently by quadrupolar interactions whereas spin- $\frac{1}{2}$ nuclei relax on a slower timescale. Thus, from the perspective of a spin- $\frac{1}{2}$ nucleus (S), the scalar coupling to a quadrupolar nucleus (I), $J\hat{S} \cdot \hat{I}(t)$, appears time-dependent, and, on the average, vanishes. Although the quadrupolar nucleus provides a source of relaxation (scalar relaxation of the second kind) for spin- $\frac{1}{2}$ nuclei, multiplet structure disappears as these spins are decoupled by the relaxation process.¹⁵

Nevertheless, there are an increasing number of studies demonstrating that various quadrupolar nuclei often exhibit narrowed lines and multiplet structure in solution state NMR studies. Such situations commonly characterize studies involving important isotopes of hydrogen, nitrogen and oxygen. In the limit where the spectrum of spin S consists of $2I + 1$ evenly spaced multiplet components, quadrupolar relaxation of spin I generally provides the dominant relaxation sink for dissipation of S -spin 1QC. However, neither I -spin adiabatic terms nor I -spin dynamic frequency shifts will influence the behavior of spin S . If it is assumed that all $2I + 1$, 1QC components are well resolved then a well-defined relaxation rate $1/T_2$ can be assigned to each coherence associated with the S -spin transition $|\frac{1}{2}, m\rangle \leftrightarrow |-\frac{1}{2}, m\rangle$:

$$(1/T_2)_{I,m} = 4(2I^2 - I)^{-2} \{ [I(I+1)(4m^2 + 1) - m^2(4m^2 + 5)]J_1^Q(\omega_I) + [I^2(I+1)^2 - 2I(I+1)(m^2 + 1) + m^2(m^2 + 5)]J_2^Q(2\omega_I) \} \quad (70)$$

A listing of these relaxation rates for half-integer spin is given in Table 2.

Also, quadrupolar–anisotropic shielding interference—for spin I !—can dramatically effect linewidths in the S spectrum,

Table 2 The Electric Quadrupolar Contribution to the Relaxation Rate $(1/T_2)_{I,m}$ for each Single Quantum Coherence Identified with the Specific Transition $|S = \frac{1}{2}, S_z = \frac{1}{2}; I, m\rangle \leftrightarrow |S = \frac{1}{2}, S_z = -\frac{1}{2}; I, m\rangle$

	$I = \frac{3}{2}$	$I = \frac{5}{2}$	$I = \frac{7}{2}$	$I = \frac{9}{2}$
$m = \pm \frac{1}{2}$	$\frac{8}{3}(J_1^Q + J_2^Q)$	$\frac{16}{25}(J_1^Q + \frac{7}{2}J_2^Q)$	$\frac{40}{147}(J_1^Q + 7J_2^Q)$	$\frac{4}{27}(J_1^Q + \frac{23}{2}J_2^Q)$
$m = \pm \frac{3}{2}$	$\frac{8}{3}(J_1^Q + J_2^Q)$	$\frac{36}{25}(\frac{14}{9}J_1^Q + J_2^Q)$	$\frac{8}{7}(J_1^Q + \frac{9}{7}J_2^Q)$	$\frac{2}{3}(J_1^Q + \frac{13}{6}J_2^Q)$
$m = \pm \frac{5}{2}$		$\frac{4}{5}(2J_1^Q + J_2^Q)$	$\frac{120}{147}(\frac{37}{15}J_1^Q + J_2^Q)$	$\frac{38}{27}(J_1^Q + J_2^Q)$
$m = \pm \frac{7}{2}$			$\frac{8}{21}(3J_1^Q + J_2^Q)$	$\frac{14}{27}(\frac{24}{7}J_1^Q + J_2^Q)$
$m = \pm \frac{9}{2}$				$\frac{2}{9}(4J_1^Q + J_2^Q)$

as shown by the following expression:

$$(1/T_2)_{I,m} = 4m(2I^2 - I)^{-1}[2I(I+1) - 2m^2 - 1] \\ \times \frac{\zeta}{5} \frac{e^2 q_I Q_I}{\hbar} \frac{\gamma_I B_0 \Delta \sigma_I \tau_2}{1 + \omega_I^2 \tau_2^2} \quad (71)$$

Finally, quadrupolar–dipolar interferences can induce significant dynamic frequency shifts of individual spin- $\frac{1}{2}$ multiplet components and serve as a novel source of scalar relaxation.¹⁶

9 SUMMARY

In this article, the essential perturbation–response characteristics of quadrupolar (multipolar) nuclei have been introduced. For electric quadrupolar relaxation in the limit where the spectral density is neither projection- (k) nor frequency-dependent, exceptionally simple behavior is predicted [cf. equation (31)]. Likewise, when residual splittings suppress transverse cross relaxation, elementary expressions adequately describe the decay of all forms of spin coherence [cf. equation (46)]. In the slow motion limit, where adiabatic terms generally dominate the decay of coherence, it is recognized that various coherences, which lack an adiabatic contribution, decay on the timescale of the longitudinal magnetization. For these coherences, the dynamic frequency shift can prove important. Although quadrupolar interactions efficiently dissipate coherence and thermalize polarization, transfer of polarization is driven by interference effects and, necessarily, by weaker interactions that generally play only a very minor role in conventional relaxation studies.

1 INTRODUCTION

Most of the magnetically active nuclei in the Periodic Table possess spins with $S > 1/2$ that are known as quadrupolar nuclei because of the quadrupolar moment of nuclei interacting with surrounding electric field gradient.¹ Quadrupolar interactions, typically in the order of MHz, often dominate over other spin interactions such as dipolar coupling and chemical shift anisotropy and make NMR spectra of powder samples very broad. When the quadrupolar splitting is small compared to the Zeeman energy differences, perturbation theory may be used to express the quadrupolar coupling Hamiltonian to first order.¹

$$H_Q^{(1)} = \frac{c_q}{4S(2S-1)}(3S_z^2 - S^2) \left(\frac{3\cos^2\beta - 1}{2} - \frac{\eta}{2}\sin^2\beta\cos 2\alpha \right) \quad (1)$$

The S_z^2 dependence immediately leads to a vanished first-order effect to the single-quantum $m_z = -1/2 \leftrightarrow 1/2$ transition of half-integer quadrupolar nuclei. Absence of a first-order effect reduces the central transition line width to the order of kHz. Magic-angle sample spinning narrows the central transition line further by suppressing chemical shift anisotropy and dipolar interactions. The improvement on spectral resolution has made NMR spectroscopy of half-integer quadrupolar nuclei a powerful tool for structural characterization of a variety of solid materials despite of the large quadrupolar interactions.²⁻⁵

There are multiple transitions among the $2S + 1$ energy-level manifolds of spins with $S > 1/2$. This article focuses on pairs of single-quantum transitions on two sides of the central transition known as satellite transitions. Satellite transitions are affected by quadrupolar interaction to first order and their static NMR spectra are usually very broad. It is not surprising that there are fewer NMR studies on satellite transitions than on central transitions. However, the advent of magic-angle spinning technology has made the acquisition of satellite transition spectra easier than ever.⁶⁻⁹ Fast sample spinning can average the first-order quadrupolar effect to zero with spinning axis precisely at the magic-angle, yielding sharp resonance lines and spinning sidebands.⁷⁻⁹ Perhaps the best-known satellite transition spectrum is that of KBr. The small quadrupolar coupling from lattice distortion of the nominally cubic KBr (~ 100 kHz) makes the ^{79}Br satellite transitions easily detectable. The sensitivity of satellite transition spinning sidebands on magic-angle setting and the convenience of the Larmor frequency very close to ^{13}C have made KBr an ideal sample for magic-angle calibration.¹⁰

For large quadrupolar couplings, spinning sidebands in MAS satellite transition spectra are broadened by the second-order quadrupolar effect similar to central transition peaks.^{7,9} Averaging the second-order quadrupolar effect has been a long-standing issue in high-resolution NMR of half-integer quadrupolar nuclei. Unlike dipolar coupling and chemical shift anisotropy, the second-order effect contains high-rank anisotropic terms that cannot be averaged by MAS.^{4,5} Residual second-order effects broaden resonance lines and may prevent resolution among nonequivalent sites. Observing satellite transitions can be advantageous in better spectral resolution over the commonly observed central transition. Samoson has discovered that the second-order effect to $\pm 3/2 \leftrightarrow \pm 1/2$ satellite transitions is $24/7$ times smaller than the central transition for $S = 5/2$ spins and the relative position between satellite and central transition peaks can be used to separate the contribution from the isotropic second-order quadrupolar shift for chemical shift measurements.⁶ Results at high magnetic fields and with fast spinning speed have clearly demonstrated these advantages.⁹ Jakobsen et al. have studied the intensities of satellite transition spinning sidebands for measuring quadrupolar coupling parameters in analogy to the analysis of chemical shift spinning sidebands by Maricq and Waugh and by Herzfeld and Berger.^{11,12} Satellite transitions are directly affected by the first-order quadrupolar interactions and the spinning sideband analysis is mostly suitable for small quadrupolar couplings with powder patterns up to 1 MHz wide.⁷ Satellite transitions also play an important role in spin dynamics of central transitions such as in nutation and spin-lock experiments. The central transition matrix element of spin operator S_x equals to $(S + 1/2)$ therefore the nutation frequency of the central transition is $(S + 1/2)$ times faster than a $S = 1/2$ spin with the assumption of an isolated two-level system for the central transition. The presence of satellite transitions causes the central transition coherence to nutate at multiple frequencies that can affect the excitation and the quantitative nature of central transition spectra.¹³ Spin-lock is important in cross-polarization and coherence transfer and can be easily achieved by a continuous-wave RF field for $S = 1/2$ spins. For half-integer quadrupolar nuclei, however, the presence of satellite transitions makes spin-lock of central transitions a non-trivial matter under magic-angle spinning.

The central transition coherence can leak through satellite transitions during repeated zero-crossings induced by the sample rotation.¹⁴

The second-order quadrupolar effect remains even under MAS and broadens resonance lines. Although high magnetic fields can reduce the second-order effect, ideally it is the best to average all anisotropic terms for so-called isotropic NMR spectra. This goal was first achieved by double rotation (DOR). The first rotation at the magic-angle averages the $l = 2$ anisotropic terms and the second rotation inside the MAS rotor at an angle that $P_4(\cos 30.56^\circ) = 0$ averages the residual high-rank $l = 4$ anisotropic terms.¹⁵ A two-dimensional experiment with flipping spinning axis, namely dynamic angle spinning (DAS), was also proposed to refocus the signal decay caused by the anisotropic second-order effect.¹⁶ Both DOR and DAS techniques lead to isotropic NMR spectra of half-integer quadrupolar nuclei; nevertheless the implementation of non-fixed axes sample spinning is technically difficult.^{17,18} The invention of multiple-quantum magic-angle spinning (MQMAS) by Frydman et al. opened a new avenue toward isotropic NMR spectra.^{19,20} Correlation between $-m_q/2 \leftrightarrow m_q/2$ multiple-quantum and central transitions refocuses the signal decay caused by the second-order effect and results in isotropic spectra. Transition-correlated experiments can be performed with commercially available MAS probes and it has gained a widespread use. However, low sensitivities and the poor quantitative nature of the MQ experiment remain as the major obstacles to its applications and a number of excitation and conversion schemes have been developed to improve the efficiencies of manipulating MQ coherence.^{21–32} Recently, a different approach was proposed to dramatically improve the efficiency of transition-correlated experiments.³³ The satellite transition magic-angle spinning (STMAS) experiment correlates single-quantum satellite transitions that can be directly excited and efficiently converted to central transitions.³⁴ The high efficiencies of the satellite transition experiment have been demonstrated. It has also been shown that accurate magic-angle setting and stable sample spinning are required to average out the first-order quadrupolar interactions to satellite transitions for generating isotropic NMR spectra of half-integer quadrupolar nuclei.³⁴

The scope of this article focuses on recent developments on satellite transition NMR spectroscopy particularly the STMAS experiment. The first half presents the theory of satellite transition NMR. The second-order quadrupolar effect to satellite transitions is expanded in rotation matrix elements. The expansion and the comparison with central transitions reveal important features of satellite transition NMR spectra. These features are demonstrated experimentally with model samples of various spins. The second half describes the STMAS experiment. The principle of the experiment to obtain isotropic NMR spectra is explained and the excitation and conversion of satellite transitions are studied. The experiment is demonstrated with various pulse sequences and model samples and the strict requirements on magic-angle setting and sample spinning stability are discussed.

2 QUADROPOLAR EFFECTS

When the Zeeman splitting is sufficiently large compared to the effect of electric field gradients, the magnetization quantum number $m_z = S, S - 1, \dots, -S$ may be used to describe

Zeeman interaction First-order effect Second-order effect

Figure 1 Energy level diagram of a $S = 3/2$ spin

the system to the first order. The energy levels of a nuclear spin S are split into a $2S + 1$ manifold separated by Larmor frequency. The first-order quadrupolar interaction shifts the energy levels by $\omega_q [3m_z^2 - S(S + 1)]$ and has no effect on $-m_z \leftrightarrow m_z$ transition (see Figure 1). For half-integer spins, the $-1/2 \leftrightarrow 1/2$ central transition is a single-quantum transition that can be observed directly. For integer spins, all single-quantum transitions are affected by the first-order quadrupolar interaction and double-quantum transitions may have a vanished first-order effect. High-resolution double-quantum spectroscopy has been explored with indirect detection for ^2H nuclei and with overtone detection for ^{14}N nuclei.^{35–37} The topics on integer-spins can be found in these references and will not be discussed further here. A number of review articles are also recommended for general aspect of central transition NMR and early works on satellite transition spectroscopy.^{38–41}

The second-order quadrupolar effect is derived using Average Hamiltonian theory.⁴² The full quadrupolar Hamiltonian can be expressed in terms of irreducible second-rank spin operators

$$H_Q = \omega_q \sum_{m=-2}^2 (-1)^m Q_{2,-m} T_{2,m}, \quad \omega_q = \frac{2\pi e^2 q_{zz} Q}{2S(2S-1)h} \quad (2)$$

$$T_{2,0} = \frac{(3S_z^2 - S^2)}{\sqrt{6}}$$

$$T_{2,\pm 1} = \frac{\mp(S_{\pm}S_z + S_zS_{\pm})}{2} \quad (3)$$

$$T_{2,\pm 2} = \frac{S_{\pm}^2}{2}, \quad S_{\pm} = S_x \pm iS_y$$

The quadrupolar coupling tensor components $Q_{2,m}$ can be obtained from the components in the principal axis system (PAS) frame through a rotation to the laboratory frame (α, β, γ)

$$Q_{2,m} = \sum_{m'=-2}^2 \rho_{2,m'} D_{m',m}^2(\alpha, \beta, \gamma) \quad (4)$$

$$\rho_{2,0} = \sqrt{\frac{3}{2}}, \quad \rho_{2,\pm 1} = 0, \quad \rho_{2,\pm 2} = -\frac{\eta}{2} \quad (5)$$

$\eta = (q_{yy} - q_{xx})/q_{zz}$ is the asymmetry factor of the EFG tensor. The $T_{2,0}$ term in the quadrupolar Hamiltonian commutes with Zeeman interaction and affects the transitions in the first-order.

The second-order effect can be obtained by applying Average Hamiltonian theory in the NMR rotating frame:⁴³

$$H_Q^{(2)} = - \left\{ Q_{2,-1} Q_{2,1} [T_{2,-1}, T_{2,1}] + \frac{Q_{2,-2} Q_{2,2} [T_{2,-2}, T_{2,2}]}{2} \right\} \frac{\omega_q^2}{\omega_0} \quad (6)$$

where $\omega_0 = -\gamma B_0$ is Larmor frequency. The commutators in the second-order Hamiltonian can be derived explicitly

$$\begin{aligned} [T_{2,-1}, T_{2,1}] &= -(4S^2 - 8S_z^2 - 1) S_z / 2 \\ [T_{2,-2}, T_{2,2}] &= -(2S^2 - 2S_z^2 - 1) S_z \end{aligned} \quad (7)$$

and the product of spatial parameters

$$\begin{aligned} Q_{2,-m} Q_{2,m} &= \sum_{m', m''=-2}^2 \rho_{2,m'} \rho_{2,m''} D_{m',m}^2(\alpha, \beta, \gamma) \\ &\times D_{m'',-m}^2(\alpha, \beta, \gamma) \end{aligned} \quad (8)$$

can be expanded using the Clebsch-Gordon series^{44,45}

$$\begin{aligned} D_{m',m}^2 D_{m'',-m}^2 &= \sum_{l=0}^4 \sum_{m'+m''=-l}^l c(22l, m' m'') \\ &\times c(22l, m - m) D_{m'+m'',0}^l \end{aligned} \quad (9)$$

Equations (6)–(9) lead to the second-order quadrupolar Hamiltonian expanded in rotation matrix elements

$$H_Q^{(2)} = \frac{\omega_q^2}{\omega_0} \sum_{l=0,2,4} C_l(S, S_z) \sum_{m=-l}^l a_{l,m}^{(2)} D_{m,0}^l(\alpha, \beta, \gamma) \quad (10)$$

$$\begin{aligned} C_l(S, S_z) &= c(22l; 1-1) (4S^2 - 8S_z^2 - 1) S_z \\ &+ c(22l; 2-2) (2S^2 - 2S_z^2 - 1) S_z \end{aligned} \quad (11)$$

$$a_{l,m}^{(2)} = \sum_{m'+m''=m} c(22l; m' m'') \rho_{2,m'} \rho_{2,m''} / 2 \quad (12)$$

The expansion coefficients $a_{l,m}^{(2)}$ vanish for $l = 1$ and 3 because of the relation $c(l_1 l_2 l; m_1 m_2) = (-1)^{l_1+l_2+l} c(l_2 l_1 l; m_2 m_1)$ of Clebsch-Gordon coefficients.^{43,44} Thus, the second-order quadrupolar Hamiltonian contains an $l = 0$ isotropic term, the $l = 2$ terms and the high-rank $l = 4$ anisotropic terms.

The shift to transition frequencies by the second-order effect can be calculated from the expectation values of the $C_l(S, S_z)$ in $H_Q^{(2)}$. For central transitions $m_z = -1/2 \leftrightarrow 1/2$

$$\begin{aligned} \omega_{CT} &= \sum_{l=0,2,4} C_l(\alpha, \beta, \gamma) \\ C_l &= \frac{\omega_q^2 [S(S+1) - 3/4]}{\omega_0} \sum_{m=-l}^l c_{l,m} D_{m,0}^l(\alpha, \beta, \gamma) \end{aligned} \quad (13)$$

$$\begin{aligned} c_{l,m} &= -[2c(22l; 1-1) + c(22l; 2-2)] \\ &\times \sum_{m'+m''=m} c(22l; m' m'') \rho_{2,m'} \rho_{2,m''} \end{aligned} \quad (14)$$

Table 1 Expansion Coefficients c_{lm} of the Second-Order Quadrupolar Effect to Central Transitions

	$m = 0$	$m = \pm 2$	$m = \pm 4$
$l = 0$	$\frac{3}{10} \left(1 + \frac{\eta^2}{3} \right)$		
$l = 2$	$\frac{6}{7} \left(1 - \frac{\eta^2}{3} \right)$	$\frac{2\sqrt{6}}{7} \eta$	
$l = 4$	$-\frac{81}{70} \left(1 + \frac{\eta^2}{18} \right)$	$\frac{27\sqrt{10}}{140} \eta$	$-\frac{9\sqrt{70}}{280} \eta^2$

The explicit expressions of $c_{l,m}$ are listed in Table 1.

The second-order quadrupolar Hamiltonian in equation (10) implies that the second-order effect varies among transitions only through the expectation values of $C_l(S, S_z)$. For $m_S - 1/2 \leftrightarrow m_S + 1/2$ satellite transition, the frequency shift from the second-order effect can be expressed in terms of the expansion coefficients of the central transitions and corresponding scaling factors

$$\omega_{ST} = \sum_{l=0,2,4} R_{S,m_S}^l C_l(\alpha, \beta, \gamma) \quad (15)$$

$$R_{S,m_S}^l = 1 - \frac{12m_S^2 [4c(22l; 1-1) + c(22l; 2-2)]}{[4S(S+1) - 3] \cdot [2c(22l; 1-1) + c(22l; 2-2)]} \quad (16)$$

The explicit expressions of the scaling factors for $l = 0, 2$ and 4 are

$$R_{S,m_S}^0 = 1 - \frac{36m_S^2}{4S(S+1) - 3}, \quad l = 0 \quad (17)$$

$$R_{S,m_S}^2 = 1 - \frac{18m_S^2}{4S(S+1) - 3}, \quad l = 2$$

$$R_{S,m_S}^4 = 1 - \frac{68m_S^2}{3[4S(S+1) - 3]}, \quad l = 4$$

Table 2 lists the scaling factors for all satellite transitions with spins S up to $9/2$.

3 1D SATELLITE TRANSITION MAGIC-ANGLE SPINNING SPECTRA

The previous section derived the first and second-order quadrupolar effect to central and satellite transitions. For

Table 2 Scaling Factors of Expansion Coefficients between Satellite and Central Transitions

	$l = 0$	$l = 2$	$l = 4$
$S = 3/2, m_S = \pm 1$	-2	-1/2	-8/9
$S = 5/2, m_S = \pm 1$	-1/8	7/16	7/24
$m_S = \pm 2$	-7/2	-5/4	-11/6
$S = 7/2, m_S = \pm 1$	2/5	7/10	28/45
$m_S = \pm 2$	-7/5	-1/5	-23/45
$m_S = \pm 3$	-22/5	-17/10	-12/5
$S = 9/2, m_S = \pm 1$	5/8	13/16	55/72
$m_S = \pm 2$	-1/2	1/4	1/18
$m_S = \pm 3$	-19/8	-11/16	-9/8
$m_S = \pm 4$	-5	-2	-50/18

Figure 2 ^{23}Na free-induction-decay (a) and MAS spectrum (b) of NaNO_2 with 10 kHz spinning frequency. The insert shows the expansion to one of the rotational echoes

samples spinning at the magic-angle, the quadrupolar effects are modulated by the sample rotation. The expansion of quadrupolar effects in rotation matrix elements is advantageous because the rotation from the PAS frame to laboratory frame can be expressed as

$$D_{m',m}^l(\alpha, \beta, \gamma) = \sum_{m''=-l}^l D_{m'',m}^l(-\omega_r t, -\theta_M, 0) D_{m',m''}^l(\alpha_r, \beta_r, \gamma_r) \quad (18)$$

$$= \sum_{m''=-l}^l d_{m'',m}^l(\theta_M) e^{im''\omega_r t} D_{m',m''}^l(\alpha_r, \beta_r, \gamma_r)$$

where $(\alpha_r, \beta_r, \gamma_r)$ is the rotation from the PAS frame to the rotor frame and $(-\omega_r t, -\theta_M, 0)$ describes the sample rotation with frequency ω_r and angle θ_M . Under fast sample spinning, various expansion terms of quadrupolar effects are scaled accordingly by $d_{0,0}^l(\theta_M) = P_l(\cos \theta_M)$. With the spinning axis at the magic-angle, the first-order quadrupolar effect and the $l = 2$ terms of the second-order effect are averaged. The high-rank $l = 4$ terms, however, still remain under MAS and the anisotropic second-order effect, scaled by $P_4(\cos \theta_M)$, broadens both central and satellite lines.

With finite spinning frequencies, modulation of the large first-order quadrupolar interaction yields rotational echoes in the time-domain signals and spinning sidebands in the

frequency-domain spectra. Figure 2 shows a train of rotational echoes and an array of spinning sidebands as a result of averaging the first-order quadrupolar effect with spinning frequencies much lower than the quadrupolar coupling constant. The complete average of the large first-order effect occurs very briefly at the exact rotor cycles. The matching of evolution time to rotor cycles and the setting of magic-angle are the most important factors in averaging the first-order quadrupolar interactions.

The intensities of spinning sidebands show a line shape very similar to the static powder pattern. The first-order quadrupolar effect shifts satellite transition frequencies and splits the $\pm m_S - 1/2 \leftrightarrow \pm m_S + 1/2$ pair as

$$\Delta \nu_{m_S}^{(1)} = \frac{3m_S c_q}{S(2S-1)} \left(\frac{3 \cos^2 \beta - 1}{2} - \frac{\eta}{2} \sin^2 \beta \cos 2\alpha \right) \quad (19)$$

The maximum splitting occurs at $\beta = 0$ and leads to the full width of the powder pattern $3c_q/S(2S-1)$ for the inner pair of satellite transitions. The width increases linearly with $|m_S|$ for outer pairs of satellite transitions.

The second-order quadrupolar effect is responsible for the line shape of both central and satellite peaks under MAS. Among the expansion terms, the isotropic term $l = 0$ merely shifts the resonance frequency from the isotropic chemical shift and causes no additional line broadening. For the central

Figure 3 Satellite transition spectra of Na_2SO_4 under 10 kHz MAS

transition, the isotropic second-order quadrupolar shift is upfield (note the negative sign in $\omega_0 = -\gamma B_0$)

$$\omega_{CT}^0 = \frac{3[S(S+1) - 3/4]\omega_q^2}{10\omega_0} \left(1 + \frac{\eta^2}{3}\right) \quad (20)$$

The terms $l = 2$ are averaged by MAS and the terms $l = 4$ become the only remaining anisotropic terms that broaden resonance lines. Because all transitions are shifted by the same anisotropic terms, $C_4(\alpha, \beta, \gamma)$, different only by the scaling factor R_{S,m_S}^4 , the line shape for satellite transitions should be the same as the central transition except only the relative width determined by the scaling factors R_{S,m_S}^4 . A negative R_{S,m_S}^4 represents a reversed line shape.

The scaling factors R_{S,m_S}^4 with explicit values listed in Table 2 are important when comparing spectral features between satellite and central transitions. Figure 3 shows the satellite transition spectra of Na_2SO_4 with spinning axis carefully calibrated to the magic-angle. The line shape of the satellite transition spinning sidebands is close to a mirror image of the central transition peak, in agreement with the scaling factor $R_{S,\pm 1}^4 = -8/9$ for the $S = 3/2$ spin.

Figure 4 displays the ^{27}Al satellite and central transition spectra of $9\text{Al}_2\text{O}_3 + 2\text{B}_2\text{O}_3$, a model system for spins $S = 5/2$. The sample has four non-equivalent ^{27}Al sites with quadrupolar coupling constants ranging from 6–9 MHz and the central transition lines are partially overlapped due to the line broadening by the second-order quadrupolar effects. The comparison between satellite and central transition spectra shows much narrower line width for satellite transition lines because the scaling factor of inner satellite transitions over the central transition is less than 30% ($R_{S/2,\pm 1}^4 = 7/24$). The outer satellite transitions in comparison are nearly twice as broad as the central transitions, $R_{S/2,\pm 2}^4 = -11/6$. Most of the outer satellite transition intensities are immersed in the baseline because of the broad line width and the poor excitation of outer satellite transitions. Only the relatively narrow Al_{VI} site shows a visible outer satellite transition peak. Checking

Figure 4 ^{27}Al MAS (20 kHz) spectrum of $9\text{Al}_2\text{O}_3 + 2\text{B}_2\text{O}_3$. The two inserts show the central (CT) and the satellite (ST) transition spectra within 20 kHz spectral window

through Table 2, it is interesting to find that the $\pm 5/2 \leftrightarrow \pm 3/2$ satellite transitions of $S = 9/2$ spins have a second-order effect 18 times smaller than the central transition that could provide much higher resolution.

The isotropic $l = 0$ term contributes no additional line broadening; however, it can change the relative peak position and affect the resolution among nonequivalent sites. In amorphous or disordered systems, the isotropic terms can become a factor in the line width. Distribution on quadrupolar couplings leads to a spread of the isotropic second-order quadrupolar shift to broaden spectral lines. For $S = 5/2$ spins, the isotropic second-order shift to the inner pair ($m_S = \pm 1$) satellite transitions is 8 times smaller than the central transition and is expected to causes less line broadening by the mentioned mechanism in disordered systems.⁶ In any case, satellite transition spectra compliment central transition spectra to find the best spectral resolution.

4 2D SATELLITE TRANSITION MAGIC-ANGLE SPINNING EXPERIMENT

The two-dimensional satellite transition MAS experiment correlates satellite (ω_1) with central (ω_2) transitions under magic-angle spinning.³³ The timing of the evolution period t_1 is synchronized with the rotor cycles such that the first-order quadrupolar effects to the satellite transitions are averaged by sample spinning precisely at the magic-angle. The resonance frequencies along the two dimensions are contributions from the isotropic chemical shift, the isotropic and the anisotropic $l = 4$ second-order effects

$$\begin{aligned}\omega_1 &= \omega_\delta + R_{S,m_S}^0 \omega_{CT}^0 + R_{S,m_S}^4 C_4(\Omega_r) P_4(\cos \theta_M) \\ \omega_2 &= \omega_\delta + \omega_{CT}^0 + C_4(\Omega_r) P_4(\cos \theta_M)\end{aligned}\quad (21)$$

For powder samples, superposition over Ω_r yields a ridge-shaped peak in the 2D STMAS spectra. The peak centers at $(\omega_\delta + \omega_{CT}^0 R_{S,m_S}^0, \omega_\delta + \omega_{CT}^0)$ and tilts at slope R_{S,m_S}^4 . A shear of the 2D spectrum along ω_1 can make the peak parallel with the ω_2 axis and a projection to the ω_1 axis yields an isotropic peak at the position

$$\omega_{iso} = (1 - R_{S,m_S}^4) \omega_\delta + (R_{S,m_S}^0 - R_{S,m_S}^4) \omega_{CT}^0 \quad (22)$$

In the time-domain, the signal from the correlation between satellite and central transitions can be written as

$$\begin{aligned}S(t_1, t_2) &= \sum_{p_1, p_2 = \pm 1} \sum_{\Omega_r} E_{p_1}(\Omega_r) C_{p_1, p_2}(\Omega_r) \\ &\times e^{ip_1[\omega_\delta + R_{S,m_S}^0 \omega_{CT}^0 + R_{S,m_S}^4 C_4(\Omega_r)]t_1} e^{ip_2[\omega_\delta + \omega_{CT}^0 + C_4(\Omega_r)]t_2}\end{aligned}\quad (23)$$

where the factors $E_{p_1}(\Omega_r)$ and $C_{p_1, p_2}(\Omega_r)$ represent the excitation and coherence transfer of satellite transitions; $p_1, p_2 = \pm 1$ are coherence orders of the single-quantum satellite and central transitions during the t_1 and t_2 periods, respectively. Superposition over Ω_r causes the signal to decay rapidly except at $t_2 = -(p_2/p_1)R_{S,m_S}^4 t_1$ where coherence transfer echoes are formed. For coherence orders with $R_{S,m_S}^4 p_2/p_1 > 0$, the echoes are outside the $t_1, t_2 > 0$ quadrant of the 2D time coordinate and are known as antiechoes.⁴⁵ For coherence orders with $R_{S,m_S}^4 p_2/p_1 < 0$, coherence transfer echoes occur inside the $t_1, t_2 > 0$ quadrant and can be acquired directly. The signal intensities along the echo ridge $t_2 = -(p_2/p_1)R_{S,m_S}^4 t_1$ oscillate at the frequency $\omega_{iso} = (1 - R_{S,m_S}^4) \omega_\delta + (R_{S,m_S}^0 - R_{S,m_S}^4) \omega_{CT}^0$, the same expression as equation (22), and yield an isotropic NMR spectrum with a Fourier transformation.

Excitation and conversion of satellite transition coherence are critical to the efficiency of the 2D STMAS experiment. Satellite transitions are single-quantum transitions that can be excited directly. Short and strong pulses can cover the large frequency offsets caused by the first-order quadrupolar effect on the satellite transition. In Figure 4, the satellite and central transition spectra are plotted on the same intensity scale and the relative intensities indicate the efficiency of satellite transition excitation. Although individual spinning sidebands that span more than 1 MHz wide are low, the total spectral intensities from all spinning sidebands are actually higher than the CT peaks. The ratio between ST and CT intensities approaches

the value $Tr(S_x^{ST} S_x) : Tr(S_x^{CT} S_x) = 16 : 9$ for the $S = 5/2$ spin assuming a uniformly excited coherence $\sigma = S_x$.

A single mixing pulse can transfer satellite transition coherence directly to central transitions. Figure 5 displays simulations and experimental results of the coherence transfer. The simulations show that the transfer is in-phase, i.e., $S_x^{(ST)} \rightarrow S_x^{(CT)}$ and $S_y^{(ST)} \rightarrow S_y^{(CT)}$ regardless of the pulse phase. Out-phase pulses, e.g., S_y pulse for $S_x^{(ST)} \rightarrow S_x^{(CT)}$ transfer, are more efficient than in-phase pulses. Simulations also show that a 180° phase shift to RF pulses has no effect on the single-pulse coherence transfer. These results suggest that a phase cycle $+x, +y, -x, -y$ to the mixing pulse balances the difference on transfer amplitude between in-phase and out-phase pulses and consequently selects the $p = -1 \rightarrow -1$ coherence transfer pathway. This pathway generates coherence transfer echoes for negative $R_{S,m}^4$ such as $S = 3/2$ spins ($R_{3/2, \pm 1}^4 = -8/9$) but yields coherence transfer antiechoes for spins with positive $R_{S,m}^4$. A selective π -pulse to the central transition prior to signal acquisition can convert the coherence transfer antiechoes to echoes for isotropic spectra of $S = 5/2$ spins and other spins with negative $R_{S,m}^4$. The simulations for $S = 5/2$ spins show much higher transfer amplitudes from inner satellite transitions than from outer satellite transitions. This difference can be interpreted qualitatively as the follows. Mixing of spin states by a RF pulse can be described as $|i\rangle \rightarrow \sum_j p_{ij} |j\rangle$ with $p_{ii} \rightarrow 1$ and $p_{i \neq j} \rightarrow \varepsilon$ for short pulses. For satellite transitions that share energy levels with central transition, e.g., $|1/2\rangle\langle 3/2|$, the coherence transfer $|1/2\rangle\langle 3/2| \rightarrow |1/2\rangle\langle -1/2|$ is in the order of ε . The transfer becomes second-order ε^2 for any transitions not sharing energy levels with the targeted transition. In Figure 5, the experimental optimization illustrates the high efficiency of the single-pulse mixing of inner satellite transition coherence. The optimized peak height from coherence transfer is close to 50% of peak height in the conventional central transition spectrum acquired under the same experimental conditions.

A pair of mixing-pulses sandwiched with a z-filter can also be used for the coherence transfer. The first mixing-pulse transfers satellite transition coherence to the polarization of central transitions. The second mixing-pulse flips the stored polarization for detection after the z-filter. The pulse sequence with two-pulse mixing is identical to the sequence used for 2D exchange experiments and selects both $p_1 = \pm 1$ coherence-orders during the evolution period. Half of the transferred coherence contributes to the coherence transfer echoes and the other half goes to the anti-echoes. The two-pulse mixing has an advantage of pure-absorptive line shape irrespective to the signs of $R_{S,m}^4$.^{33,34}

Figure 6 shows the 2D STMAS spectra of a mixed sample of Na_2SO_4 and $\text{Na}_2\text{C}_2\text{O}_4$. The correlation of satellite and central transitions yields ridge-shaped peaks that clearly resolve the overlap between two components. The peaks tilt at the slope $R_{3/2, \pm 1}^4 = -8/9$. A shear of the 2D spectrum corrects the tilt and results in an *isotropic* versus *anisotropic* spectrum where the projection to the isotropic-dimension shows two resolved isotropic peaks. The pulse sequence with two-pulse mixing is the same as the sequence used for 2D exchange experiments and the peak along the diagonal resulting from the central transition to central transition (CT-CT) peak is not affected by the frequency offset of satellite transitions. Thus, the relative intensities between diagonal and cross peaks

Figure 5 Coherence transfer from satellite to central transition by a single mixing pulse with RF field strength $\omega_1/2\pi = 100$ kHz and pulse length $\omega_1\tau = 18^\circ$ (circles) and 36° (stars). The coherence transfer was calculated as a function of satellite transition frequency of an $S = 3/2$ and an $S = 5/2$ spins including both inner and outer satellite transitions. The two columns show the transfer by out-phase (left) and in-phase (right) pulses relative to the satellite transition coherence $S_x^{(ST)}$. The array of spectra in the bottom shows the optimization for the mixing pulse length with $\omega_1/2\pi = 60$ kHz for Na_2SO_4 along with a conventional central transition spectrum acquired under the same experimental conditions

are good indicators to measure the efficiencies experimentally. The two-pulse mixing yields ST-CT peaks about 30% of the diagonal peak. When the diagonal peak is compared with the ST-CT peaks (see Figure 5) obtained by the one-pulse mixing sequence under the same experimental conditions the ratio rises to nearly 80%.

Figure 7 illustrates the 2D STMAS spectrum of $9\text{Al}_2\text{O}_3 + 2\text{B}_2\text{O}_3$ for $S = 5/2$ spins. The spectrum was obtained with one-pulse mixing and a selective π -pulse before the data acquisition. The spin-echo sequence converts coherence transfer

anti-echoes to echoes. The resulting spectrum is similar to $S = 3/2$ spins except that the ridge-shape peaks tilt at the opposite direction because of the sign change to the scaling factor $R_{5/2,\pm 1}^4 = 7/24$.

Magic-angle setting is the most critical factor in satellite transition NMR experiments. Deviations of the spinning axis from magic-angle reintroduce the first-order quadrupolar effects. Residual first-order effects can distort the satellite transition line shape and cause line broadening in 2D STMAS spectra. The line broadening can be estimated by the full width

Figure 6 2D ^{23}Na STMAS spectra of a mixture of Na_2SO_4 and $\text{Na}_2\text{C}_2\text{O}_4$ acquired with (a) two-pulse mixing and (b) one-pulse mixing. The spectrum in (c) is obtained by a spectral tilt of (b) to correct the slope of ridge-shaped peaks. The projection to the isotropic dimension and the line shape along the anisotropic dimension are also plotted. The three projections in (d), from left to right, are obtained from the diagonal peak in (a) along the thin line, the cross peaks in (a), and the cross peaks in (b). The pulse sequence in (a) is identical to the sequence used for 2D exchange experiments. The phase cycle for the one-pulse mixing in (b) can be found in the text and the soft pulse is used for presaturation of the central transitions

of satellite transition powder pattern, $3c_q/S(2S-1)$, and the scaling factor $P_2(\cos \theta_S)$ by MAS

$$\Delta\nu_1 = \frac{3c_q}{S(2S-1)} P_2(\cos \theta_S) \quad (24)$$

A scaling factor $< 10^{-4}$ (0.004° in magic-angle setting) is required to reduce typical quadrupolar interactions from a few MHz to less than a few hundred Hz. Stable sample spinning is also critical to synchronize the evolution time with the rotor cycles for complete average of the first-order quadrupolar effect. A drift $\Delta\nu_r$ on spinning frequency causes a mismatch

$t_1 \Delta\nu_r/\nu_r$ to the synchronization condition. The mismatch at $t_1 \approx T_2^*$ should be small compared the width of the satellite transition rotational echoes Δt_1 (see Figure 1)

$$\Delta\nu_r < \nu_r \cdot \Delta t_1/T_2^* \quad (25)$$

With typical values $\nu_r \approx 10$ kHz, $1/T_2^* \approx 300$ Hz and $\Delta t_1 \approx 1 \mu\text{s}$, the stability on spinning frequency required for the STMAS experiment can be estimated about ± 3 Hz.

Finally, a comparison between MQMAS and STMAS experiments is summarized as follows. Both experiments correlate transitions of half-integer quadrupolar nuclei to obtain

Figure 7 2D STMAS pulse sequence and spectrum of $9\text{Al}_2\text{O}_3 + 2\text{B}_2\text{O}_3$ with 20 kHz MAS. The pulse sequence uses a single pulse for mixing and the central transition selective π -pulse after the mixing generates coherence transfer echoes for $S = 5/2$ spins. The soft pulse in the beginning presaturates central transition coherence

isotropic NMR spectra under MAS. The satellite transition experiment requires accurate magic-angle setting and stable sample spinning to average out the first-order quadrupolar interactions whereas the multiple-quantum experiment correlates two transitions, both with vanished first-order effect. The excitation and the conversion of the single-quantum satellite transitions are much more efficient than that of multiple-quantum transitions. The relatively higher efficiencies allow rapid acquisition of high-resolution isotropic NMR spectra of half-integer quadrupolar nuclei (note the spectra in Figures 6 and 7 were acquired in just a few minutes).

5 CONCLUSIONS

Theoretical analysis and experimental results display the attractive features and technical requirements of satellite transition MAS NMR spectroscopy. Correlation between satellite and central transitions yields isotropic NMR spectra of half-integer quadrupolar nuclei. The transition-correlated experiment takes the advantage of efficient excitation and conversion of single-quantum satellite transitions for high-resolution NMR spectra of half-integer quadrupolar nuclei. In order to average out large first-order quadrupolar interactions, satellite transition experiment requires accurate setting of magic-angle and stable sample spinning.

1 INTRODUCTION

The earliest NMR experiments required samples with significant bulk magnetization, and thus it is not surprising that some concentration-dependent effects were first characterized more than 40 years ago.¹ However, improvements in instrumental sensitivity, coupled with the advent of Fourier transform techniques, dramatically reduced the number of spins needed for an observable signal. As a result, most routine applications, such as determining the structure of small organic molecules, take place in moderately dilute solution (<1% concentration). Much of the solvent magnetization can be removed by deuteration. Even if the solvent peak is intense, it is often true that bulk effects contribute at most an additional effective inhomogeneity that can be shimmed away.

In recent years, magnetically concentrated samples have once again become important, in large part because of the quest for ever-greater sensitivity in biomolecular applications. This sensitivity is achieved by increasing sample volumes, redesigning probes to increase responsivity, and strengthening the static magnetic field. In addition, the solvent is typically water, and deuteration is often undesirable because exchangeable protons are lost. As a result, the bulk magnetization can be far larger than in the earliest NMR experiments. The last few years have seen a significant resurgence of interest in these effects, which have been shown to profoundly alter molecular spectra.

In this article, the two most important phenomena stemming from a large bulk magnetization will be described in detail. Either of these effects can generate additional peaks, particularly in the indirectly detected dimensions of multidimensional experiments. *Radiation damping* occurs because the bulk magnetization induces a current in the probe coil, which in turn acts like a weak pulse back on the sample; this field causes the system to return to equilibrium faster than through relaxation alone. Radiation damping is generally a nuisance, partly because the already very large water signal in a spectrum is broadened and obscures signals in its vicinity, and partly because this 'weak pulse' makes the solvent peak effectively see a different pulse sequence than does the solute. *Magnetization anisotropy* is most dramatic when magnetic field gradients are employed in the pulse sequence (see *Field Gradients and Their Application*), although some effects can be seen with any nonspherical sample. It causes additional signals that can falsify a spectral analysis, or, when properly interpreted, *enhance*

the information content of a spectrum. This leads to a new type of pulse sequence using gradient pulses to elucidate intermolecular correlations.

2 RADIATION DAMPING

2.1 The Physical Picture

Radiation damping was observed and described¹ in the first decade of NMR. The time-dependent transverse magnetization of the system (the observable signal) is always detected via the electric current which it induces in the coil. This current, in turn, generates an *additional magnetic field* at the sample. According to elementary classical physics (Lenz's law), a current that is induced by a time-varying magnetic field creates a magnetic field that acts to oppose the original one. This is also obvious from the principle of conservation of energy; the energy stored in a magnetic field is partially converted into the energy of the current that is induced. Energy is coupled out of the spins in a time comparable to the probe risetime (microseconds) and, since the energy of the spins in the magnetic field is $E = -\boldsymbol{\mu} \cdot \mathbf{B}$, the net effect must tend to rotate the spins back towards equilibrium.

2.2 Experimental Consequences

In dilute solutions, typical relaxation times for protons in small molecules at room temperature are of the order of 1 s, giving a linewidth [half width at half maximum (HWHM)] of 0.3 Hz. Radiation damping changes this drastically. In pure water the decay after a $\pi/2$ pulse becomes nonexponential, and can be approximately 100 times shorter. After a near- π pulse, the magnetization actually grows (Figure 1). Since the water peak is very intense, the width of the line at the base is yet much larger, and neighboring peaks will be disturbed or obscured altogether.

Figure 1 Free induction decays in a water sample. Note that the behavior is grossly different from the Bloch equation prediction unless the probe is detuned. (Reproduced by permission from Q. He, W. Richter, S. Vathyam, and W. S. Warren, *J. Chem. Phys.*, 1993, **98**, 6779)

Figure 2 Two-dimensional spectrum obtained from the simple two-pulse sequence $(\pi/2)_x - t_1 - (\pi/2)_x - t_2$ on a sample of 80% H_2O in D_2O . Note that additional resonances are still seen in the ω_1 dimension, despite the normal expectation that a two-pulse sequence cannot generate and detect multiple quantum coherences. (Reproduced by permission of AIP from Q. He, W. Richter, S. Vathyam, and W. S. Warren *J. Chem. Phys.*, 1993, **98**, 6779)

In a two-dimensional spectrum, for example in a COSY experiment, radiation damping can lead to harmonic peaks (at integral multiples of the resonance offset) in the indirectly detected dimension (Figure 2). The reason for these peaks is the nonlinearity of the radiation damped signal.²

2.3 Theoretical Description

For most practical purposes, a mathematical description based on the classical physical picture given above is sufficient if we deal with isolated spins $\frac{1}{2}$, as in water; it is possible to write a field-quantized version of these equations, which gives some additional insight, but which has not yet been shown to predict any new phenomena.^{1,3,4} Neglecting relaxation for the moment, the transverse component of the magnetization after a pulse with flip angle θ has magnitude $M_0 \sin \theta$, and precesses about the z axis at the Larmor frequency ω_0 . The voltage induced in the coil by the precessing magnetization is given by

$$V = -nA\eta\mu_0 \frac{dM_x}{dt} = Rl \left(\frac{Q}{n} \right) \eta M_0 \sin \theta \cos(\omega_0 t) \quad (1)$$

where n is the number of turns in the coil, A its cross-section, η the filling factor, R the electrical resistance, l the length

of the coil, M_x the component of the magnetization in the x direction, and ω the precession frequency. $Q = (\mu_0 \omega n^2 A)/Rl$ is the quality factor of the probe circuit. The filling factor η is the fraction of the coil volume occupied by the sample, weighted by the product of the magnetic field that a unit current in the coil produces at each point in the sample (B_c), and the magnetization at that point:

$$\eta = \frac{\int_V M B_c dV}{M_0 \int_V B_c dV} \quad (2)$$

where M is the magnetization per unit volume, and M_0 its average value. If the coil were fully immersed in the sample, the filling factor would be 1.

This voltage produces a current, and hence a field

$$B_x = \frac{\mu_0 I n}{l} = \mu_0 \eta Q M_0 \sin \theta \cos(\omega t) \quad (3)$$

This field, in turn, exerts a torque on the magnetization. The expression for the evolution of the magnetization vector is simplest in polar coordinates ($|M|$, θ , ϕ):

$$\begin{aligned} \frac{d\theta}{dt} &= -\frac{\mu_0 \eta M_0 Q \gamma \sin \theta}{2} = -\sin \tau_r, & \frac{d\phi}{dt} &= 0, \\ \frac{d|M|}{dt} &= 0 \end{aligned} \quad (4)$$

Following Bloembergen and Pound,¹ we have defined a ‘radiation damping time’

$$\tau_r = \frac{2}{\mu_0 \eta M_0 Q \gamma} \quad (5)$$

Unlike relaxation, radiation damping does not change the *length* of the magnetization vector, but only its angle with the static magnetic field. No dephasing, either reversible or irreversible, takes place. These terms are added to the phenomenological Bloch equations, giving

$$\frac{dM_x}{dt} = \Delta\omega M_y + \omega_{1,y} M_z - \frac{M_x}{T_2} - \frac{M_x M_z}{\tau_r M_0} \quad (6a)$$

$$\frac{dM_y}{dt} = -\Delta\omega M_x - \omega_{1,x} M_z - \frac{M_y}{T_2} - \frac{M_y M_z}{\tau_r M_0} \quad (6b)$$

$$\begin{aligned} \frac{dM_z}{dt} &= -\omega_{1,y} M_x + \omega_{1,x} M_y - \frac{M_z - M_0}{T_1} \\ &\quad + \frac{M_0^2 - M_z^2}{\tau_r M_0} \end{aligned} \quad (6c)$$

For 80% water in a 750 MHz spectrometer, probe Q of 500 and $\eta = 0.1$, $\tau_r = 2.7$ ms. Since both the transverse and the longitudinal relaxation times are of the order of 1 s, the decay of transverse magnetization is dominated by radiation damping, and the evolution after a pulse with flip angle θ is given by:

$$S(t) = M_x + iM_y = M_0 \operatorname{sech} \left(\frac{t - t_0}{\tau_r} \right) \exp(i\omega_0 t) \quad (7)$$

This is a universal solution if $\omega_1 = 0$ and relaxation can be neglected.⁵ The effects of radiation damping when the externally applied rf does not vanish are explored extensively in Warren et al.³ In that case, the dynamics can be quite different from what the unmodified Bloch equations would have predicted; for example, if ω_1 is constant, the magnetization vector spirals towards a ‘fixed point’ the position of which is determined by $\Delta\omega$, ω_1 , and τ_r .³

Fourier transformation of equation (7) gives the lineshape in the frequency domain, which is particularly simple for a $\pi/2$ or near- π pulse.⁶ After a $\pi/2$ pulse the lineshape is

$$S(\omega) = \frac{\pi M_0 \tau_r}{2} \operatorname{sech} \left[\frac{\pi \tau_r}{2} (\omega - \omega_0) \right] \quad (8)$$

Suppose the radiation damping time of a given sample is 2.7 ms. If the concentration of the molecule of interest is 1 mM and the solvent is pure water, the tails of the water peak have the same intensity as a singlet of one proton of the dilute molecule at a resonance offset frequency of 250 Hz, assuming a Lorentzian lineshape for the solute.

The extra peaks in Figure 2 are highly nonintuitive. A rigorous density matrix treatment readily shows that the indirectly detected dimension of a COSY experiment is expected to contain only the peaks in the normal spectrum. In fact, however, even the modified Bloch equations [equation (6)] predict these peaks. As shown by He et al.,⁷ this occurs because these modified Bloch equations grossly violate quantum mechanics; they generate a propagator for the time evolution which depends explicitly on the initial direction of the magnetization. A fully quantum mechanical treatment must reveal that frequencies in the indirectly detected dimension reflect actual energy differences between eigenstates (in the rotating frame); but such a treatment requires field quantization, is quite complex and does not appear to be necessary for quantitative interpretation.

2.4 Remedies

There are two general approaches to eliminating the adverse effects of radiation damping. The most obvious way is for the experimenter to choose the conditions such that radiation damping does not occur at all. For a given sample, this can be achieved by decreasing the quality factor of the circuit (for instance, by detuning), or by decreasing the filling factor (for instance, by using a capillary tube). In both cases, sensitivity will be greatly reduced, which is unacceptable in many applications. Alternatively, the sample can be magnetically diluted, in the case of an aqueous solution by the addition of D₂O. Often, though, exchangeable protons are present in the molecule under investigation, necessitating the use of H₂O. Work in progress in several laboratories aims at suppressing radiation damping with active probe design.

Alternatively, radiation damping can be put to advantage. As shown above, a magnetization vector evolves differently in the presence of radiation damping. This difference in evolution can, in principle, be used to suppress the unwanted solvent resonance by a suitably tailored pulse sequence, or by a *shaped pulse*³ (see also *Shaped Pulses*).

3 MAGNETIZATION ANISOTROPY

3.1 Boundary Effects

Perhaps the most visible effect in concentrated samples is that the lineshape deteriorates considerably. The reasons for this are the large magnetic susceptibility of the liquid and the resulting discontinuity at the walls of the sample tube. This effect has recently been investigated mathematically by Vlassenbroek⁸ for a few cases. For most practical applications, this magnetic field inhomogeneity can be compensated for by shimming.

3.2 Reintroduction of Dipolar Couplings in Solution

3.2.1 The Physical Picture

The magnitude of the dipolar coupling between two spins has an angular dependence of $3 \cos^2 \theta - 1$, where θ is the angle between the interspin vector and the static magnetic field. These couplings are easily seen in solid state NMR. The spectrum of a liquid sample is considerably sharper and simpler than that of a solid because dipolar (and higher order) couplings are invisible.

The reason for sharp lines in liquids is more subtle than has been commonly appreciated. For a spin pair separated by a short distance R , the direction of the interspin vector will change rapidly in a liquid because of diffusion. The average value of $3 \cos^2 \theta - 1$ then becomes zero, and the dipolar couplings vanish. However, for a spin pair separated by a large distance, not all angles are sampled by the interspin vector. The couplings fall off as R^{-3} , but the number of spins a distance R from a given spin is proportional to R^2 , so the net effect of couplings from one spin to 10^{20} others in a typical sample can be considerable. However, under ordinary circumstances (in the absence of gradient pulses) *the orientation of the magnetization vector is uniform throughout the sample*, and angular averaging over all the spins at distance R makes the net magnetic field vanish.

If the magnetization direction in a liquid is made anisotropic (for example, because of gradient pulses), the averaging of long range couplings might no longer hold, and dipolar couplings reappear. Spatial correlations can be established between different molecules, generating extra peaks and distorting intensities of expected peaks.

3.2.2 Experimental Consequences

Dipolar couplings in liquids were first invoked to explain multiple echoes in experiments involving magnetic field gradients. If a pulse sequence consisting of two $\pi/2$ pulses separated by a time τ is applied to a sample, an echo appears in the free induction decay at $t_2 = \tau$ (the ‘Hahn spin echo’).⁹ In the presence of a magnetic field gradient, however, multiple echoes after $t_2 = n\tau$ are also observed.^{10,11} For a typical set of experimental parameters (80% H₂O in D₂O, $B_0 = 7$ T, $G = 5 \times 10^{-3}$ T m⁻¹), the second echo has about 10% of the intensity of the first one. These echoes are not caused by radiation damping—the ratio of the second to first echo is independent of Q or η , but is reduced by diluting the sample.

Figure 3 CRAZED pulse sequence. This sequence can be viewed as a two-pulse COSY sequence modified to include a pair of gradient pulses as a coherence transfer echo. The observable magnetization (I_y or I_x) comes entirely from one-quantum operators. The 1:2 length ratio of the two gradient pulses guarantees that only coherences that evolved as two-quantum operators during t_1 will be refocused. (Reproduced by permission of AAAS from W. S. Warren, W. Richter, A. H. Andreotti, and B. T. Farmer II, *Science*, 1993, **262**, 2005)

A simple sequence which shows the potential of these couplings to generate extra peaks in two-dimensional experiments is the CRAZED sequence (COSY revamped by asymmetric z gradient echo detection) (Figure 3).^{7,12} The CRAZED experiment serves as a prototype for a whole class of experiments using magnetization anisotropy, the theoretical description for all of which is similar.

This two-dimensional pulse sequence consists of two $\pi/2$ rf pulses and two magnetic field gradient pulses along the direction of the static magnetic field. The gradient pulses have a strength of typically 0.01–0.1 T m⁻¹ and are applied through a z shim coil, unless a special gradient probe is used.

Figure 4 CRAZED spectrum of a mixture of benzene and chloroform in C₆D₆. The transmitter frequency is on resonance with chloroform. The cross-correlation resonance pairs appear at the sum of resonances of the two protons in different molecules. (Reproduced by permission of AIP from Q. He, W. Richter, S. Vathyam, and W. S. Warren, *J. Chem. Phys.*, 1993, **98**, 6779)

If the areas of the gradient pulses are in an integer ratio, peaks in the indirectly detected dimension at the frequencies of *intermolecular multiple quantum coherences* are created and detected by this pulse sequence.^{7,12} Figure 4 presents a two-pulse experiment with a 1:2 ratio of gradient pulse lengths (making the gradient pulses act as a double quantum filter) on a mixture of benzene and chloroform.⁷ Note that the f_2 dimension (horizontal) contains only the two expected resonances. The gradients eliminate all but two-quantum coherences in the ω_1 dimension (vertical); the nature of these resonances (two benzene spins flipping, two chloroform spins flipping, or one of each) is easily determined by peak position. Figure 4 shows intermolecular coherence transfer (cross peaks) between these independent molecules, but not all possible peaks are present—for example, the one-quantum chloroform resonance correlates only with two-quantum resonances which include at least one chloroform resonance. These peaks are huge—typically 10–20% of the amplitude of the diagonal peaks in a gradient-free COSY experiment on the same sample. Three-component mixtures (e.g. benzene/acetone/chloroform) show exactly the same pattern.⁷ For example, the benzene resonance (ν_{benzene}) in f_2 is correlated with peaks at $f_1 = 2\nu_{\text{benzene}}$, $\nu_{\text{benzene}} + \nu_{\text{acetone}}$, or $\nu_{\text{benzene}} + \nu_{\text{chloroform}}$, but not with $f_1 = \nu_{\text{acetone}} + \nu_{\text{chloroform}}$.

He et al.⁷ showed that the cross peaks are not due to radiation damping by taking CRAZED spectra with coaxially separated samples within the same coil. This should not modify radiation damping effects, since they are macroscopic, but it eliminates the cross peaks.

A similar spectrum of a peptide molecule in water is shown in Figure 5.¹² There are the peptide resonances (and the water resonance) in f_1 , and peaks at the sum of a peptide proton frequency and the water frequency in f_1 . These are intermolecular double quantum resonances between water and the peptide molecule.

3.2.3 Theoretical Description

Modified Bloch equations (including the ‘dipolar demagnetizing field’, which is a mean field approximation to the full dipolar interaction) can be used to give an approximate description of multiple echoes and the CRAZED experiment. For simplicity, we will describe the experiment for a sample with only one spin species, e.g. pure water. The secular part of $B_d(\mathbf{r})$ is given by

$$B_d(\mathbf{r}) = \frac{\mu_0}{4\pi} \int_V d^3r' \frac{1 - 3\cos^2\theta_{rr'}}{2|\mathbf{r} - \mathbf{r}'|^3} [3M_z(\mathbf{r}')\mathbf{e}_z - \mathbf{M}(\mathbf{r}')] \quad (9)$$

(where $\mathbf{e}_z$ is the unit vector in the z direction) which is just the continuous version of the usual expression (summed over all spins) for the local magnetic field generated by the direct dipole–dipole interaction. The difficulty in calculating $B_d(\mathbf{r})$ stems from the nonlocal nature of the interaction—even edge effects in the sample can play a significant role. However, a spatial Fourier transform simplifies the relation between $B_d(\mathbf{r})$ and $\mathbf{M}(\mathbf{r})$ if the magnetization $\mathbf{M}(\mathbf{r})$ varies only in a single direction s . In that case¹⁰

$$B_d(s) = C_k \mathbf{M}(s) = \mu_0 [\Delta M_z(s) \mathbf{e}_z - \frac{1}{3} \Delta \mathbf{M}(s)] \quad (10)$$

$$\Delta \equiv [3(\mathbf{e}_s \cdot \mathbf{e}_z)^2 - 1]/2 \quad (11)$$

Figure 5 CRAZED spectrum of a 20 mM solution of a fibronectin fragment in water. The first gradient pulse was 1 ms long, with amplitude 0.06 T m^{-1} . Joint solute-solvent two-quantum coherences are seen from most of the glycopeptide peaks. (Reproduced by permission of AAAS from W. S. Warren, W. Richter, A. M. Andreotti, and B. T. Farmer II, *Science*, 1993, **262**, 2005)

The field $\mathbf{B}_d(\mathbf{r})$ is then added into the usual form of the Bloch equations, giving an additional contribution $[\mathbf{M} \times \gamma \mathbf{B}_d(\mathbf{r})]$ to $d\mathbf{M}/dt$. The magnitude (in angular frequency units) of the field generated by equation (10) is approximately $\Delta\gamma\mu_0 M_0$; in He et al.,⁷ the quantity $(\Delta\gamma\mu_0 M_0)^{-1}$ is defined as the ‘dipolar demagnetizing time’ τ_d . For pure water at 750 MHz and $\Delta = 1$, $\tau_d \approx 50 \text{ ms}$.

In the CRAZED experiment, the first rf pulse rotates all magnetization into the horizontal plane. In t_1 , the magnetization rotates about the z axis. During the first gradient pulse, the static magnetic field and hence the resonance frequency (or rate of rotation) become position dependent. The individual magnetic moments are wound up into a helix about the z axis, and the magnetization becomes anisotropic. The second rf pulse transforms this anisotropy in the horizontal magnetization component into an anisotropy in the vertical component. Now the local static magnetic field at each spin depends on its position in the sample. The spins then evolve under this new magnetic field during t_2 .

This approach qualitatively yields the observed spectrum for a sample of pure water. However, the peak intensities are not predicted correctly. Furthermore, classical calculations fail as soon as slightly more complicated pulse sequences are

employed. This is not surprising, in view of the fact that a classical picture, replacing nuclear spins by tiny bar magnets and predicting their behavior by classical dynamics, neglects the correlations which are at the very heart of signals evolving at the sum of the resonance frequencies of two different spins.

A density matrix treatment is much more general. At the beginning of the pulse sequence, the spins are in thermal equilibrium. There is a slightly higher probability for a spin to point parallel to the magnetic field (‘up’) than antiparallel. Therefore, spins are (formally) correlated, independent of distance. The strongest such correlation is between any two spins. We will therefore focus on spin pairs. That means that we will expand the equilibrium density operator

$$\hat{\rho}_{\text{eq}} = \frac{\exp(-\beta\hat{\mathcal{H}})}{\text{Tr}[\exp(-\beta\hat{\mathcal{H}})]} \quad \beta \equiv \frac{1}{kT} \quad \hat{\mathcal{H}} = \hbar\omega_0 \sum_{i=1}^N \hat{I}_{zi} \quad (12)$$

up to the term quadratic in β :

$$\hat{\rho}_{\text{eq}} \approx (2^{-N}) \left[1 - \beta\hbar\omega_0 \sum_{i=1}^N \hat{I}_{zi} + \frac{1}{2}(\beta\hbar\omega_0)^2 \sum_{i=1}^N \sum_{j=1}^N \hat{I}_{zi} \hat{I}_{zj} \right] \quad (13)$$

Usually, this expansion is terminated after the linear term (the so-called ‘high-temperature approximation’). It is commonly argued that the term quadratic in $\beta\hbar\omega_0$ is small; indeed, $\beta\hbar\omega_0 \approx 10^{-4}$ for a 17.6 T spectrometer. However, there are of the order of 10^{44} spin pairs $\hat{I}_{zi} \hat{I}_{zj}$ in a typical sample. It turns out that the quadratic term gives rise to a signal approximately 10% as large as the signal stemming from the linear term. In fact, the term proportional to $(\beta\hbar\omega_0)^3$ generates observable three-quantum signals if the ratio of gradient pulse lengths is set at 1:3, and effects of the $(\beta\hbar\omega_0)^4$ term have been observed as well.

From the equilibrium two-spin correlation, the first $\pi/2$ pulse creates a *two-spin, two-quantum coherence* which evolves during t_1 . At the end of t_1 , the first gradient pulse causes a variation of the static magnetic field along the z direction, and therefore a z -dependent resonance frequency. The coherences are wound into a helix about the z direction. The second rf pulse converts the two-spin, two-quantum coherences into two-spin, one-quantum coherences that evolve with approximately half the frequency of the two-quantum coherences. Since the second gradient pulse is twice as long as the first one, the helix is unwound, and the coherences refocus.

As described above, the magnetization anisotropy created by the gradient pulses causes the reintroduction of observable effects from dipolar couplings. The time evolution of the density operator after the second gradient pulse is such that the dipolar couplings transform the two-spin, one-quantum operators into observable one-spin, one-quantum operators which evolve during t_2 . The expected signals agree quantitatively with the experiments. Figure 6 shows schematically the evolution of coherences of different order during the pulse sequence.

3.2.4 Remedies and Applications

It has been shown both theoretically and experimentally that magic angle gradients remove the extra peaks, at least for

Figure 6 Schematic illustration of the dominant pathway for generating observable signals from a CRAZED sequence. Black dots illustrate operators that are not spatially modulated. The black square represents the one-spin, one-quantum operators $\hat{I}_{xi}$ and $\hat{I}_{yi}$, which are observable. The $\beta\hbar\omega_0\hat{I}_z$ term in the equilibrium density matrix is a sum of one-spin, zero-quantum operators, which are turned into an observable signal during t_2 by the first pulse. However, the coherence transfer echo imposes a strong spatial modulation on these operators, and they do not generate an observable signal during t_2 . The $(\beta\hbar\omega_0)^2$ term, on the other hand, gives a two-quantum operator during t_1 (plus a zero-quantum operator which is omitted here for clarity). The fraction of this two-quantum, two-spin operator which is transferred to one-quantum, two-spin operators by the coherence transfer echo is only mildly modulated. The dipolar couplings can then act to create an unmodulated, one-spin, one-quantum operator (observable magnetization). The quantitative calculation shows that very large signals are possible. simple sequences¹² (Figure 7). In addition, the density matrix treatment described by Warren et al.¹² suggests a variety of applications which are currently under development. The most obvious ones are in imaging, and based on the fact that correlations between different molecules at a fixed distance can be measured and that the correlation distance can be selected by the strength of the gradient.

4 NOTE ADDED IN PROOF

Recent papers^{13–15} have dramatically extended and clarified the theoretical picture of concentrated solution effects presented here, and have provided further applications.^{16,17}

Warren et al.¹³ present a corrected version of the classical dipolar demagnetizing field treatment^{7,10} which gives quantitative agreement with experiment. Lee et al.¹⁴ extend the density matrix picture to provide exact calculations for expected signals from simple sequences, such as the CRAZED sequence, and show that the corrected classical picture of reference¹³ is equivalent to the density matrix picture under assumptions usually met in liquids. The relationship between the quantum and classical pictures is also explored by Jeener et al.¹⁵ All three of these papers show that extra resonances can be observed with gradient-free sequences as well, although gradient pulses dramatically enhance the signal. Richter et al.¹⁶ demonstrate imaging with intermolecule multiple-quantum coherences, and Vathyam et al.¹⁷ show that intermolecular zero-quantum coherences can be used to suppress inhomogeneous broadening

Figure 7 Comparison of two CRAZED experiments with different gradient directions. (a) An experiment on the same sample as in Figure 5, with the gradient pointed along the z direction. (b) The same experiment, with the gradient pointed along the magic angle; as expected, the two-quantum peaks are substantially reduced, here by a factor of 15. In order to compare the two spectra, a very low contour level was used for both

without suppressing chemical shifts or J couplings. References to other recent developments can be found in those papers.^{13–17}

1 INTRODUCTION

In the usual presentation of pulsed NMR spectroscopy, the spins are initially in equilibrium in a large constant external magnetic field. Then, a short pulse of rf current in the coil surrounding the sample tips the nuclear magnetization into a state where it precesses freely around the direction of the large field. This precession induces a small emf in the coil, which excites the resonance of the tuned sample circuit, and the resulting rf voltage is fed into the acquisition circuit of the spectrometer (after suitable amplification). However, this description ignores the 'small' effects which are the topic of the present article: (i) the rf current induced in the coil generates a (small) transverse magnetic field which acts back on the spins and (ii), independently of the coil, the bulk nuclear magnetization of the sample directly generates a (weak) magnetic field which also acts back on the spins.

With the rough technology of the early days of NMR, these back effects could be discarded on the ground that they were too small to observe, with the exception of the slow tipping of the spins by the additional rf field generated by the (observed) rf current in the tuned sample circuit. This phenomenon was described in 1954 by Bloembergen and Pound¹ under the name of 'radiation damping'. It is typical of the often counter-intuitive behavior of these back effects that the original authors unwillingly chose an unrealistic model for discussing radiation damping effects in CW spectroscopy, hence reaching some flawed conclusions; this was corrected two years later.²

As a consequence of the continuous improvement of NMR technology (higher fields, improved homogeneity, better electronics, computer controlled experiments, ...), radiation damping has become an important issue whenever a large transverse spin magnetization is present, typically that of abundant solvent nuclei with a large $|\gamma|$ (¹H, ¹⁹F, ...). In structural studies by NMR, radiation damping is routinely exploited as a component of solvent suppression strategies; otherwise it appears as a nuisance, complicating selective excitation of solvent resonances and generating misleading

spectral features in 2D experiments (see, for instance, the multiple peaks in Figure 1). The surprise caused by the first observations of these additional peaks was such that it was suggested that quantification of the rf field was necessary for a consistent prediction of the effect.³ It soon became clear that this quantification is much more difficult to treat than originally anticipated and that, after all, it is not required.^{4,5}

In the present article, the main emphasis about radiation damping is on electronic schemes for its control and suppression, leaving out important issues like the prediction of the various spectral artifacts indicated by Figure 1, and the role of radiation damping in equilibrium fluctuations.

An important contribution to relaxation in liquids comes from the fast random modulation of the dipolar couplings between nearby spins by the Brownian motion. Dipolar couplings between distant spins remain approximately constant and their effect on each spin can be described as that of a classical average dipolar field (also called 'demagnetizing field' and 'distant dipole field') generated by the bulk magnetization in the whole sample. This field was explicitly (and rightfully) 'neglected' by Torrey in 1956 (sentence before equation (5) in Ref.⁶). In single pulse experiments, the dipolar field causes

Figure 1 This is adapted from Figure 1(b) of Ahn et al.,²⁴ showing a radiation damped 600 MHz ^1H COSY spectrum of a 2:1 mixture of 1,1,2-trichloroethane (CH protons at -200 Hz, CH_2 protons at -1300 Hz) and methylene chloride (-500 Hz). In the absence of collective effects, COSY peaks are expected only at the positions marked by arrows. At the methylene chloride acquisition frequency F2, the strong additional harmonic peaks in the indirectly detected direction F1 are due to the radiation damping signal at the methylene chloride frequency, and the satellites caused by trichloroethylene are much weaker due to the large differences in chemical shift. At the trichloroethylene acquisition frequencies, much richer patterns of satellite peaks appear, combining the CH and CH_2 offsets. As shown by Ahn et al.,²⁴ these features are due to the combined effects of radiation damping and the J -coupling between CH and CH_2 protons (this J -coupling is too weak to be observed directly in the above spectrum). Under the conditions of this experiment (short evolution and acquisition times), dipolar field effects are very small. (Reproduced by permission of Taylor and Francis from S. Ahn, S. Lee, and W. S. Warren, *Mol. Phys.*, 1998, **95**, 769; <http://www.tandf.co.uk/journals>)

Figure 2 This is adapted from Figure 2 in Broekaert et al.,²³ showing cross sections along the indirectly detected direction ω_1 , taken at acquisition offsets ω_2 as indicated, through a simple absolute value 600 MHz ^1H COSY spectrum acquired with standard phase cycling. Without collective effects, only the three peaks marked with a * would be observed. The vertical scale is larger for acetone to improve the visibility of the peaks. The offset of acetone is denoted a and the other ticks under the cross sections are separated by the water offset. In order to avoid strong radiation damping, the composite sample contains only a thin cylindrical core of a solution of 10% (by volume) acetone in 90% water (H_2O). This core is parallel to the external field, and it is surrounded by a larger volume filled with D_2O containing about 0.6% HDO. Deuterium lock was active throughout the experiment. Realistic numerical simulations (see Section 4.3.4), which include the calculated dipolar field, measured rates of relaxation, together with the phase cycling and apodisation actually used, faithfully reproduce the complex structure of the water and acetone cross sections. The small additional peak on the HDO cross section is due to weak radiation damping. (Reproduced by permission of Academic Press from P. Broekaert, A. Vlassenbroek, J. Jeener, G. Lippens, and J.-M. Wieruszeski, *J. Magn. Reson. A*, 1996, **120**, 97)

small shifts in the frequency of each line, which are a function of the components of the bulk nuclear magnetization and shape of the sample. As a result, the observed frequencies vary with the tipping angle and evolve due to relaxation.⁷ These effects were first observed in 1979 in echo experiments, in which they generate multiple echoes.⁸ The same improvements in NMR technology which made radiation damping an important issue, also made the effects of the dipolar field conspicuous whenever a large nuclear magnetization is affected by rf pulses. In 2D experiments, the dipolar field shifts modulate the acquisition

frequency as a function of the duration of the evolution delay, causing the appearance of a multiplicity of additional peaks in the indirectly detected direction, as illustrated in Figures 2 and 3.

Without the interpretation in terms of radiation damping or dipolar field, the strong additional satellite peaks shown by Figures 1 and 2 might suggest the existence of long lived molecular aggregates in many liquids. This flawed interpretation would even seem to be ‘confirmed’ by observing that the satellite peaks have exactly the same phase relation with the excitation pulses as the usual *intramolecular* multiple quantum coherences. The ‘Warren’ procedure (see Section 5.2) reconciles many of these observations by showing that dipolar field effects can be described as manifestations of *intermolecular* multiple quantum coherences, which are appreciable only for concentrated samples but do not require the participating spins to be close together. For radiation damping, the predictions still rest on a combination of analytical work and numerical simulations.

New applications and new phenomena are uncovered at a high rate: medical imaging,^{9,10} high-resolution spectra in high fields of poor homogeneity and stability,^{11,12} spectral clustering and dynamical instability,^{13,14} all due to dipolar field effects.

In spite of the repeated success of the interpretation of multiple echoes in terms of a classical average dipolar field,^{8,15–18} the surprise caused by the observation of the corresponding additional peaks in COSY experiments also led the Warren group to question the validity of the ‘classical’ interpretation and to propose an alternative in which all spins in the sample are treated as a single quantum system.^{19–21} This proved to be an extremely fruitful move, which introduced the important new concept of *intermolecular* multiple quantum coherence and the idea that, in the new context, the ‘high-temperature’ approximation had to be completely re-examined. However, the earliest papers describing the new formalism also contain, besides the actual calculations and discussions, a number of provocative and questionable statements about general theoretical issues. This triggered a fierce controversy

Figure 3 This is Figure 4B from Sobol et al.,²⁵ showing contour plots of a (600 MHz ^1H) 2D $\{^{15}\text{N}^1\text{H}\}$ -HSQC-relayed NOE difference experiment used to study macromolecular hydration. The two small rectangles show subtraction artifacts originating from dipolar field effects. (Reproduced by permission of Academic Press from A. G. Sobol, G. Wider, H. Iwai, and K. Wüthrich, *J. Magn. Reson.*, 1998, **130**, 262)

which is now progressively cooling down. Fortunately, the two approaches systematically led to the same predictions for all observable effects, and their equivalence was progressively established (see Section 5.3).^{21,22}

In the present article, the emphasis concerning dipolar field effects is mainly on issues of principle (the status of the equations of motion, the high temperature approximation, ‘secular’ versus ‘non-secular’, coherences versus correlations, the incorporation of molecular diffusion in the equations of motion, the equivalence between the ‘Warren’ and the ‘classical’ formalisms, spectral clustering and dynamical instability), with simple examples in which the classical calculations are performed carefully and in detail.

Most of the ideas and results presented here are taken from the published literature, but no attempt has been made to offer a complete survey. The discussions in Sections 2.4, 2.5, 4.6, 5.2, 5.3, and 6.2 are partly new. The final version of the present article was accepted in early February, 2001. A few recent references have been added subsequently.

2 GENERALITIES

2.1 NMR Without Collective Effects

The standard presentation and interpretation of NMR spectroscopy completely ignores the possibility that the individual spins may be influenced, directly or indirectly, by the bulk nuclear magnetization of the whole sample. For pulse experiments in liquids, this general scheme is sketched in Figure 4 with, at the top, the Bloch–Redfield equation of motion for the density operator $\hat{\rho}_p(t)$ for the spins in molecule p . $\hat{H}_0$ is the spin Hamiltonian for molecule p (averaged over the molecular Brownian motion, and including chemical shifts, spin–spin couplings, . . .), the relaxation term is symbolically indicated as $\hat{\mathcal{R}}\hat{\rho}_p(t)$, and $\hat{\mathbf{m}}_p = \sum_{j \text{ in } p} \gamma_j \hbar \hat{\mathbf{I}}_j$ is the total nuclear magnetic moment operator for molecule p . Of course, the equation of motion is different for different molecular species in the liquid, and further enhancements of the description have to be introduced to incorporate inhomogeneous fields, molecular diffusion, and intermolecular nuclear Overhauser effect (NOE). In all cases, the operator in the curly braces in the Bloch–Redfield

Figure 4 Sketch of the standard theory for NMR in liquids (ignoring collective effects)

equations on top of Figure 4 is independent of the state $\hat{\rho}_p(t)$ of the spins, hence, these equations are linear in the $\hat{\rho}_p(t)$ s (except for minor complications originating from spin lattice relaxation towards the correct equilibrium situation). Furthermore, these equations have the form of the bona fide von Neumann equations of standard quantum mechanics when one neglects the relaxation terms.

On the right-hand side of Figure 4, the pulse transmitter causes rf current to circulate in the sample coil, and this generates the rf field $\mathbf{B}_1^{\text{emit}}(t)$ which is assumed to be the only field seen by the sample (besides the large external field $\mathbf{B}_0$ and the fast fluctuations causing relaxation).

The left-hand side of Figure 4 shows a step-wise description of the processes involved in the actual observation of the nuclear response. The collective effect of the average nuclear magnetic moment $\langle \mathbf{m}_p \rangle(t)$ of all molecules p in the sample is described by the nuclear magnetization density $\mathbf{M}(\mathbf{r}, t)$ (i.e., the nuclear magnetic moment per unit volume), which is proportional to the number density N/V of the molecules. The magnetic field $\mathbf{B}^M(\mathbf{r}, t)$ is the direct contribution of $\mathbf{M}(\mathbf{r}, t)$ to the magnetic field in the sample and in the surrounding space. The time derivative of the flux of $\mathbf{B}^M(\mathbf{r}, t)$ through the sample coil, which is proportional to the filling factor η , gives an induced emf which excites the resonance of the sample circuit, leading to rf currents and voltages which are further proportional to the quality factor Q of the circuit. This finally provides the input to the acquisition electronics.

It is easy to verify that, for a single spin 1/2,

$$\hat{\rho}(t) = \frac{1}{2}(\hat{1}_{\text{op}} + 4\langle \mathbf{I} \rangle(t) \cdot \hat{\mathbf{I}}) \quad (1)$$

where $\hat{\mathbf{m}} = \gamma \hbar \hat{\mathbf{I}}$ and $\langle \mathbf{m} \rangle(t) = \gamma \hbar \langle \mathbf{I} \rangle(t) = \text{Tr}\{\hat{\rho}(t) \gamma \hbar \hat{\mathbf{I}}\}$, hence, in this case, the classical vector $\langle \mathbf{m} \rangle(t)$ carries exactly the same information as the density operator. For a system of equivalent spins 1/2, equation (1) can be used to cast the equation of motion at the top of Figure 4 as the familiar Bloch equation

$$\frac{\partial}{\partial t} \langle \mathbf{m} \rangle(t) = \langle \mathbf{m} \rangle(t) \times \gamma \{ \mathbf{B}_0 + \mathbf{B}_1^{\text{emit}}(t) \} + \text{Relax} \quad (2)$$

and vice versa.

The equations of motion on top of Figure 4 [also equation (2)] and the processes shown on the left of this figure are all linear in the state of the nuclear spins. Modern acquisition electronics is also (very close to) linear, hence, the convenient and efficient tools of linear mathematics are directly applicable to the design and analysis of actual experiments. In particular, the spectral properties of the spin Hamiltonians $\hat{H}_0$ and relaxation superoperators $\hat{\mathcal{R}}$ are clearly displayed by the Fourier transforms (often multiple transforms) of suitable experiments (or computer organized sets of such experiments). These powerful and general methods are at the root of the impressive success of modern NMR.

2.2 NMR with Collective Effects

However, the provocative layout of Figure 4 clearly suggests that there is no general justification for neglecting the effect on each spin of the magnetic field $\mathbf{B}^M(\mathbf{r}, t)$ generated directly by the collectivity of all spins in the sample,

and the effect of the magnetic field generated by the rf current induced in the coil by the collective precession of these spins, except perhaps for the fact that these additional couplings would be too small to show up in actual experiments. If we stick to the ‘hydrodynamic’ description of the collective couplings as mediated by additional macroscopic magnetic fields generated by the bulk nuclear magnetization, the resulting improved scheme for the theory of NMR in liquids is sketched in Figure 5, where $\mathbf{B}_1^{\text{coil}}(t)$ stands for the rf field generated by the actual current in the coil, and the subtle difference between the dipolar field $\mathbf{B}_d(\mathbf{r}, t)$ ‘seen’ by the spins, and the Maxwell B-field $\mathbf{B}^M(\mathbf{r}, t)$ generated by the bulk nuclear magnetization, will be discussed later [see e.g., equation (29)]. Obviously, the additional macroscopic magnetic fields have components oscillating at the various NMR frequencies of the spin system; hence these will react resonantly on the spins. The dipolar field also has Z-components near zero frequency, which have a significant influence on the motion of all spins in the sample, whatever their kind.

In the simple case of equivalent spins 1/2, the equation of motion on top of Figure 5 can be written as a generalized Bloch equation [see derivation of equation (2)],

$$\frac{\partial}{\partial t} \langle \mathbf{m}_p \rangle(t) = \langle \mathbf{m}_p \rangle(t) \times \gamma \{ \mathbf{B}_0 + \mathbf{B}_d(\mathbf{r}_p, t) + \mathbf{B}_1^{\text{coil}}(t) \} + \text{Relax} \quad (3)$$

In the scheme of Figure 5, the fields $\mathbf{B}_d(\mathbf{r}, t)$ and $\mathbf{B}_1^{\text{coil}}(t)$ depend explicitly upon the state of the spins as described by the set of $\hat{\rho}_p(t)$ s for all molecules in the sample, hence the equation of motion for $\hat{\rho}_p(t)$ shown on top of Figure 5 is no longer a linear equation of motion and the general features of spin dynamics can no longer be discussed safely in the convenient and powerful framework of linear mathematics. Of course, weak collective effects can be discussed by perturbative techniques starting from the well understood situation without collective effects, but the range of validity of such techniques is often difficult to assess. For strong collective effects, analytical solutions have been found for a few particular problems but

Figure 5 Sketch of the theory for NMR in liquids (including collective effects)

one usually has to resort to numerical solutions of sets of non-linear differential equations.

The effects of the contributions of $\mathbf{B}_1^{\text{coil}}(t)$ from the spins themselves have been called (rather inappropriately) ‘radiation damping’ by Bloembergen and Pound¹ in the early days of NMR, and the field $\mathbf{B}_d(\mathbf{r}, t)$ is called ‘dipolar field’, ‘distant dipolar field’, or (rather inappropriately) ‘demagnetizing field’, and its effects are occasionally given the misleading name of ‘susceptibility effects’.

The magnitude of the observed collective effects is proportional to the magnitude of the nuclear magnetization which is present during the experiment. In the early days of proton resonance at 30 MHz or 60 MHz and poor $\mathbf{B}_0$ homogeneity (by present standards), for room temperature experiments, dipolar field effects were too small to be disturbing and radiation damping appeared as just a nasty contribution to the line width for very strong lines such as those of protons in pure organic liquids or water. Nowadays, with the development of high field superconducting magnets with excellent homogeneity, the impressive improvement in performance of the spectrometers, and the widespread use of fancy multiple pulse sequences, collective effects are an essential feature of many experiments.

Taking the example of the proton resonance in water (i.e., H_2O) at room temperature at 600 MHz, the equilibrium proton magnetization generates a dipolar field which shifts the proton NMR frequency by about 1 Hz (depending upon the shape of the sample), and radiation damping rotates the proton magnetization back towards its equilibrium direction with a characteristic time which can be as short as a few milliseconds for a large sample and a typical large product ηQ . Clearly, under these circumstances, radiation damping dominates the spin dynamics of the water protons and it is essential to regain control over these protons. One way to do this is to apply a pulsed field gradient which essentially suppresses the total transverse magnetization, and hence the fid signal and the radiation damping (see, however, Refs.^{14,78}). Some freedom in the design of experiments would be recovered by the use of electronic suppression of radiation damping, but suitable circuitry for this is not yet available from the manufacturers. One should also not forget that weak radiation damping of lines of moderate intensity generates correspondingly weak stray additional peaks in 2D experiments.²³ The radiation damping signal emitted by the excitation of one spectral line is a weak rf field at the exact frequency of that line, hence, it directly affects lines only in a correspondingly narrow spectral range centered on the emitting line (see, however, Refs.^{24,25}).

Dipolar field effects are much more insidious because, superficially, they seem to just cause minor changes of the NMR frequencies. However, the dipolar field follows the motion of the spins by which it is generated, hence, in 2D experiments, the frequency of each ‘line’ during the acquisition period (τ_2) will be modulated according to the duration (τ_1) of the corresponding evolution period. As a result, the Fourier transform with respect to τ_1 will have each expected peak ‘decorated’ by sidebands separated by multiples of the offset of the ‘lines’ affecting the dipolar field. For pure water, more than 10 such sidebands are easily visible where a single line would be expected. The Z-component of the dipolar field is ‘seen’ by all spins in the sample, hence, sidebands on one spin species can be generated by strong lines of another spin species, possibly located on different molecules. Clearly,

all this threatens to play havoc if these new effects are not well understood and, preferably, suppressed. Fortunately, these unwanted peaks were usually discarded as irrelevant by NMR users, who understood their origin or thought they were due to non-linearity in the acquisition channel of the spectrometer.

For obvious reasons of simplicity, most predictions and experiments on the collective effects have been performed in spatially uniform situations for the magnetization and the dipolar field, or with the simple spatial distributions created by pulsed field gradients. However, it has been predicted that small spatial inhomogeneities, or small deviations from the simple distributions often tend to grow exponentially due to the inhomogeneities in the dipolar field, leading to ‘spin turbulence’¹³ and irrecoverable loss of the NMR signal. In the case of pure water discussed above, after a $\pi/2$ pulse starting from equilibrium, the inhomogeneities are expected to double for every 0.1 s time interval. If radiation damping is also present, this doubling time is significantly shortened,^{14,78} particularly for helical distributions of magnetization created by field gradient pulses. This, again, stresses the importance of understanding, controlling, and preferably suppressing the collective effects.

As a counter-weight to the above catastrophic enumeration, we also mention a number of constructive uses of the collective effects. Radiation damping, undisturbed or controlled, is a useful ingredient of some of the ‘water suppression’ schemes,²⁶ and of a technique for the study of slow proton exchange between water and solute molecules,²⁷ and may lead to sensitive detection of very weak resonances.²⁸ The dipolar field effect can also be the basis of sensitive detection schemes for low- γ nuclei¹⁷ and, remarkably, to imaging techniques with new selectivities,²⁹ and to the observation of high resolution spectra in high magnetic fields of moderate homogeneity and stability.¹¹

2.3 The Status of the Equations of Motion

2.3.1 In the Absence of Collective Effects

The standard formulation of orthodox quantum dynamics uses the Schrödinger equation of motion

$$\frac{\partial}{\partial t}|t\rangle = \frac{1}{i\hbar}\hat{H}(t)|t\rangle \quad (4)$$

where the ket $|t\rangle$ gives the most precise quantum mechanical description of the state of the dynamical system under discussion, and the Hermitian operator $\hat{H}(t)$ is the observable associated with the energy of the system. This equation holds for any ket $|t\rangle$, and $\hat{H}(t)$ is *independent* of the state of the system. A general formal solution of this equation of motion can be written under the form

$$|t\rangle = \hat{U}(t, t_0)|t_0\rangle$$

with

$$\frac{\partial}{\partial t}\hat{U}(t, t_0) = \frac{1}{i\hbar}\hat{H}(t)\hat{U}(t, t_0) \quad \text{and} \quad \hat{U}(t_0, t_0) = \hat{I}_{\text{op}} \quad (5)$$

where the unitary evolution operator $\hat{U}(t, t_0)$, also called propagator, is *independent* of the state of the system. When the state of the system is known only in a statistical sense,

as in most NMR situations, it is more convenient to describe this (average) state by the density operator $\hat{\rho}(t)$ which is the average projector on all possible kets $|t, k\rangle$ weighted by the probability p_k of the ket $|t, k\rangle$,

$$\hat{\rho}(t) = \sum_k p_k |t, k\rangle \langle t, k| \quad (6)$$

By this definition, $\hat{\rho}(t)$ is a Hermitian operator with eigenvalues in the interval between 0 and 1, and $\text{Tr}\{\hat{\rho}(t)\} = 1$. When $\hat{\rho}(t)$ is known, the quantum and statistical average value $\langle A \rangle(t)$ of any observable $\hat{A}$ can be evaluated as

$$\langle A \rangle(t) = \text{Tr}\{\hat{A}^\dagger \hat{\rho}(t)\} \quad (7)$$

where the adjoint (†) transformation is relevant when average values are evaluated for non-Hermitian operators like $\hat{I}_+$ or $\hat{I}_-$ (see Section 5.2). Corresponding to the Schrödinger equation of motion for kets, we have the von Neumann equation of motion for the density operator

$$\frac{\partial}{\partial t} \hat{\rho}(t) = \frac{1}{i\hbar} [\hat{H}(t), \hat{\rho}(t)]$$

hence

$$\hat{\rho}(t) = \hat{U}(t, t_0) \hat{\rho}(t_0) \hat{U}(t_0, t) = \hat{\hat{U}}(t, t_0) \hat{\rho}(t_0) \quad (8)$$

where the unitary superoperator $\hat{\hat{U}}(t, t_0)$, defined by equation (8), is *independent* of the state of the system. The Schrödinger equation is linear in the ket $|t\rangle$ and the von Neumann equation is linear in the density operator $\hat{\rho}(t)$.

When relaxation is taken into account, the simplest situation arises for the spins on a single molecule, ignoring couplings with other molecules and assuming that the rotational Brownian motion which causes the relaxation has a very short auto-correlation time. In this case, one can derive a Bloch–Redfield equation of motion of the form

$$\frac{\partial}{\partial t} \overline{\hat{\rho}(t)} = \frac{1}{i\hbar} [\overline{\hat{H}(t)}, \overline{\hat{\rho}(t)}] + \hat{\hat{R}} \overline{\hat{\rho}(t)} \quad (9)$$

where the overline indicates averaging over all realizations of the molecular Brownian motion, $\hat{\hat{R}}$ is the linear relaxation superoperator, and any time dependence of $\overline{\hat{H}(t)}$ arises from the time dependence of the macroscopic magnetic field (rf field, gradients, ...). $\overline{\hat{\rho}(t)}$ has all the desirable properties mentioned after equation (6) and $\overline{\hat{H}(t)}$ is an acceptable Hamiltonian. Hence, if relaxation is ignored, equation (9) has the status of a von Neumann equation. However, it loses this status when relaxation is taken into account. For instance, it is no longer possible to write the general solution of equation (9) under the form $\overline{\hat{\rho}(t)} = \hat{U}(t, t_0) \overline{\hat{\rho}(t_0)} \hat{U}(t_0, t)$, whatever the choice made for $\hat{U}(t, t_0)$.³⁰ This does not prevent equation (9) from being an acceptable and useful ‘kinetic’ equation of motion. In the present case, the equation remains linear in $\overline{\hat{\rho}(t)}$, hence linear mathematics are still applicable for its solution. The overlines used here are traditionally not shown explicitly, but we shall keep them in the present subsection for clarity.

2.3.2 In the Presence of Collective Effects

When collective effects are taken into account following the ‘classical’ approach, which uses density operators for the

spins in single molecules, the kinetic equations of motion are of the type shown in Figure 5, namely

$$\frac{\partial}{\partial t} \overline{\hat{\rho}_p(t)} = \frac{1}{i\hbar} [\{\hat{H}_0 - \hat{\mathbf{m}}_p \cdot (\mathbf{B}_d(\mathbf{r}, t) + \mathbf{B}_1^{\text{coil}}(t)), \overline{\hat{\rho}_p(t)}\} + \hat{\hat{R}} \overline{\hat{\rho}_p(t)}] \quad (10)$$

where the fields $\mathbf{B}_d(\mathbf{r}, t)$ and $\mathbf{B}_1^{\text{coil}}(t)$ depend explicitly upon the states $\{\overline{\hat{\rho}_p(t)}\}$ of all the spins in the sample, making the equation non-linear. This dependence also prevents equation (10) from recovering the von Neumann status when relaxation is ignored. A third major change in status caused by the collective effects is that the problem becomes non-local in space: whatever happens at one location depends upon the spin state at all locations in the sample.

These differences in status and their consequences have not always been fully appreciated in the recent literature, and the unorthodox notion of a state-dependent propagator, used for solving equation (10) with collective effects, has led to some unjustified conclusions. However, the following idea may help in this context. Consider an experiment in which collective effects are important, involving a given (unique) sequence of pulses at times $t > t_0$, and an *exactly specified initial condition* at $t = t_0$ for all $\overline{\hat{\rho}_p(t_0)}$ s. Under these precise conditions, the complete evolution, including the fields $\mathbf{B}(\mathbf{r}, t)$ and $\mathbf{B}_1^{\text{coil}}(t)$ in equation (10), is completely determined by this set of equations supplemented by the expressions for the collective fields in terms of the density operators $\hat{\rho}_p(t)$ indicated in Figure 5. At this point, we may (i) consider the collective fields as *known* functions of $\mathbf{r}$ and t , (ii) change the interpretation of the collective fields in equation (10) from ‘depending upon the $\overline{\hat{\rho}_p(t)}$ s’ to ‘known functions of $\mathbf{r}$ and t ’, and (iii) solve the new version of equation (10) with the initial condition $\{\overline{\hat{\rho}_p(t_0)}\}$ used above. The new version of equation (10) is linear in the $\overline{\hat{\rho}_p(t)}$ s, the solution obtained under (iii) above can be expressed in terms of an evolution operator [see equation (8)] if relaxation is neglected, and it coincides with the ‘exact’ solution. However, these desirable properties are just an illusion in the present context because the ‘new version’ of equation (10) is valid only for a single initial condition (the collective fields change for different initial conditions), hence linearity is useless here because it cannot be used to combine evolutions with different initial conditions. Also, the collective fields are known only if the complete non-linear problem has been solved in the first place.

The issue of relaxation deserves special attention in the context of collective effects. ‘Spin–spin’ and ‘spin–lattice’ relaxation in fluids result from random processes which take place independently in each molecule (or in each pair of close by molecules if one considers intermolecular relaxation and NOE effects). In contrast, the radiation damping field and the dipolar field are macroscopic fields which act in the same way on all molecules in each small macroscopic region of the sample. Hence, for each of these macroscopic regions, the collective effects do not provide a relaxation mechanism any more than the usual rf irradiations or field inhomogeneities. This still holds when the dipolar field effects are ‘suppressed’ by rf irradiation²³ or by magic angle spinning (MAS),³¹ and when radiation damping is controlled electronically in any way.^{32–34}

The dipolar field describes dipolar interactions among spins (in different molecules), so that its contribution to the motion conserves total spin energy (i.e., for all molecules in the

sample). This does not prevent the dipolar field from possibly increasing $\langle \mathbf{m}_p \rangle_Z$ in some regions of the sample with a compensating decrease in other regions.

2.4 Incorporating Molecular Diffusion in the Kinetic Equations

At the microscopic level, the translational diffusion of molecules manifests itself as an important source of spin relaxation by the fast modulation of the large intermolecular spin–spin couplings at short distances. At the macroscopic level, the same translational diffusion is a major source of damping of spin echoes and pulsed field gradient responses. In these experiments, large position-dependent NMR phase shifts are created by macroscopically inhomogeneous fields and, subsequently, the phase shifts are refocused, hence producing a maximum fid if the molecules are immobile. Molecular diffusion disturbs this refocusing by randomly moving the molecules through locations with significantly different fields over the duration of the experiment. Equivalently, molecular diffusion can also be viewed as a mechanism for the spatial transport of the average spin properties, analogous to heat transport or ordinary diffusion.

This macroscopic mechanism was well understood very early and still provides the most accurate and general technique for measuring molecular diffusion in liquids. In the simple case of a single line spectrum, experiments can be adequately discussed in terms of a nuclear spin magnetization density $\mathbf{M}(\mathbf{r}, t)$ moving according to Bloch's equations complemented by a suitable molecular diffusion term and, if appropriate, by collective contributions. A very detailed and illuminating derivation of this diffusion term was given by Torrey⁶ in 1956.

For more complicated situations, involving polyatomic molecules with non-trivial NMR spectra and multiple pulse preparation of intramolecular N-quantum coherences, a density operator description of the spin state of each individual molecule is, of course, required. Somewhat surprisingly, the role of molecular diffusion in this context is traditionally discussed separately for each order N of coherence, and only for particular experiments.^{35–38} This limitation has the drawback of hiding the general features of spin dynamics, and constitutes an undesirable weakness when this dynamics is further complicated by dipolar field effects.

This section presents a method³⁹ for incorporating the effects of molecular diffusion (and also bulk flow) in the equation of motion of the density operator for the spins in a single molecule. The derivation follows Torrey's original discussion,⁶ using concepts similar to the 'stochastic Liouville equation' as presented, for instance, by Schneider and Freed.⁴⁰

The position $\mathbf{r}_p$ of molecule p is an important parameter whenever the initial condition or the magnetic field are not spatially uniform. When these non-uniformities are very small over the average distance between first neighbors and over the mean free path, a hydrodynamic type of description is more appropriate than one which focuses on the fate of individual molecules. The essential ingredients of such a description are that (i) each molecule carries its spin state in bulk flow and Brownian motion, and that (ii), over the relevant scales of distance and duration, the probability distribution for the future position of any molecule depends only upon its present position (and, usually very weakly, upon its present spin state), and not upon its past motion. For simplicity, the following detailed discussion is pursued for molecules all of the same kind.

A satisfactory hydrodynamic description of the spin state of the molecules in a liquid can be given in terms of the generic density operator $\hat{\rho}(\mathbf{r}, t)$, defined as the average density operator for all molecules which are very close to $\mathbf{r}$ at time t . $\hat{\rho}(\mathbf{r}, t)$ has the general static properties of a density operator (Hermitian, $\text{Tr} \{ \hat{\rho}(\mathbf{r}, t) \} = 1$, all eigenvalues between 0 and 1), and provides the complete information required to evaluate any average spin property for the molecules close to $\mathbf{r}$ at time t . As an example, the nuclear magnetization density is given by $\mathbf{M}(\mathbf{r}, t) = n \text{Tr} \{ \hat{\mathbf{m}}_p \hat{\rho}(\mathbf{r}, t) \}$, where n is the number of molecules per unit volume (which is taken as constant and uniform), and the magnetic moment operator $\hat{\mathbf{m}}_p$ is the same as in Section 2.1.

If diffusion and flow are absent, the molecules which are close to position $\mathbf{r}$ are always the same, they 'see' the same macroscopic fields, hence their $\hat{\rho}(t)$ s evolve according to the same equation of motion (10), and this also holds for the generic density operator at position $\mathbf{r}$,

$$\left(\frac{\partial}{\partial t} \right)_{\substack{\text{no diff} \\ \text{no flow}}} \hat{\rho}(\mathbf{r}, t) = \hat{\mathcal{R}} \hat{\rho}(\mathbf{r}, t) + \frac{1}{i\hbar} \left[\{ \hat{H}_0 - \hat{\mathbf{m}}_p \cdot (\mathbf{B}_d(\mathbf{r}, t) + \mathbf{B}_1^{\text{coil}}(t)) \}, \hat{\rho}(\mathbf{r}, t) \right] \quad (11)$$

where the collective fields are generated by $\mathbf{M}(\mathbf{r}, t)$ defined just above.

In order to enhance the analogy with the standard discussion of heat transport or diffusion, it is useful to introduce the notion of a (generic) density operator per unit volume $n\hat{\rho}(\mathbf{r}, t)$, such that the sum of the density operators for all molecules in a small volume ΔV can be expressed as $n\hat{\rho}(\mathbf{r}, t)\Delta V$. If we now take molecular diffusion and flow into account, $n\hat{\rho}(\mathbf{r}, t)\Delta V$ will evolve by two mechanisms, (i) the usual spin dynamics given by equation (11) for the molecules inside ΔV , and (ii) the difference between the $\hat{\rho}$ of the molecules which enter and leave ΔV through its boundary, given by the divergence of the flux density $\hat{\mathbf{J}}_{n\hat{\rho}}(\mathbf{r}, t)$ of the quantity $n\hat{\rho}(\mathbf{r}, t)$. The flux density $\hat{\mathbf{J}}_{n\hat{\rho}}(\mathbf{r}, t)$ is the sum of three contributions: (i) a flow term $\mathbf{v}(\mathbf{r}, t)n\hat{\rho}(\mathbf{r}, t)$, (ii) an 'unbiased diffusion term' $-D\nabla_r \{ n\hat{\rho}(\mathbf{r}, t) \}$, and (iii) a small drift term $\hat{\mathbf{J}}_{\text{drift}}(\mathbf{r}, t)$ arising from the force exerted by the magnetic field *gradient* on each molecule depending upon its actual spin state (the same force which operates in the Stern–Gerlach experiment), hence

$$\hat{\mathbf{J}}_{n\hat{\rho}}(\mathbf{r}, t) = \mathbf{v}(\mathbf{r}, t)n\hat{\rho}(\mathbf{r}, t) - D\nabla_r \{ n\hat{\rho}(\mathbf{r}, t) \} + \hat{\mathbf{J}}_{\text{drift}}(\mathbf{r}, t) \quad (12)$$

where $\mathbf{v}(\mathbf{r}, t)$ is the bulk velocity of the liquid at position $\mathbf{r}$ and time t , and D is the coefficient of self diffusion of the relevant molecules (which may be a tensor in anisotropic fluids like liquid crystals). The drift term is easily evaluated by considering the situation of complete thermal equilibrium in the absence of bulk flow. In this case, all net flows vanish, but the equilibrium density operator $\hat{\rho}^{\text{eq}}(\mathbf{r}, t)$ is not uniform if the magnetic field is not uniform, hence equation (12) takes the form

$$0 = -D\nabla_r \{ n\hat{\rho}^{\text{eq}}(\mathbf{r}, t) \} + \hat{\mathbf{J}}_{\text{drift}}(\mathbf{r}, t) \quad (13)$$

which gives an explicit expression for $\hat{\mathbf{J}}_{\text{drift}}(\mathbf{r}, t)$ in equilibrium. For all standard NMR situations, which are very close to complete spin disorder ('high spin temperature'), equation (13)

remains a good approximation out of equilibrium, hence, equation (12) can be written as

$$\hat{\mathbf{J}}_{n\hat{\rho}}(\mathbf{r}, t) = \mathbf{v}(\mathbf{r}, t)n\hat{\rho}(\mathbf{r}, t) - D\nabla_r\{n\hat{\rho}(\mathbf{r}, t) - n\hat{\rho}^{\text{eq}}(\mathbf{r}, t)\} \quad (14)$$

We can now combine the effects of local spin dynamics ('no diffusion, no flow') with those of diffusion and flow to obtain a continuity equation for $n\hat{\rho}^{\text{eq}}(\mathbf{r}, t)$,

$$\left(\frac{\partial}{\partial t}\right)n\hat{\rho}(\mathbf{r}, t) = \left(\frac{\partial}{\partial t}\right)_{\substack{\text{no diff} \\ \text{no flow}}}n\hat{\rho}(\mathbf{r}, t) - \nabla_r \cdot \hat{\mathbf{J}}_{n\hat{\rho}}(\mathbf{r}, t) \quad (15)$$

Combining now equations (11), (14), and (15), and taking account that $\nabla_r \cdot \mathbf{v}(\mathbf{r}, t)$ vanishes for an incompressible fluid, we obtain finally

$$\begin{aligned} \left(\frac{\partial}{\partial t}\right)\hat{\rho}(\mathbf{r}, t) &= \hat{\mathcal{R}}\hat{\rho}(\mathbf{r}, t) \\ &+ \frac{1}{i\hbar} \left[\{\hat{H}_0 - \hat{\mathbf{m}}_p \cdot (\mathbf{B}_d(\mathbf{r}, t) + \mathbf{B}_1^{\text{coil}}(t)), \hat{\rho}(\mathbf{r}, t)\} \right] \\ &- \mathbf{v}(\mathbf{r}, t) \cdot \nabla_r \hat{\rho}(\mathbf{r}, t) + \nabla_r D \nabla_r \{\hat{\rho}(\mathbf{r}, t) - \hat{\rho}^{\text{eq}}(\mathbf{r}, t)\} \end{aligned} \quad (16)$$

where the drift term involving $D\nabla_r \hat{\rho}^{\text{eq}}(\mathbf{r}, t)$ can be neglected in all practical situations, as discussed by Torrey.⁶ Equation (16) leads directly to the usual expressions for the effects of molecular diffusion on intramolecular N-quantum coherences.³⁵⁻³⁸ For mixtures of molecules of different types, a different generic density operator is introduced for each type of molecule, as usual (and also a different coefficient of self diffusion D and a different number density n).

In the simple case of a single line NMR spectrum (strictly speaking, similar molecules bearing a single spin 1/2), equation (16) can be simplified considerably by using equation (1), and the result no longer involves quantum operators,

$$\begin{aligned} \frac{\partial}{\partial t}\mathbf{M}(\mathbf{r}, t) &= \mathbf{M}(\mathbf{r}, t) \times \gamma\{\mathbf{B}_0 + \mathbf{B}_d(\mathbf{r}, t) + \mathbf{B}_1^{\text{coil}}(t)\} \\ &- \mathbf{v}(\mathbf{r}, t) \cdot \{\nabla_r \mathbf{M}(\mathbf{r}, t)\} \\ &+ \nabla_r \cdot (D\nabla_r \{\mathbf{M}(\mathbf{r}, t) - \mathbf{M}^{\text{eq}}(\mathbf{r}, t)\}) + \mathcal{R}\text{elax} \end{aligned} \quad (17)$$

This is the usual Bloch equation, with additional terms describing radiation damping and dipolar field effects (see equation (3)), and Torrey's term⁶ to account for molecular diffusion. In order to avoid ambiguities, note that the meaning of the vectorial notation used in equation (17) is $\mathbf{A} \cdot \{\nabla_r \mathbf{M}(\mathbf{r})\} = \sum_{u=x,y,z} \mathbf{1}_u \{\mathbf{A} \cdot (\nabla_r \mathbf{M}_u(\mathbf{r}, t))\}$, where $\mathbf{A}$ can be $\mathbf{v}(\mathbf{r}, t)$ or ∇_r , and $\mathbf{1}_u$ is a unit vector pointing in the direction u .

A different line of reasoning has been proposed, in which one solves the Bloch equation for a spin undergoing Brownian motion, taking into account the changing macroscopic magnetic field encountered during this random walk.^{41,42} Of course, averages have to be evaluated at the end over all initial positions and over all realizations of the Brownian random walk.

Both methods should lead to the same conclusions (and, indeed, they do) so that the choice should be a matter of taste or convenience. However, in the presence of a position dependent magnetic field, the averaging over all realizations of the Brownian motion is tricky and proved to be prone to errors,^{41,42} particularly in the presence of a dipolar field caused by the spins themselves.⁴³

2.5 The High Temperature Approximation, Validity and 'Breakdown'

In the absence of collective effects, the high temperature approximation is a perfectly clear concept in liquid NMR: for non-cryogenic experiments starting from thermal equilibrium, and for any given pulse sequence, all observable NMR signals $\text{fid}(t, T_S)$ are proportional to the inverse of the initial spin temperature T_S ,

$$\text{fid}(t, T_S) = \left(\frac{1}{T_S}\right) \text{fid}_1(t) \quad (18)$$

where $\text{fid}_1(t)$ is independent of T_S , and the dependence of the rates of relaxation upon the temperature of the liquid has been ignored. Starting from the equation on top of Figure 4, it is easy to verify that all contributions neglected in the high temperature approximation are too small to be observed.

In the presence of collective effects, the concept of the 'high temperature approximation' can be interpreted in different ways, and this caused some confusion and a flurry of fierce controversy in liquid NMR for the last 10 years. Two of these interpretations will now be illustrated on a simple example in which the dipolar field has observable effects, radiation damping is neglected, all magnetic fields are homogeneous throughout the sample, and all spins are equivalent (for instance, a thin cylinder of water parallel to the direction Z of the large external field). With the notation of Figures 4 and 5, the average equilibrium magnetic moment per spin $\langle \mathbf{m} \rangle_{\text{equil}}$ is proportional to the inverse temperature $1/T$, hence $\langle \mathbf{m} \rangle_{\text{equil}} = (1/T)W\mathbf{1}_Z$, where W is a constant and $\mathbf{1}_Z$ is the unit vector along Z . For this simple configuration and a uniform magnetization throughout the sample, the relevant part of the dipolar field is given by $\mathbf{B}_d^{\text{homol}}(t) = q\langle m_Z \rangle(t)\mathbf{1}_Z$ [see equation (38)], and this will just cause a shift of the NMR frequency by $\Delta\omega_d(t) = K\langle m_Z \rangle(t)$, where q and K are constants. For simplicity, relaxation will be ignored.

The response to a pulse of angle θ in the Y direction, occurring at $t = t_0$, is given by

$$\begin{aligned} \langle m_X \rangle(t) + i\langle m_Y \rangle(t) &= \text{fid}(t, T) \\ &= (1/T)W \sin \theta \exp(i\{\omega_0 + \Delta\omega_d\}\{t - t_0\}) \\ &= (1/T)W \sin \theta \exp(i\{\omega_0 + K(1/T)W \cos \theta\}\{t - t_0\}) \\ \text{and } \langle m_Z \rangle(t) &= (1/T)W \cos \theta \end{aligned} \quad (19)$$

where ω_0 is the NMR frequency in the absence of collective effects. Clearly, the predicted NMR frequency depends upon the pulse angle and the initial spin temperature or spin magnetization. The results of this simple and direct experiment were reported by Edzes,⁷ with excellent quantitative agreement between predictions and measurements.

In the derivation of equation (19), the high temperature approximation is invoked in two different contexts, each time with single molecules in mind: the absolute magnitude of the fid , and the dipolar shift in NMR frequency. In each case, the term in $(1/T)$ is sufficient. However, the discussion of more complex, multiple pulse experiments is often clarified by the use of a different implementation of the 'high temperature approximation' concept, in which properties of the whole spin system, like the fid or the density operator for all spins, are

expressed as a ‘systematic’ series expansion in powers of $(1/T)$. In the case of equation (19), this gives

$$\begin{aligned} \text{fid}(t, T) &= \left(\frac{1}{T}\right) \text{fid}_1(t) + \left(\frac{1}{T}\right)^2 \text{fid}_2(t) + \dots \\ \text{fid}_1(t) &= W \sin \theta \exp(i\omega_0\{t - t_0\}) \\ \text{fid}_2(t) &= \text{fid}_1(t) i K W \cos \theta \{t - t_0\}, \dots \end{aligned} \quad (20)$$

where the functions $\text{fid}_n(t)$ are independent of T . Admittedly, the ‘systematic’ series expansion does not seem particularly illuminating for this simple, single pulse experiment. However, if one performs an elementary COSY experiment on the same sample and analyzes the signals by the usual double Fourier transform, the traditional peaks are ‘decorated’ by a number of satellites in the ω_1 direction, separated by integer multiples of the offset of ω_0 . In this case, and for most other multiple pulse experiments, the ‘systematic’ series expansion in powers of $(1/T)$ nicely separates the satellite peaks in small groups with similar phase properties with respect to the phase difference between the two excitation pulses. The Warren group has shown^{19–21} that this separation can be understood in an illuminating way by first performing a ‘systematic’ series expansion in powers of $(1/T)$ on the equilibrium density operator for the quantum system of all spins in the sample (see Section 5.2). Unfortunately the expression ‘spectacular breakdown of the high temperature approximation’, which they used in announcing their results, was not well understood at the time.

3 RADIATION DAMPING

3.1 A Simple Example

By way of introduction,^{1,44} consider a sample of equivalent spins, subjected to homogeneous fields $\mathbf{B}_0$ and $\mathbf{B}_1^{\text{coil}}(t)$, and neglect relaxation and dipolar field effects. The relevant equation of motion is equation (3). In equilibrium, $\langle \mathbf{m} \rangle_{\text{eq}}$ points in the same direction as $\mathbf{B}_0$, which we choose as the Z-direction. Now consider a situation with $\langle \mathbf{m} \rangle(t)$ tilted from $\mathbf{B}_0$ by an angle $\theta(t)$. To a first approximation (neglecting radiation damping), $\langle \mathbf{m} \rangle(t)$ precesses around Z at the large angular velocity $\omega_0 = -\gamma \mathbf{B}_{0Z}$, hence $\langle m_x \rangle(t) = |\langle \mathbf{m} \rangle| \sin(\theta(t)) \cos(\omega_0 t + \phi_x)$, and the emf induced in the coil (with its axis in the X-direction) is proportional to the time derivative of $\langle m_x \rangle(t)$, hence $\text{emf}(t) = K \omega_0 |\langle \mathbf{m} \rangle| \sin(\theta(t)) \sin(\omega_0 t + \phi_x)$, where K is proportional to (N/V) , η , the cross-section of the coil, and the number of turns. In all practical NMR situations, the time dependence of the amplitude and phase ϕ_x of $\text{emf}(t)$ is very much slower than the damping of the tuned sample circuit, hence steady state AC circuit theory applies and the current $i(t)$ in the coil is proportional to $\text{emf}(t)$ (with an appropriate phase shift), $i(t) = k K \omega_0 |\langle \mathbf{m} \rangle| \sin(\theta(t)) \cos(\omega_0 t + \phi_i)$, where k is proportional to the quality factor Q of the sample circuit divided by its characteristic impedance.

This current $i(t)$ flows through the series resistance R_s of the circuit and generates an average Joule power (averaged over one period at frequency $\omega_0/2\pi$) $\mathcal{P}(t) = \frac{1}{2} R_s (i_{\text{max}})^2$ as heat in R_s ,

$$\mathcal{P}(t) = \frac{R_s}{2} [k K \omega_0 |\langle \mathbf{m} \rangle| \sin(\theta(t))]^2 \quad (21)$$

In the present model without relaxation, this power can originate only from a corresponding rate of decrease of the total spin energy

$$E_S(t) = -N \langle \mathbf{m} \rangle(t) \cdot \mathbf{B}_0 = -N |\langle \mathbf{m} \rangle| |\mathbf{B}_0| \cos(\theta(t)) \quad (22)$$

where N is the number of spins in the sample. This is a plausible scenario, because the rf field generated by the rf current $i(t)$ in the coil can, indeed, affect the spin energy by rotating $\langle \mathbf{m} \rangle(t)$. Combining the above relations as $dE_S(t)/dt = -\mathcal{P}(t)$, we obtain

$$\frac{d}{dt} \theta(t) = -\frac{1}{\tau_r} \sin(\theta(t)) \quad (23)$$

where the characteristic rate of radiation damping $(1/\tau_r)$ is given by

$$\frac{1}{\tau_r} = 2\pi Q \eta |\gamma| \frac{N |\langle \mathbf{m} \rangle|}{V} \quad (24)$$

for a circuit tuned exactly at the NMR frequency of the spins, and decreases for increasing mistuning (never changing sign). It is easy to check that, for this simple example with a perfectly tuned sample circuit, radiation damping rotates $\langle \mathbf{m} \rangle(t)$ in a fixed vertical plane in a frame rotating around Z at the ‘unperturbed’ NMR angular velocity of the spins $\omega_0 \mathbf{1}_Z$.

Of course, the same conclusions can be reached by following the more detailed reasoning indicated in Figure 5, with the advantage of lifting the restrictions of perfect tuning,⁴⁵ single line, homogeneous fields,⁴⁶ neglect of relaxation, ... However, the detailed calculations involve a number of issues of sign which have been too often treated with contempt. The energy argument used above has the advantage of showing unambiguously that radiation damping rotates the nuclear magnetization towards the direction of $\mathbf{B}_0$, and not the opposite which would imply an absorption of heat by the resistance R_s (contrary to the second law of thermodynamics). Note that this argument breaks down when additional sources of organized energy participate in the process, as happens in active electronic control of radiation damping.^{32,33}

The solution of equation (23) for $\theta(t_0)$ known at time t_0 is

$$\theta(t) = 2 \arctan \left[\tan \left(\frac{\theta(t_0)}{2} \right) \exp \left(\frac{-(t - t_0)}{\tau_r} \right) \right] \quad (25)$$

Figure 6 shows this solution for the usual range of θ , between 0 and π .

Assuming perfect tuning (and no relaxation) for simplicity, the response to a hard rf y-pulse of angle θ_0 applied at $t = t_0$ is easily evaluated with the help of equation (25),

$$\langle m_x \rangle(t) + i \langle m_y \rangle(t) = \sin(\theta(t)) \exp(i\delta\omega\{t - t_0\}) \quad (26)$$

Figure 6 The solid line shows equation (25) for $t_0 = 0$ and $\theta(t_0) = \pi/2$. The dots show, respectively, approximations for θ close to 0 and close to π . The tick marks on the t scale are at τ_r intervals

Figure 7 The effects of radiation damping on the response to a θ_0 hard pulse, for a single line spectrum (same conditions as for equation (24)). Top row: the x -component of the spin magnetization after a y -pulse, as a function of time (in the rotating frame, with a small offset of the spectral line). Lower row: the 'absorption component' of the Fourier transform of the upper row, as a function of frequency. For $\theta_0 = 0.1$, the dotted graphs are enlarged vertically by a factor of 10 for visibility

where the subscripts x and y indicate rotating frame components, and $\delta\omega$ is the offset of the nuclear spin Larmor frequency from the reference frequency of the transmitter and rotating frame. As illustrated in Figure 7, the response to a pulse of (very) small angle is damped exponentially with the characteristic time τ_r , in complete analogy with the usual damping by 'spin-spin' relaxation with $T_2 = \tau_r$ and no radiation damping. The Fourier transform of this response has the usual Lorentzian line shape (with the role of T_2 played by τ_r). For larger pulse angles, the response is not damped exponentially any more, and the Fourier transform is visibly non-Lorentzian.⁴⁷ A particularly striking situation occurs after a pulse with an angle very close to π , where the magnetization first points very close to the direction opposite to that of $\mathbf{B}_0$, with a very small transverse magnetization generating a very weak radiation damping. However, this radiation damping will rotate the magnetization towards the direction of $\mathbf{B}_0$, i.e., away from the opposite direction, hence, the transverse magnetization will increase together with its rate of increase, and θ will soon decrease through $\pi/2$ and tend to its steady state value 0, as shown also by Figure 6. For such a pulse close to π , the Fourier transform of the fid is qualitatively very different from a Lorentzian line shape.

The general properties of Fourier transforms imply that the integral over frequency of the (complex) line shapes is equal (with proper normalization) to the initial value of the (complex) transverse magnetization, irrespective of the mechanism causing the eventual decay of the nuclear response. This is the basis of the important general relation between the area under an absorption line and the number of spins participating in the line. However, in the case of radiation damped signals, a small initial transverse magnetization, hence a small area under the absorption component of the Fourier transform, does not necessarily imply that the Fourier transform itself is small (in absolute value), as shown by the examples on the left and right of Figure 7. A number of other unexpected features are discussed in a review article by Mao and Ye⁴⁸ (attention should be paid to the non-standard definitions given and used by these authors, see also Ref.⁴⁹).

It has already been pointed out that radiation damping is not a relaxation mechanism for the spins, hence, the 'line shapes' obtained by Fourier transform of radiation damped signals cannot (and should not) be interpreted as absorption-dispersion spectra. However, radiation damping affects the transverse and longitudinal components of the spin magnetization in ways

which are quite similar to relaxation effects, and this is a major problem for the measurement of long relaxation times T_1 and T_2 of spins which are not very diluted.⁵⁰

In 2D and more sophisticated experiments, radiation damping causes the appearance of stray peaks after Fourier transforms.⁴⁵ The main culprit is, typically, the water signal. However, this very large signal is usually not the interesting one, and its taming is the purpose of the many 'water suppression' schemes.

3.2 Electronic Control of Radiation Damping

3.2.1 Introduction

Radiation damping is mediated by the electrical current flowing through the sample coil. This is a physical quantity *completely external* to the sample, hence under the direct control of the experimenter (hopefully, at least); different schemes have been proposed and demonstrated to achieve this control. An *ideal* scheme should not interfere with the normal operation of the spectrometer in any way, and retain high efficiency in all cases. For instance, it should operate during acquisition without degradation of signal to noise ratio or generation of spurious signals, and allow the use of 'digital quadrature' and other refinements. It should also provide suppression of radiation damping during 'soft pulses', hence allowing the use of very selective 'soft pulses' weaker than the radiation damping signal generated by the relevant spins.

3.2.2 A Digression about Electrical Engineering

The more ambitious and promising schemes use some simple notions of the electrical engineering of coaxial cables, which are usually not familiar to the users of NMR. For the convenience of the reader, some of these notions are now briefly reviewed, without providing detailed proofs or derivations.

Our model of coaxial cable ignores losses in the cable (electrical resistance of the conductors, dielectric losses in the insulator), and uses approximations valid for wavelengths of the signal much longer than the diameter of the cable. The only situations examined are the desirable ones in which the signal is entirely inside the cable and does not extend outside, as shown in Figure 8(a). The relevant variables are the position x along the cable, the time t , the intensity $i(x, t)$ of the current in the inner conductor, and the difference in electrical potential $V(x, t)$ between inner and outer conductor, both at every position x and every time t .

Any distribution of intensity $i(x, t)$ and voltage $V(x, t)$ in the cable can be decomposed uniquely as a sum of two 'running waves' propagating in opposite directions at the velocity v of light in the cable dielectric,

$$\begin{aligned}
 (a) \quad i(x, t) &= i_p(x - vt) + i_m(x + vt) \quad \text{and} \\
 (b) \quad V(x, t) &= V_p(x - vt) + V_m(x + vt); \quad \text{with} \\
 (c) \quad V_p(x - vt) &= +Z_c i_p(x - vt) \quad \text{and} \\
 (d) \quad V_m(x + vt) &= -Z_c i_m(x + vt)
 \end{aligned} \tag{27}$$

where the (real, positive) characteristic impedance Z_c depends upon the log of the ratio of the inner and outer diameters of the conductors of the cable. A typical value for Z_c is 50 ohms.

Figure 8 (a) Exactly opposite currents circulate, respectively in the inner and the outer conductor, at any position x and date t . This cancels all magnetic fields generated by these currents, except in the cable dielectric. The convention of sign used is that the arrow points in the direction of transport of conventional positive charges when the associated symbol, e.g., $i(x, t)$, has a positive value. (b) A running wave is completely absorbed when the cable is terminated by a resistance equal to its characteristic impedance Z_c .

The subscript p stands for propagation in the positive direction (i.e., increasing x), and m for the negative direction.

In order to discuss realistic situations, we still have to supplement equations (27), which describe the propagation in the cable, with information about the electrical circuits connected at both ends of the cable. Only a few very simple situations will be examined here. First, assume that the cable is cut at $x = x_0$, and that each half cable remains open-circuited. This will prevent electrical current from circulating at $x = x_0$, hence, $i(x_0, t) = 0$ at all t , hence, $i_p(x_0 - vt) = -i_m(x_0 + vt)$. The running waves are reflected by an open-circuited end, with a change in sign of the ‘running’ i ’s, hence no change in sign of the ‘running’ V ’s. This holds independently for each half cable. The situation is similar for a short-circuited end, on which reflection also takes place, but with a change of sign of the ‘running’ V ’s. A more interesting termination would not reflect incoming signals at all, like a ‘black’ surface in optics. For this, consider a signal propagating *only* to the right, hence, $i_m = 0$, $V_m = 0$, $i(x, t) = i_p(x - vt)$, and $V(x, t) = V_p(x - vt)$. Equation (27c) shows that, in this case, the relation between $i(x, t)$ and $V(x, t)$ in the cable is exactly the same as it would be in a resistance $R = Z_c$, hence, if we remove the right-hand side of the cable and replace it by this resistance, as shown in Figure 8(b), the p -signal in the cable, which hits the resistor, is not reflected at all (all its energy appears as heat in the resistor). Conversely, a generator connected to the left end of the cable of Figure 8(b) will have the same relation between current and voltage as if it were connected to a resistance $R = Z_c$.

Figure 9 describes the directional coupler, a very useful circuit element which offers the possibility of interacting separately with each of the two ‘running wave’ components of any signal in a cable. Figure 10 shows how a directional coupler can be used in a configuration in which, for small signals, the current in the coil (hence, the rf field in the coil) is the sum of the currents caused separately by the spins and by the ‘soft pulse’ generator, whereas the input to the preamplifier originates only from the spins (this last property is exact only for perfect tuning and matching, and for an ideal directional coupler perfectly terminated at B).

3.2.3 The ‘Brussels’ Feedback Scheme

This scheme follows the standard idea of active control by negative feedback in linear servo-systems. The quantity to be

Figure 9 An idealized model of directional coupler, a passive linear device with four connecting cables. A running wave signal which enters through one of the cables (D in (a)) exits with small attenuation through the ‘continuation’ cable (E in (a)), an attenuated version exits through the ‘diagonally opposite’ cable (B in (a)), and no signal exits through the fourth cable (A in (a)) or the input cable. The coupling coefficient k is a positive number smaller than 1, typically of the order of 0.1. The position variable x is the same for the whole figure and increases from left to right. Terminating resistances $R = Z_c$ have been drawn on every free cable end to avoid ambiguities arising from reflected signals. (b) illustrates the idea that the properties discussed above in the context of (a) are unchanged by permutation of AD with BE or permutation of AB with DE.

controlled here is the total rf current in the sample coil. In the absence of rf irradiation, ‘hard’ or ‘soft’, the target value of this rf current is zero, and this ‘zero’ is easily monitored by looking for a ‘zero’ at the output of the preamplifier under the conditions shown on the right-hand side of Figure 10, in which the ‘generator’ must be inactive. The desired control can be implemented by (weakly) coupling a suitably amplified version of the preamplifier output directly to the sample coil in such a way that the rf current caused by feedback subtracts from that present in the coil. Figure 11(a) shows the principles of a successful circuit of this type,³² in which an additional coaxial cable is required to carry the feedback signal, and the small loop at the end of this cable induces a rf emf in the coil which subtracts from that generated by the precessing nuclear magnetization.

A rough quantitative understanding of the performance of such a scheme is easily obtained by first looking at the favorable perspective in which the feedback loop is stable and radiation damping is suppressed to a large extent. In all steady state situations we have $i_{\text{coil}}(t) = i_{\text{fid}}(t) - i_{\text{feedback}}(t)$, where $i_{\text{coil}}(t)$ is the total current in the coil, $i_{\text{fid}}(t)$ is the current originating from the spins alone, and $i_{\text{feedback}}(t)$ originating from the feedback signal alone. Note that strong suppression of radiation damping requires that $i_{\text{coil}}(t)$ should be very small compared to $i_{\text{fid}}(t)$, hence, $i_{\text{feedback}}(t)$ very close to $i_{\text{fid}}(t)$. The feedback signal $i_{\text{feedback}}(t)$ is an amplified version of $i_{\text{coil}}(t)$, hence, $i_{\text{feedback}}(t) = G i_{\text{coil}}(t)$, where G is the gain around the feedback loop (in a complete discussion, G must include rf phase shifts, and retardation around the loop). Combining the above relations, one obtains $i_{\text{coil}}(t) = i_{\text{fid}}(t)/(G + 1)$, hence radiation damping is decreased by a factor $(G + 1)$, and $i_{\text{feedback}}(t) = i_{\text{fid}}(t)[G/(G + 1)]$, hence, $i_{\text{feedback}}(t)$ is very close to the quantity $i_{\text{fid}}(t)$ which we are directly interested in, at least for any large gain G .

A detailed discussion³² confirms these conclusions, and shows that the circuit is stable over a range of phase shifts

Figure 10 ‘Small signal’ equivalent circuit, from probehead to preamplifier. The sample resonant circuit is perfectly tuned, and matched to the cable, hence, the equivalent internal damping resistance shown is equal to Z_c . Cable B is terminated in its characteristic impedance Z_c to avoid undesired reflections, the ‘soft pulse’ generator and the preamplifier also have impedances equal to Z_c . (ϕ) indicates that a rf phase factor has been ignored for simplicity of notation. The position variable x increases from bottom to top of the figure. The constants K_0 and K_c are properties of the probehead, k is the coupling coefficient of the directional coupler. The relation between current and voltage at the connection between cable E and probehead is $V_E(x_0, t) = -Z_c i_E(x_0, t)$ for signals originating only in the generator, and $V_E(x_0, t) = +Z_c i_E(x_0, t)$ for signals originating only in the probehead. When spins and generator are both active, the current in the coil (hence, the rf field in the coil) is the sum of the currents caused separately by the spins and by the generator, whereas the input to the preamplifier originates only from the spins

of $\pi/2$ or more around the loop, and for gains up to, at least, a few hundred at the NMR frequency of the relevant spins. Satisfactory performance does not require any fine adjustment of these two parameters. When the scheme is used in the configuration of Figure 11(a), suppression of radiation damping does not deteriorate the signal to noise ratio for the observed NMR signals in spite of the fact that the remaining signal in the coil, $i_{\text{coil}}(t)$, is very small.

As shown by Figure 11(a), ‘soft pulses’ can be applied to the spins while radiation damping is being suppressed. The ‘soft pulse’ signal reaches the spins without interfering with the feedback system, as explained in Figure 10(left part).

In Ref.³² the ‘narrow filter’ is implemented by quadrature detection, followed by single stage RC filtering and balanced remodulation, and some hardware is saved by using these RC filtered signals also as input for acquisition. Suppression of radiation damping would be more independent of all other aspects of NMR experiments with the design of Figure 11(a), in which the acquisition circuit contains its own low pass filter (optimized for acquisition, not shown on the figure).

3.2.4 The ‘École Polytechnique’ Neutralization Scheme

This scheme³³ is sketched in Figure 11(b), and Figure 10 illustrates the discussion. It is useful to visualize the current

Figure 11 Two ways of using essentially the same additional electronic hardware for active electronic control of radiation damping. (a) The ‘Brussels’ scheme provides robust suppression of radiation damping by a large factor, but requires an additional coaxial connection to the probehead. (b) The ‘École Polytechnique’ scheme provides enhancement, inversion and suppression of radiation damping without modification of the probehead. Efficient suppression requires a precise and delicate adjustment of phase and gain of the signal sent back to the probehead; enhancement and inversion are robust

$i_{\text{coil}}(t)$ in the coil (also the rf field generated by this current) as a sum of two distinct components, $i_{\text{spins}}(t)$ which arises from the precession of the spins and propagates to the input of the preamplifier, and $i_{\text{neut}}(t)$ which is generated by the additional electronics as a transformed version of $i_{\text{spins}}(t)$ and does not propagate towards the preamplifier. Hence, $i_{\text{coil}}(t) = i_{\text{spins}}(t) + i_{\text{neut}}(t)$.

A first interesting situation is reached by adjusting the gain and phase along the neutralization path in such a way that $i_{\text{neut}}(t) = -i_{\text{spins}}(t)$, hence $i_{\text{coil}}(t) = 0$, hence radiation damping is suppressed. The criterion for satisfactory adjustment here is that the spins, as observed via the preamplifier, behave in the way predicted without radiation damping. A rough adjustment is not difficult to reach in this way, but fine tuning is a delicate and time consuming process which is fragile for any small change in the sample or the probehead.

A robust use of the neutralization scheme is to increase the rate of radiation damping by making adjustments such that $i_{\text{neut}}(t) \approx ki_{\text{coil}}(t)$, hence $i_{\text{coil}}(t) \approx (k + 1)i_{\text{spins}}(t)$. For positive k , this makes radiation damping faster by a factor $(k + 1)$, which may be useful in water suppression schemes²⁶ to suppress residual water signals rapidly before acquisition.

Another robust and useful situation is obtained by changing the sign of k in the above example so as to make $(k + 1)$ negative. In this ‘inversion’ mode, radiation damping rotates the total magnetization of the relevant spins towards the direction opposite to that of thermal equilibrium, hence stabilizing the

direction which is made unstable by ‘direct’ radiation damping. This can be useful for measuring weak NOE’s with abundant solvent spins.²⁷ Note that the ‘inversion’ of radiation damping has no influence on spin-lattice relaxation which still progressively brings back the spin magnetization towards its usual value in thermal equilibrium.

As shown by Figure 11(b), ‘soft pulses’ can be applied to the spins while radiation damping is being controlled. The ‘soft pulse’ signal just has to be added to the neutralization signal sent towards the directional coupler.

Part of the features described above are implemented in a preliminary circuit offered by Bruker for some of their spectrometers (Radiation Damping Control Unit, Bruker France, 1999).

3.2.5 Miscellaneous Schemes (*Q-switch*, etc.)

A simple and safe way for suppressing radiation damping is to strongly reduce the quality factor Q of the sample circuit by connecting a low resistance in parallel with it. Of course, this resistance has to be disconnected or strongly increased during ‘hard pulses’ and acquisition. A ‘*Q-switch*’ of this type is offered by Bruker and has been successfully used in realistic demonstration experiments.^{51,52} Unfortunately, this scheme requires a major modification of each probehead and lacks some of the versatility of the more ambitious techniques.

One of the difficulties caused by radiation damping is that it interferes with ‘soft pulses’ applied to abundant spins. A number of techniques have been proposed to solve this problem by designing a new class of ‘soft pulses’ which take radiation damping into account^{53,54} or, more ambitiously, generate a final rotation independent of radiation damping.⁵⁵ An obvious advantage of this approach is that it does not require any modification of the spectrometer or probehead. A tempting idea would be to replace the analog filter and adjustments used in the feedback and neutralization schemes described above by fast digital processing of the signals, with the corresponding increase in flexibility. The fast converters between analog and digital signals, and the necessary computational power, are already present in the spectrometers. Optimistically, all that would be needed is fast, low level access to the digital side of the converters and to an internal computer. A first successful, although modest, step in this direction has already been made.³⁴

4 DIPOLAR FIELD EFFECTS, THE ‘CLASSICAL’ PRESENTATION

4.1 The Classical Average Dipolar Field

In the standard presentation of NMR in liquids, quantum mechanics is used to describe the nuclear spin system of each individual molecule, carefully taking into account all intramolecular spin–spin couplings and all other effects of the molecule on its own spins (e.g., chemical shifts, spin-rotation coupling). At this point, one can take into account the fast molecular Brownian motion by using the average spin Hamiltonian as ‘unperturbed’ Hamiltonian, and the deviations from average as perturbations. In the usual case of ‘short correlation times’ (i.e., perturbations which have little effect over the correlation delay), this leads to a Bloch–Redfield kinetic equation of the type of equation (9), in which the

Hamiltonian $\overline{H}(t)$ is essentially the average Hamiltonian, and the relaxation term arises from the fast random perturbations. Small effects of the immediately neighboring molecules are also routinely taken into account (e.g., intermolecular NOEs, solvent effects on the chemical shifts). Couplings with the spins in more distant molecules have been ignored for a long time because these couplings are essentially dipolar, hence they average out to zero for isotropic distributions, and one argues that the fast molecular Brownian motion maintains such a spherically symmetrical average distribution in the neighborhood of each spin; more distant spins are then neglected without detailed discussion ‘because the coupling decreases rapidly for increasing distances.’ However, this last argument ignores that ‘distant spins’ are more numerous, and that this compensates for the smaller influence of individual distant spins. Rough numerical estimates, in agreement with experiment, indicate that the *average* influence of distant spins is easily observable in standard high-field NMR of ‘concentrated spins’ (e.g., protons in water).

The first idea which came to mind to describe this average influence in liquid NMR is to introduce an additional magnetic field $B_d(\mathbf{r}_e, t)$ acting on each spin e of molecule P , which is evaluated as the sum of the fields which are generated by the average magnetic moment of all spins g of the other molecules (all spins of the same molecule have been taken into account already),^{8,56}

$$B_d(\mathbf{r}_e) = \frac{\mu_0}{4\pi} \sum_{Q \neq P} \sum_{g \in Q} \gamma_g \hbar \frac{3(\overline{\langle \mathbf{I}_g \rangle \cdot \mathbf{1}_{e,g}} \mathbf{1}_{e,g} - \langle \mathbf{I}_g \rangle)}{|\mathbf{r}_e - \mathbf{r}_g|^3} \quad (28)$$

where $\mathbf{1}_{e,g} = (\mathbf{r}_e - \mathbf{r}_g)/|\mathbf{r}_e - \mathbf{r}_g|$, and the overline indicates an average over molecular positions. We shall neglect the effects of propagation of the field on the ground that the samples of interest are much smaller than the wavelength at NMR frequencies, hence all positions and averages in equation (28) are at the same time t .

Evaluation of $B_d(\mathbf{r}_e)$, as given by equation (28), can be performed in most practical situations with the help of the standard techniques of macroscopic magnetostatics. A similar problem arises in permanent magnets, in which $B_d(\mathbf{r}_e)$ tends to destabilize the parallel orientation of the ferromagnetic domains and is called ‘demagnetizing field’. This problem is also present in the microscopic theory of (electronic) magnetic susceptibility, where it is often called ‘susceptibility effects’. ‘Demagnetizing field’ and ‘susceptibility effects’ refer to particular situations of thermal equilibrium or steady state of weak irradiation. Many new features appear in the NMR case, where the relevant nuclear spin magnetization follows the rich dynamics typical of multiple pulse experiments, hence making the older denominations inappropriate (and possibly misleading). More satisfactory names are ‘dipolar field’ (used here) or ‘distant dipole field’.

The average macroscopic aspects of the nuclear magnetization are adequately described by the magnetization density $\mathbf{M}(\mathbf{r}, t)$, averaged over volumes large enough to smooth out the molecular structure. From this, one can evaluate the usual macroscopic fields $\mathbf{H}(\mathbf{r}, t)$ and $\mathbf{B}(\mathbf{r}, t) = \mu_0\{\mathbf{H}(\mathbf{r}, t) + \mathbf{M}(\mathbf{r}, t)\}$ due to the nuclear magnetization. We still have to go over from these macroscopic quantities to the microscopic field $B_d(\mathbf{r}_e, t)$ ‘seen’ by the spin at position $\mathbf{r}_e$. Only a brief outline of this discussion will be given here, referring the reader to the literature for details.^{57–61}

The first (conceptual) step is to remove the spin at $\mathbf{r}_e$ and all other spins in a sphere of radius R centered on $\mathbf{r}_e$. For large enough R , this creates a macroscopic empty sphere at the center of which the field $\mathbf{B}^R$ is easily evaluated by the standard macroscopic techniques as $\mathbf{B}^R(\mathbf{r}_e) = \mathbf{B}(\mathbf{r}_e) - (2/3)\mathbf{M}(\mathbf{r}_e)$, where $\mathbf{B}$ and $\mathbf{M}$ describe the situation before removing the molecules. Note that $\mathbf{B}^R(\mathbf{r}_e)$ is the field which would be ‘seen’ by a spin which would be put back in the middle of the empty sphere. We can now put the removed spins back in the sphere, except for the spin at $\mathbf{r}_e$ and the other spins of molecule P . If we assume that, on average, the molecules are uniformly distributed in position and randomly oriented, then the nuclear magnetization of the ‘spins being put back’ is distributed as spherical shells of uniform magnetization centered on $\mathbf{r}_e$. The field generated by such a shell is exactly zero at $\mathbf{r}_e$. No difficulty arises from a non-zero magnetization at position $\mathbf{r}_e$ or in its immediate vicinity because the molecular structure prevents nuclei from approaching each other too closely. As a consequence, the ‘spins being put back’ give a zero contribution at $\mathbf{r}_e$, hence

$$\mathbf{B}_d(\mathbf{r}_e) = \mathbf{B}(\mathbf{r}_e) - \frac{2}{3}\mu_0\mathbf{M}(\mathbf{r}_e) \quad (29)$$

Equation (29) shows that, for isotropic and uniform distributions of molecules, the classical (average) dipolar field $\mathbf{B}_d(\mathbf{r}_e)$ is a very smooth function of position, essentially the same for all spins in the same molecule. If the macroscopic quantities $\mathbf{B}(\mathbf{r})$ and $\mathbf{M}(\mathbf{r})$ are not uniform in space, the above result still holds, provided that one can neglect the changes of $\mathbf{M}(\mathbf{r})$ over the volume of the macroscopic cavity.

The actual calculation of $\mathbf{B}_d(\mathbf{r})$ for a known $\mathbf{M}(\mathbf{r})$ (i.e., the step $\mathbf{M}(\mathbf{r}, t) \rightarrow \mathbf{B}_d(\mathbf{r}, t)$ in Figure 5) is in general a rather nasty problem because numerical evaluations are often slow and inconvenient, and analytical solutions are known only for the very particular situations of (i) an ellipsoidal sample with uniform magnetization, and (ii) a spatially periodic distribution of magnetization with zero (spatial) average value, and superpositions of such distributions.

For an ellipsoidal sample with uniform magnetization $\mathbf{M}$, the dipolar field $\mathbf{B}_d$ is also uniform *inside* the sample,^{58,61} and the linear relation between $\mathbf{M}$ and $\mathbf{B}_d$ is conveniently expressed with reference to the directions of the axes U , V , and W of the ellipsoid as

$$\mathbf{B}_d = \sum_{\alpha=U,V,W} k_{\alpha\alpha}(\mathbf{M} \cdot \mathbf{1}_\alpha)\mathbf{1}_\alpha,$$

where

$$\sum_{\alpha=U,V,W} k_{\alpha\alpha} = 0 \quad (30)$$

Values of $k_{\alpha\alpha}$ for some simple shapes are given below.

	$k_{\alpha\alpha}$
sphere, any direction	0
very long cylinder, $\parallel$ axis	$(1/3)\mu_0$
very long cylinder, $\perp$ axis	$-(1/6)\mu_0$
very flat pancake, $\perp$ plane	$-(2/3)\mu_0$
very flat pancake, in plane	$(1/3)\mu_0$

A convenient starting point for spatially periodic distributions of $\mathbf{M}$ is the simple ‘plane wave’ distribution $\mathbf{M}(\mathbf{r}) = \mathbf{F}(\mathbf{r} \cdot \mathbf{1}_S)$, where $\mathbf{1}_S$ is a unit vector pointing in the reference direction S hence $\mathbf{M}(\mathbf{r})$ is uniform in any plane perpendicular to S , and $\mathbf{F}(\mathbf{r} \cdot \mathbf{1}_S) = \mathbf{F}(\mathbf{r} \cdot \mathbf{1}_S + \xi)$, where ξ is the spatial period. Without further specification of the function $\mathbf{F}$, evaluations of the dipolar field $\mathbf{B}(\mathbf{r})$ are still hampered by large contributions arising from $\mathbf{M}$ at distances *much* larger than $|\xi|$, reflecting the fact that no boundary has been associated with the periodic distribution $\mathbf{F}$. In the perspective of a boundary at distances much larger than ξ , this difficulty disappears for magnetization distributions with a spatial average of zero, $\int_0^\xi \mathbf{F}(s)ds = 0$, for which one ends up with the simple answer expected for a stack of very flat pancakes perpendicular to S , namely

$$\begin{aligned} \mathbf{B}_d(\mathbf{r}) &= \mu_0 \left\{ -\frac{2}{3}(\mathbf{M}(\mathbf{r}) \cdot \mathbf{1}_S)\mathbf{1}_S \right. \\ &\quad \left. + \frac{1}{3}(\mathbf{M}(\mathbf{r}) - (\mathbf{M}(\mathbf{r}) \cdot \mathbf{1}_S)\mathbf{1}_S) \right\} \\ &= -\frac{\mu_0}{3} \{ 3(\mathbf{M}(\mathbf{r}) \cdot \mathbf{1}_S)\mathbf{1}_S - \mathbf{M}(\mathbf{r}) \} \end{aligned} \quad (31)$$

The derivation of equation (31) still does not take into account the presence of a boundary at a distance comparable to ξ or smaller, hence, for a realistic sample (of finite size), equation (31) is not necessarily a good approximation in a skin of thickness $\approx \xi$ at the surface of the sample.

The dipolar field $\mathbf{B}_d(\mathbf{r})$ at position $\mathbf{r}$ is very conveniently expressed by equation (31) in terms of the magnetization $\mathbf{M}(\mathbf{r})$ *at the same position*. However, this does not reflect any general change in the relation between $\mathbf{B}$ and $\mathbf{M}$ from ‘global’ to ‘local’, but is an almost fortuitous consequence of the simple spatial periodicity and zero average value assumed in this first example. If $\mathbf{M}(\mathbf{r})$ is the sum of two simple periodic distributions with different reference directions S_1 and S_2 , then the contribution of each simple distribution to $\mathbf{B}_d(\mathbf{r})$ is still given by equation (31), but the total $\mathbf{B}_d(\mathbf{r})$ can no longer be expressed directly in terms of the total $\mathbf{M}(\mathbf{r})$ at the same position.

Equation (31) is obviously well suited for the discussion of spin-echo experiments, in which the spatial periodicity is created on purpose with the help of field gradients. This equation was already used by the first investigators of dipolar field effects, Deville et al.,^{8,56} who also give a very careful discussion of the role of the overall shape and size of the sample, and of the average magnetization. Later, many investigators overlooked these problems, occasionally running into persistent disagreement between predictions and observations¹⁹ until the error was subsequently corrected.⁶²

4.2 Secular Coupling with the Dipolar Field, Various Truncations

The static relation between the *complete* classical average dipolar field $\mathbf{B}_d(\mathbf{r})$ and its source $\mathbf{M}(\mathbf{r})$, as discussed in Section 4.1, is independent of the presence (or not) of the large external magnetic field $\mathbf{B}_0$ in which all standard NMR experiments are performed. On the contrary, the dynamic effect of $\mathbf{B}_d(\mathbf{r}, t)$ on the evolution of the spin state, hence also of $\mathbf{M}(\mathbf{r}, t)$, is strongly dependent upon $\mathbf{B}_0$ because the

coupling of the spins with $\mathbf{B}_d(\mathbf{r}, t)$ is only a small perturbation on the much larger ‘unperturbed’ coupling with $\mathbf{B}_0$. The standard procedure in such circumstances is to separate the perturbation in a ‘secular’ and a ‘non-secular’ part with respect to the unperturbed coupling, and to retain only the secular part in a first approximation. This procedure holds for a description of the spin magnetization by classical mechanics (e.g., equations (3) and (17)) or quantum mechanics (e.g., equations (10), (11) and (16)).

In the recent literature about dipolar field effects, the ‘secular part of the coupling of the spins with the dipolar field’ (i.e., the appropriate concept) has often been discussed in terms of a ‘secular dipolar field’, which has proved to be a highly misleading concept. For instance, a given part of the dipolar field may give a secular coupling with one type of spins and non-secular couplings with other spins. My attempt at avoiding these semantic problems leads to some clumsiness and repetitions in the present text.

4.2.1 Removing the Counter-rotating Terms and the Oscillating Z terms

If we take into account only the interaction of each spin with the large external field $\mathbf{B}_0$, the motion of any spin is a precession around the direction of $\mathbf{B}_0$ at an angular velocity $-\gamma_j \mathbf{B}_0$ which depends upon the spin species j . In this ‘unperturbed’ approximation, the nuclear magnetization is a sum of terms $\mathbf{M}(\mathbf{r}, t) = \sum_j \mathbf{M}_j(\mathbf{r}, t)$ precessing at the angular velocities $-\gamma_j \mathbf{B}_0$ of the relevant spin species, always around the same direction $\mathbf{B}_0$ which we shall choose as the Z direction for convenience. The Z component of $\mathbf{M}_j(\mathbf{r}, t)$ is constant (in the unperturbed approximation), and the transverse component rotates at $-\gamma_j \mathbf{B}_0$. Each term in the magnetization generates its contribution to the dipolar field, hence $\mathbf{B}_d(\mathbf{r}, t) = \sum_j \mathbf{B}_{d,j}(\mathbf{r}, t)$. Due to the orientation dependence of the dipolar coupling, the motion of each term $\mathbf{B}_{d,j}(\mathbf{r}, t)$ is slightly more complicated than that of the corresponding $\mathbf{M}_j(\mathbf{r}, t)$: The Z component of $\mathbf{B}_{d,j}(\mathbf{r}, t)$ has a constant part and one oscillating at frequency $|\gamma_j B_0|$, and the transverse component of $\mathbf{B}_{d,j}(\mathbf{r}, t)$ is the sum of a ‘co-rotating’ part, rotating at the same angular velocity as $\mathbf{M}_j(\mathbf{r}, t)$, and a ‘counter-rotating’ part, rotating in the opposite sense.

The constant Z component has a persistent effect on all spins, whatever their species, the oscillating Z component has no persistent effect on any spin because it just causes a minute back and forth azimuthal oscillation. The ‘co-rotating’ part of $\mathbf{B}_{d,j}(\mathbf{r}, t)$ has a persistent resonant effect on the spins of species j and has no persistent effect on other spins, for which it is not resonant; for the same reason, the ‘counter-rotating’ part has no persistent effect on any spin. As a conclusion, we shall not lose any dynamical effect of $\mathbf{B}_{d,j}(\mathbf{r}, t)$ (to first order) by performing a truncation which removes the oscillating Z component and the ‘counter-rotating part’, leaving only $\mathbf{B}_{d,j}^{\text{no crp}}(\mathbf{r}, t)$. Of course, the final selection of the secular part of the coupling with the dipolar field will require further discussion.

The truncation which gives $\mathbf{B}_{d,j}^{\text{no crp}}(\mathbf{r}, t)$ is easy to perform in a frame of coordinates which rotates around $\mathbf{B}_0$ at the same angular velocity as $\mathbf{M}_j$ because, in this frame, $\mathbf{B}_{d,j}^{\text{no crp}}(\mathbf{r}, t)$ is not time-dependent whereas the other parts of $\mathbf{B}_{d,j}(\mathbf{r}, t)$

oscillate at the frequencies $|\gamma_j B_0|$ and $2|\gamma_j B_0|$. Hence averaging over one period at the frequency $|\gamma_j B_0|$ leaves only $\mathbf{B}_{d,j}^{\text{no crp}}(\mathbf{r}, t)$.

As a first example of this truncation, consider the contribution $\delta \mathbf{B}_{d,g}(\mathbf{r}_e)$ arising from spin g in equation (28), assuming $\mathbf{r}_e$ and $\mathbf{r}_g$ to be fixed positions,

$$\delta \mathbf{B}_{d,g}(\mathbf{r}_e) = \frac{\mu_0 \gamma_g \hbar}{4\pi |\mathbf{r}_e - \mathbf{r}_g|^3} [3(\langle \mathbf{I}_g \rangle \cdot \mathbf{1}_{e,g}) \mathbf{1}_{e,g} - \langle \mathbf{I}_g \rangle] \quad (32)$$

In the inertial ‘laboratory’ frame, the only time dependent quantity in equation (32) is the vector $\langle \mathbf{I}_g \rangle$; conversely, in a frame rotating at the angular velocity $-\gamma_g \mathbf{B}_0$, only the unit vector $\mathbf{1}_{e,g}$ is time dependent (it rotates at the angular velocity $+\gamma_g \mathbf{B}_0$). We can now express the vectors $\langle \mathbf{I}_g \rangle$ and $\mathbf{1}_{e,g}$ in terms of the basic unit vectors $\mathbf{1}_{\bar{x}}$, $\mathbf{1}_{\bar{y}}$, and $\mathbf{1}_Z$ of the rotating frame, noting that $\mathbf{1}_{e,g} \cdot \mathbf{1}_{\bar{x}} = \cos \phi \sin \theta$, $\mathbf{1}_{e,g} \cdot \mathbf{1}_{\bar{y}} = \sin \phi \sin \theta$, and $\mathbf{1}_{e,g} \cdot \mathbf{1}_Z = \cos \theta$, where θ and ϕ are the polar angles of $\mathbf{1}_{e,g}$ in the rotating frame. θ is constant and ϕ increases at the rate $\gamma_g B_0$. After a little algebra, and averaging over a variation of ϕ by 2π , one is left with the desired truncated part of $\delta \mathbf{B}_{d,g}^{\text{no crp}}(\mathbf{r}_e)$,

$$\delta \mathbf{B}_{d,g}^{\text{no crp}}(\mathbf{r}_e) = \frac{\mu_0 \gamma_g \hbar}{4\pi |\mathbf{r}_e - \mathbf{r}_g|^3} \left[\frac{3(\cos \theta)^2 - 1}{2} \right] [3(\langle \mathbf{I}_g \rangle \cdot \mathbf{1}_Z) \mathbf{1}_Z - \langle \mathbf{I}_g \rangle] \quad (33)$$

Equation (33) already has the usual features of the secular part of dipolar couplings: the projection direction Z is that of $\mathbf{B}_0$, and $\delta \mathbf{B}_{d,g}^{\text{no crp}}(\mathbf{r}_e)$ goes through zero at the ‘magic angle’ such that $3(\cos \theta_{\text{magic}})^2 = 1$.

The same calculation can be performed in the case of an ellipsoidal sample with uniform magnetization $\mathbf{M}$, and equation (30) for $\mathbf{B}_d$ leads to

$$\mathbf{B}_d^{\text{no crp}} = \frac{1}{2} \left[\sum_{\alpha=U,V,W} k_{\alpha\alpha} (\mathbf{1}_\alpha \cdot \mathbf{1}_Z)^2 \right] [3(\mathbf{M} \cdot \mathbf{1}_Z) \mathbf{1}_Z - \mathbf{M}] \quad (34)$$

In the case of a long cylinder, this gives

$$\mathbf{B}_d^{\text{no crp}} = \frac{\mu_0}{6} \left[\frac{3(\cos \theta)^2 - 1}{2} \right] [3(\mathbf{M} \cdot \mathbf{1}_Z) \mathbf{1}_Z - \mathbf{M}] \quad (35)$$

where θ is the angle between the cylinder axis and Z, and for a simple periodic distribution with zero average magnetization, equation (31) leads to

$$\mathbf{B}_d^{\text{no crp}}(\mathbf{r}) = -\frac{\mu_0}{3} \left[\frac{3(\cos \theta)^2 - 1}{2} \right] [3(\mathbf{M}(\mathbf{r}) \cdot \mathbf{1}_Z) \mathbf{1}_Z - \mathbf{M}(\mathbf{r})] \quad (36)$$

where θ is the angle between the reference direction S and Z.

Equations like (35) and (36) are often used in the literature with a different global sign. Presumably, this reflects the widespread contempt, in NMR, of issues of sign which seem to have no major qualitative influence on the predictions or conclusions.^{63,64}

4.2.2 Secular Couplings and Further Truncation

In the quantum mechanical kinetic equation for the spins in a single molecule (see, for instance, equations (10) or

(16)), the dipolar field appears in a coupling term $-\hat{\mathbf{m}}_p \cdot \mathbf{B}_d(\mathbf{r}, t)$ which adds to the usual spin Hamiltonian H_0 ; in the corresponding classical Bloch equation (see, for instance, equations (3) or (17)), the dipolar field contributes a coupling term $-\langle \mathbf{m} \rangle(t) \cdot \mathbf{B}_d(\mathbf{r}, t)$, hence an additional term $\gamma \langle \mathbf{m} \rangle(t) \times \mathbf{B}_d(\mathbf{r}, t)$ in the time derivative $\partial \langle \mathbf{m} \rangle(t) / \partial t$.

If all spins in the sample belong to the same species, the secular approximation consists in replacing $\mathbf{B}_d(\mathbf{r}, t)$ by $\mathbf{B}_d^{\text{no crp}}(\mathbf{r}, t)$ in the coupling terms and in the contributions to time derivatives mentioned just above.

In the presence of multiple spin species, the appropriate procedure is to first decompose $\hat{\mathbf{m}}_p$ and $\mathbf{B}_d(\mathbf{r}, t)$ as sums of separated terms for the different spin species, $\hat{\mathbf{m}}_p = \sum_j \hat{\mathbf{m}}_{p,j}$ and $\mathbf{B}_d(\mathbf{r}, t) = \sum_k \mathbf{B}_{d,k}(\mathbf{r}, t)$, and then to express the coupling term as a double sum over j and k . For the ‘homonuclear’ couplings, the secular approximation is the same as for a single spin species: replace $-\hat{\mathbf{m}}_{p,j} \cdot \mathbf{B}_{d,j}(\mathbf{r}, t)$ by the corresponding $-\hat{\mathbf{m}}_{p,j} \cdot \mathbf{B}_{d,j}^{\text{no crp}}(\mathbf{r}, t)$. The ‘heteronuclear case’ (i.e., $j \neq k$) requires some further truncation because the co-rotating part of the dipolar field is no longer resonant for different spins, hence only the constant Z component remains, which we shall denote $\mathbf{B}_{d,j}^{Z \text{ only}}(\mathbf{r}, t)$. As an example, equation (35) for a long cylinder with uniform magnetization $\mathbf{M}_j$ of the j spins leads to

$$\mathbf{B}_{d,j}^{Z \text{ only}} = \frac{\mu_0}{6} \left[\frac{3(\cos \theta)^2 - 1}{2} \right] [2(\mathbf{M}_j \cdot \mathbf{1}_Z) \mathbf{1}_Z] \quad (37)$$

For the ‘heteronuclear’ terms, the secular approximation consists in replacing each term $-\hat{\mathbf{m}}_{p,k} \cdot \mathbf{B}_{d,j}(\mathbf{r}, t)$ by the corresponding $-\hat{\mathbf{m}}_{p,k} \cdot \mathbf{B}_{d,j}^{Z \text{ only}}(\mathbf{r}, t)$.

In the first run of exploration of the dipolar field effects, which is presently underway, much attention has been devoted to the simplest idealized situations: single spin species with a single NMR line, combined with a simple geometry and distribution of magnetization, such that the total effective dipolar field at any point $\mathbf{r}$ can be expressed in terms of the total nuclear magnetization at the same point $\mathbf{r}$ by a relation of the type of equations (34)–(36). For this type of relation, the classical equation of motion (3) or (17) clearly shows that the term $-\mathbf{M}$ in the second square bracket has no effect on the motion because $\mathbf{M}(\mathbf{r}, t) \times \mathbf{M}(\mathbf{r}, t) = 0$, hence it may be dropped, leaving a truncated dipolar field which we shall denote $\mathbf{B}_d^{\text{homol}}(\mathbf{r}, t)$ where ‘homol’ stands for ‘homonuclear idealized’. Of course, it is also perfectly legitimate to keep the term $-\mathbf{M}$, and this does not lead to any error or any additional complication in the calculations. As an example, equation (35) for a long cylinder with uniform magnetization $\mathbf{M}$ leads to

$$\mathbf{B}_{d,j}^{\text{homol}} = \frac{\mu_0}{6} \left[\frac{3(\cos \theta)^2 - 1}{2} \right] [3(\mathbf{M} \cdot \mathbf{1}_Z) \mathbf{1}_Z] \quad (38)$$

However, it is important to note that the validity of this truncation is strictly limited to the very particular situations specified above. Once the truncation is made, one is no longer in a position to discuss the effects of ‘non-idealities’ like inhomogeneities in $\mathbf{B}_0$ or $\mathbf{B}_1$, imperfect shape of the sample, non-zero total magnetization, dynamical instabilities, ... As a conclusion, my recommendation is to avoid this unnecessary and misleading truncation.

4.3 Simple Examples: Homogeneous and Helical Spatial Distributions of Magnetization (‘Classical’ Discussion)

We shall now examine some typical examples of pulsed NMR experiments in which the dipolar field effects do not cause major changes in the spatial symmetry of the distribution of magnetization. The discussion given in this section will follow the ‘classical’ presentation, deferring the ‘Warren’ interpretation of the same effects to the section on intermolecular multiple-quantum coherences. Finally, spectral clustering and dynamic instability will be discussed in Section 6.

4.3.1 Multiple Spin Echoes (Equivalent Spins)

In the absence of collective effects, a sequence of two hard pulses, applied to the equilibrium spin state, generates a single echo in a constant field gradient;⁴¹ an additional echo of order n may also appear for each order of intramolecular n -quantum coherence which has been prepared in the initial spin state.⁶⁵ Radiation damping⁴⁵ and the dipolar field⁸ can also cause the appearance of multiple spin echoes, even for molecules bearing a single spin 1/2, which cannot support intramolecular n -quantum coherence for $|n| > 1$.

This first example, multiple echoes caused by the dipolar field alone in a liquid in which all spins are equivalent, has been discussed in great detail by the first investigators, Deville et al.,⁸ in a study on solid ^3He . In the simplified version of their derivation presented here, relaxation, molecular diffusion (and flow) will be ignored. Radiation damping is usually not a major problem in spin echo experiments, because the fid signal is large only during the short echoes (see, however, Section 6.3); this problem will also be ignored here without further discussion.

A last delicate issue is the role of the shape and size of the sample on the relation between $\mathbf{M}(\mathbf{r}, t)$ and the relevant part $\mathbf{B}_d^{\text{no crp}}(\mathbf{r}, t)$ of the dipolar field, as discussed already in connection with equation (31). Deville et al.⁸ discuss the problem for realistic sample shapes; here, the problem will be avoided by considering a sample in the shape of a cylindrical pancake perpendicular to the direction S of the field gradient, so that equation (31) applies for the ‘plane wave’ modulated component $\mathbf{M}_S(\mathbf{r}, t) = \mathbf{F}_S(\mathbf{r} \cdot \mathbf{1}_S)$ of $\mathbf{M}(\mathbf{r}, t)$ as well as for its average value, except for a small (neglected) region along the cylindrical edge with a width comparable to the thickness of the pancake. If the direction S is changed, equation (36) shows that the relevant part of the dipolar field changes as $(3 \cos^2 \theta - 1)/2$, hence dipolar field effects are maximum for $\theta = 0$ and disappear when the field gradient is at the magic angle. The overall shape of the sample is not a very important issue whenever the pitch of the magnetization helix is much larger than the size of the sample.

For simplicity in the present section, the direction S will be chosen parallel to Z , so that the external magnetic field $\mathbf{B}_0$ will be given by $\mathbf{B}_0(z) = \mathbf{B}_0(0) + Gz\mathbf{1}_Z$ and the relevant part of the dipolar field by (see equation (36)) $\mathbf{B}_d^{\text{no crp}}(z, t) = -\mu_0[(\mathbf{M}(z, t) \cdot \mathbf{1}_Z) \mathbf{1}_Z - (1/3)\mathbf{M}(z, t)]$. With the above simplifications and notations, and ignoring non-secular terms, the equation of motion (17) for $\mathbf{M}(z, t)$ becomes

$$\left(\frac{\partial}{\partial t} \right)_{\text{lab}} \mathbf{M}(z, t) = \mathbf{M}(z, t) \times \gamma \{ \mathbf{B}_0(0) + Gz\mathbf{1}_Z - \mu_0(\mathbf{M}(z, t) \cdot \mathbf{1}_Z) \mathbf{1}_Z + \mathbf{B}_1^{\text{co rot}}(t) \} \quad (39)$$

where $\mathbf{B}_1^{\text{co rot}}(t)$ is the co-rotating part of the pulsed rf field. Further discussions are simplified by rewriting this equation of motion in a frame of coordinates $(\tilde{X}, \tilde{Y}, Z)$ which rotates with respect to the ‘lab’ frame (X, Y, Z) at the ‘unperturbed’ angular velocity $-\gamma\mathbf{B}_0(0)$,

$$\left(\frac{\partial}{\partial t}\right)_{\text{rot}} \mathbf{M}(z, t) = \mathbf{M}(z, t) \times \gamma \{(Gz - \mu_0 M_Z(z, t))\mathbf{1}_Z + \mathbf{B}_1^{\text{co rot}}(t)\} \quad (40)$$

In the absence of rf pulse, this gives the convenient relations

$$\begin{aligned} \frac{\partial}{\partial t} M_{\pm}(z, t) &= -i\gamma(Gz - \mu_0 M_Z(z, t))M_{\pm}(z, t) \\ \frac{\partial}{\partial t} M_Z(z, t) &= 0 \end{aligned} \quad (41)$$

where $M_{\pm}(z, t) = M_{\tilde{X}}(z, t) + iM_{\tilde{Y}}(z, t)$.

It is easy to check that, if one starts with the uniform equilibrium distribution $\mathbf{M}^{\text{eq}}$ and assumes homogeneous rf fields $\mathbf{B}_1(t)$, then equations (39)–(41) lead to distributions $\mathbf{M}(\mathbf{r}, t)$ which are ‘plane wave’ modulated only in the Z -direction, in agreement with the assumption on which these equations are based. This is a necessary condition for the self consistency of the derivation. However, in any real experiment, there will be (hopefully small) deviations from the ideal conditions described above, and most of these deviations do not have the simple symmetries assumed in equations (39)–(41), hence these simplified equations are not suitable to discuss the consequences of the deviations on the observed signals. If the perturbations are ‘stable’, their presence is not very disturbing, but it has been shown¹³ that, in a number of dynamic situations, ‘unstable’ perturbations grow exponentially in time and eventually lead to ‘spin turbulence’ with rather sudden loss of NMR signal (see Section 6). These difficulties show up only together with very strong dipolar field effects, so that many realistic NMR experiments can still be discussed safely in terms of equations (39)–(41).

The initial spin state is the uniform equilibrium magnetization $\mathbf{M}^{\text{eq}} = M^{\text{eq}}\mathbf{1}_Z$. At time t_0 , a first hard rf pulse is applied (see Figure 12), of tipping angle $\pi/2$ and phase ϕ (ϕ is the angle from $\tilde{X}$ to $\mathbf{B}_1^{\text{co rot}}$), resulting in a spin state

$$M_{\pm}(z, t_{0+}) = -M^{\text{eq}} e^{i\phi}, \quad M_Z(z, t_{0+}) = 0 \quad (42)$$

Thereafter, the spin state evolves according to equation (41) and, after a delay τ_1 without rf pulse we have

$$\begin{aligned} M_{\pm}(z, t_0 + \tau_{1-}) &= -M^{\text{eq}} e^{i\phi} e^{-i\gamma Gz\tau_1} \\ M_Z(z, t_0 + \tau_{1-}) &= 0 \end{aligned} \quad (43)$$

Figure 12 Timing of the hard rf pulses for equations (42)–(47), and (49). The dots show the timing of the echoes

At this point, the second $\pi/2$ pulse is applied, with phase 0, which transforms the spin state into

$$\begin{aligned} M_{\pm}(z, t_0 + \tau_{1+}) &= -M^{\text{eq}} \text{Re}[e^{i\phi} e^{-i\gamma Gz\tau_1}] \\ &= -\frac{1}{2} M^{\text{eq}} [e^{i\phi} e^{-i\gamma Gz\tau_1} + e^{-i\phi} e^{i\gamma Gz\tau_1}] \\ M_Z(z, t_0 + \tau_{1+}) &= -M^{\text{eq}} \text{Im}[e^{i\phi} e^{-i\gamma Gz\tau_1}] \\ &= -M^{\text{eq}} \cos[\phi - \gamma Gz\tau_1] \end{aligned} \quad (44)$$

From now on, $M_{\pm}$ rotates at the angular velocity $-\gamma(Gz + \mu_0 M^{\text{eq}} \cos[\phi - \gamma Gz\tau_1])$, hence

$$\begin{aligned} M_{\pm}(z, t_0 + \tau_1 + \tau_2) &= M_{\pm}(z, t_0 + \tau_{1+}) e^{-i\gamma Gz\tau_2} \\ &\times e^{-i\gamma \mu_0 M^{\text{eq}} \tau_2 \cos[\phi - \gamma Gz\tau_1]} \end{aligned} \quad (45)$$

At this point, one may choose to simplify the discussion by restricting it to small dipolar field effects, specifically to small values of $|\gamma \mu_0 M^{\text{eq}} \tau_2|$, by expanding the factor $e^{-i\gamma \mu_0 M^{\text{eq}} \cos[\phi - \gamma Gz\tau_1] \tau_2}$ in equation (45) as a power series in $\gamma \mu_0 M^{\text{eq}} \tau_2$ and keeping only the first few terms, which are easy to manipulate analytically even in a derivation which includes relaxation and molecular diffusion.¹⁵ Here, we shall deal with this factor by expanding it in terms of Bessel functions,⁸ using the relation

$$\exp(ia \cos b) = \sum_{p=-\infty}^{+\infty} i^p J_p(a) \exp(ipb) \quad (46)$$

where a and b are real, and the summation extends over all integer values of p . Some other properties of the Bessel functions, which will be used here, are given in Figure 13. With these relations, and after some algebra, equation (45) can be written as

$$\begin{aligned} M_{\pm}(z, t_0 + \tau_1 + \tau_2) &= -\frac{1}{2} M^{\text{eq}} \sum_{n=-\infty}^{+\infty} i^{-n} e^{-in\phi} e^{-i\gamma Gz(\tau_2 - n\tau_1)} \{J_{n-1}(\omega_d \tau_2) + J_{n+1}(\omega_d \tau_2)\} \\ &= -\frac{1}{2} M^{\text{eq}} \sum_{n=-\infty}^{+\infty} i^{-n} e^{-in\phi} e^{-i\gamma Gz(\tau_2 - n\tau_1)} \frac{2n J_n(\omega_d \tau_2)}{\omega_d \tau_2} \end{aligned} \quad (47)$$

where $\omega_d = \gamma \mu_0 M^{\text{eq}}$ is the ‘dipolar angular velocity’, which is the inverse of the ‘dipolar demagnetizing time’ τ_d used by the Warren group.

In order to evaluate the observed fid signal, we still have to integrate over the whole sample, i.e., to perform a z integral of equation (47) over the thickness d of the flat disk. The typical echo situation occurs when the transverse magnetization is wound in a helix with a large number of turns $|\gamma G d \tau_1 / 2\pi|$ during the delay between the two pulses. In this case, the z integral of $e^{-i\gamma Gz(\tau_2 - n\tau_1)}$, when considered as a function of τ_2 , has a sharp maximum for $\tau_2 = n\tau_1$, and this associates a well defined echo with each positive value of n in equation (47), as shown in Figure 14.

The above calculations may seem less formal with the help of the following pictorial, and hopefully intuitive, presentation: (i) during the delay between the two rf pulses, the field gradient G progressively creates a simple helical distribution of transverse magnetization $M_{\pm}$ with the spatial

Figure 13 Some properties of the Bessel functions $J_n(x)$ for real x and integer n

period $|2\pi/\gamma G\tau_1|$ (see equation (43), the dipolar field plays no important role here); (ii) the second pulse transforms this simple helical distribution into a superposition of a grating of M_Z and a related grating of $M_{\pm}$, both with the same spatial period $|2\pi/\gamma G\tau_1|$; it is convenient to see the grating of $M_{\pm}$ as a superposition of two simple helical distributions twisted in opposite directions (see equation (44)); (iii) after the second rf pulse, the grating of dipolar field created by the grating of M_Z progressively distorts the helical distributions of $M_{\pm}$, and parts of the distorted distributions are refocused by the field gradient G into multiple echoes (see equation (47)). The complex process just described under (iii) also operates in many related experiments (heteronuclear echoes, CRAZED sequence, ...).

A very convenient feature of echo experiments of the type discussed here is that some meaningful results can already be obtained without careful shimming of the field, or precise adjustment of offsets and phases (for pulses and acquisition). The clear separation in time of the echoes of different orders n , and the absolute value of the peak of each echo do not depend upon these details. The magnitude of the n th echo, as given by equation (47), is $V|M^{\text{eq}} J_n(\omega_d \tau_2)/\omega_d \tau_2|$, where V is the volume of the sample. It is instructive to examine the limit of very weak dipolar field effects, characterized here by a small value of the dimensionless parameter $|\omega_d \tau_1| = |\gamma \mu_0 M^{\text{eq}} \tau_1|$, by performing a power series expansion of the magnitude of the echoes. At positive orders n , we have

$$V|M^{\text{eq}} J_n(\omega_d \tau_2)/\omega_d \tau_2| = V|M^{\text{eq}}| \left| \frac{(\omega_d \tau_1)^{n-1}}{(n-1)! 2^n} + \dots \right| \quad (48)$$

where $\dots$ stands for terms in $(\omega_d \tau_1)^{n+1}$ and higher powers. This shows clearly how the echo amplitude rapidly decreases for increasing order n in the case of a small parameter $|\omega_d \tau_1|$. Equations (47)–(48) also suggest that large echoes could be observed up to large orders n in any situation in which $|\omega_d| \neq 0$, by just choosing a long enough delay τ_1 between the excitation pulses. However, this possibility is limited in

Figure 14 Multiple echoes due to the dipolar field after a $[(\pi/2, \tilde{X}) - \tau_1 - (\pi/2, \tilde{X}) - \tau_2 - \text{acq.}]$ sequence, in a constant field gradient. The simulations are based on the extended Bloch equation (3) or (17), and on equation (36) for the dipolar field. Relaxation, molecular diffusion and radiation damping have been ignored for simplicity. The ‘sample’ is a wide slice perpendicular to Z , with a thickness such that the field gradient creates a 16-turn helix of transverse magnetization over the delay τ_1 between the two pulses. $\omega_d = \gamma \mu_0 M^{\text{eq}}$ is the ‘dipolar angular velocity’. The dot below each $n = 1$ echo shows the magnitude of this echo when $\omega_d = 0$, for reference

real experiments by the processes of relaxation and molecular diffusion which have been ignored in the simplified model discussed above. Relaxation alone will strongly damp the echoes whenever τ_1 or τ_2 become significantly longer than the transverse relaxation time T_2 , so that the largest dipolar field effects can be expected for $\tau_1 \approx T_2$. As an example, it is not uncommon to have $\omega_d T_2 \approx 10$ for the water protons in

aqueous solutions in a standard high field magnet, and this can lead to very conspicuous echoes of order up to 10 or more.

Molecular diffusion is also a source of damping of spin echoes whenever the pitch of the magnetization helix is not much greater than the characteristic molecular displacements $(D\tau_1)^{1/2}$ and $(D\tau_2)^{1/2}$ during the experiment. This effect has been understood quantitatively (including the usual relaxation processes) very early in the development of NMR, and has ever since been the method of choice for the study of molecular diffusion in fluids. The Bloch equation, complemented with a suitable diffusion term as shown by Torrey⁶ (see also Section 2.4), provides a safe and convenient starting point for the quantitative interpretation of experimental results. Deville et al.^{8,56} have shown how this quantitative discussion can be extended to take into account dipolar field effects.

Equation (48) is almost in the form of a 'systematic' power series expansion in terms of the inverse of the initial spin temperature T (see Section 2.5), because M^{eq} and ω_d are both proportional to $(1/T)$, at least to a very good first approximation. Seen in this way, the amplitude of the echo of order n has a leading contribution proportional to $(1/T)^n$, which dominates for weak dipolar field effects.

An even simpler general property of dipolar field effects illustrated by equation (47) is the dependence upon the phase difference ϕ between the two excitation pulses: ϕ appears in the expression of the response of order n as a single multiplicative factor $e^{-in\phi}$. This opens the possibility of separating the components of the response according to the order n by phase cycling.⁶⁶ In this context, it is useful to examine the situation in which the reference frequency $|\omega_{\text{ref}}/2\pi|$ of the coherent spectrometer is (slightly) different from the unperturbed resonance frequency $|\gamma B_{0Z}(0)/2\pi|$ of the spins. The usual definition of phases, for pulses and for acquisition, is given in the spectrometer rotating frame, hence we shall also write the equation of motion for the spin magnetization in this rotating frame. In the case of equation (40), this just adds a contribution $\mathbf{M}(\mathbf{r}, t) \times (-\delta\omega \mathbf{1}_Z)$ to the right-hand side of the equation, where the small offset $\delta\omega = [-\gamma B_{0Z}(0) - \omega_{\text{ref}}]$, and ω_{ref} has been given the same sign as that of $-\gamma B_{0Z}(0)$. For the first line of equation (41), the corresponding additional term is $i\delta\omega M_{\pm}(z, t)$. When these additional terms are taken into account, equation (47) for the z -distribution of magnetization at acquisition time becomes

$$M_{\pm}(z, t_0 + \tau_1 + \tau_2) = -\frac{1}{2}M^{\text{eq}} \sum_{n=-\infty}^{+\infty} \left\{ \frac{2nJ_n(\omega_d\tau_2)}{\omega_d\tau_2} \times i^{-n} e^{-in\phi} e^{-in\delta\omega\tau_1} e^{i\delta\omega\tau_2} e^{-i\gamma Gz(\tau_2 - n\tau_1)} \right\} \quad (49)$$

In simple echo experiments, each echo is labeled by the corresponding order n so that, for well separated echoes, no additional separation procedure is needed and the various phase factors in equation (49) may seem almost pedantic details. However, in more complex spectral situations or as a check about the general interpretation of the data, one can use the $e^{-in\phi}$ phase dependence of the terms in equations (47) and (49) to achieve a systematic separation according to n , by Fourier transform of the data with respect to ϕ , as discussed at the end of Section 4.3.4.

4.3.2 Multiple Spin Echoes (Two Spin Species)

As an example of the extension of the techniques discussed above to multiple spin species, we shall now briefly discuss the very simple multiple echo experiment sketched by Figure 15, on a homogeneous mixture of spins of two different species, labeled a and b . For simplicity, the sample will still be a wide slab perpendicular to Z , and we shall ignore relaxation, molecular diffusion, and radiation damping. Different rotating frames will be used for the different spins: the frame denoted by 'rot, a', rotating at the angular velocity $-\gamma_a \mathbf{B}_0(0)$ for spins a , and a corresponding frame for spins b . As discussed in Section 4.2.2, the magnetization and the dipolar field are decomposed according to the spin species, $\mathbf{M}(\mathbf{r}, t) = \mathbf{M}_a(\mathbf{r}, t) + \mathbf{M}_b(\mathbf{r}, t)$, and $\mathbf{B}_d(\mathbf{r}, t) = \mathbf{B}_{d,a}(\mathbf{r}, t) + \mathbf{B}_{d,b}(\mathbf{r}, t)$, where $\mathbf{M}_a(\mathbf{r}, t)$ is the source of $\mathbf{B}_{d,a}(\mathbf{r}, t)$ and $\mathbf{M}_b(\mathbf{r}, t)$ that of $\mathbf{B}_{d,b}(\mathbf{r}, t)$. With the same simplifications as for equations (39) to (40), the equations of motion are

$$\left(\frac{\partial}{\partial t} \right)_{\text{rot, a}} \mathbf{M}_a(z, t) = \mathbf{M}_a(z, t) \times \gamma_a \left\{ \left(Gz - \mu_0 \left[M_{aZ}(z, t) + \frac{2}{3} M_{bZ}(z, t) \right] \right) \mathbf{1}_Z + \mathbf{B}_{1,a}^{\text{co rot}}(t) \right\} \quad (50)$$

and the analogous equation obtained by permuting the labels a and b . The factor $2/3$ is for the heteronuclear secular coupling between a and b .

Starting from equilibrium for a and b spins, the Z components of the spin magnetization between t_0 and $t_0 + \tau_1$ (see Figure 15) is $M_{aZ}(t, z) = 0$ and $M_{bZ}(z, t) = M_b^{\text{eq}}$, hence the transverse magnetization of the a spins immediately before $t_0 + \tau_1$ is

$$M_{a\pm}(z, t_0 + \tau_1-) = -M_a^{\text{eq}} i e^{i\phi} e^{i\gamma_a \frac{2}{3} \mu_0 M_b^{\text{eq}} \tau_1} e^{-i\gamma_a Gz\tau_1} \quad (51)$$

hence the magnetizations immediately after $t_0 + \tau_1$ are

$$\begin{aligned} M_{a\pm}(z, t_0 + \tau_1+) &= -M_a^{\text{eq}} \text{Re} \left[i e^{i\left(\phi + \gamma_a \frac{2}{3} \mu_0 M_b^{\text{eq}} \tau_1\right)} e^{-i\gamma_a Gz\tau_1} \right] \\ M_{aZ}(z, t_0 + \tau_1+) &= -M_a^{\text{eq}} \cos \left[\left(\phi + \gamma_a \frac{2}{3} \mu_0 M_b^{\text{eq}} \tau_1 \right) - \gamma_a Gz\tau_1 \right] \\ M_{b\pm}(z, t_0 + \tau_1+) &= -M_b^{\text{eq}} i, \quad M_{bZ}(z, t_0 + \tau_1+) = 0 \end{aligned} \quad (52)$$

During acquisition, the a spins behave essentially as if the b spins were absent, leading to the same echoes as in

Figure 15 Timing of the hard rf pulses for equations (51)–(53). The dots show the timing of the echoes for $\gamma_b = 2.5\gamma_a$

Section 4.3.1, at $\tau_2 = n\tau_1$ for all positive integers n . For the b spins, similar calculations lead to

$$\begin{aligned} M_{b\pm}(z, t_0 + \tau_{1+}) &= -M_b^{\text{eq}} i e^{-i\gamma_b G z \tau_2} \\ &\times e^{-i\gamma_b \frac{2}{3} \mu_0 M_a^{\text{eq}} \tau_2 \cos\left[\left(\phi + \gamma_a \frac{2}{3} \mu_0 M_b^{\text{eq}} \tau_1\right) - \gamma_a G z \tau_1\right]} \\ &= -M_b^{\text{eq}} i \sum_{p=-\infty}^{+\infty} \left\{ i^{-p} e^{-ip\phi} e^{-ip\frac{2}{3} \gamma_a \mu_0 M_b^{\text{eq}} \tau_1} \right. \\ &\quad \left. \times e^{-iGz(\gamma_b \tau_2 - p\gamma_a \tau_1)} J_p\left(\gamma_b \frac{2}{3} \mu_0 M_a^{\text{eq}} \tau_2\right) \right\} \quad (53) \end{aligned}$$

In typical echo situations, the integral over z of the factor $e^{-iGz(\gamma_b \tau_2 - p\gamma_a \tau_1)}$, considered as a function of τ_2 , has a sharp maximum for $\tau_2 = p(\gamma_a/\gamma_b)\tau_1$, and this, again, associates a well defined echo with each *positive* value of the integer p in equation (53). The new feature is the delay $(\gamma_a/\gamma_b)\tau_1$ between successive echoes.

These indirect echoes have been observed by Bowtell,¹⁷ who gives a detailed discussion including relaxation and molecular diffusion, and shows that rare spins a with a small $|\gamma_a|$ can be observed with favorable sensitivity on the first indirect echo of abundant (solvent) spins b with a much larger $|\gamma_b|$.

In a more complete spin echo experiment, a rf pulse would also be applied to the b spins at time t_0 , and a slight extension of the above calculation shows that multiple echoes are expected for all integers p , q , r , and s (positive and negative), such that $\tau_2 = [s + r(\gamma_b/\gamma_a)]\tau_1 > 0$, for a spins, and, $\tau_2 = [q + p(\gamma_a/\gamma_b)]\tau_1 > 0$ for b spins.

4.3.3 The CRAZED and HOMOGENIZED Experiments

Figure 16 shows the timing of the sequence introduced by the Warren group under the acronym CRAZED,^{19,21} which can be seen as a variant of the echo sequence, in which (see ‘pictorial presentation’ in Section 4.3.1) τ_1 -evolution, winding by the gradient, unwinding by the gradient, and distortion of the helix during τ_2 -acquisition, take place in separated time intervals. This offers increased freedom in the design of experiments, notably access to the $n = 0$ echo, and provides a glimpse at the interplay between pulsed field gradients and the dipolar field in more complex situations.

Figure 16 Timing for the basic CRAZED experiment. The field gradient pulses are characterized by the product $(G\tau_G$ or $nG\tau_G)$ of the (strong) gradient and its (short) duration. n can be positive, negative or zero. For the simplified HOMOGENIZED experiment, $n = 0$. For the COSY experiment, $G\tau_G = 0$

In this introductory discussion, we shall make the same drastic simplifications as in Section 4.3.1: all spins equivalent, neglect of relaxation, molecular diffusion, and radiation damping, flat sample perpendicular to Z , spectrometer reference frequency exactly on resonance. A discussion which includes relaxation and diffusion for $n = 2$, for weak dipolar field effects, is given by Ardelean et al.⁶⁷

Immediately after the first rf pulse, $M_Z(t_{0+}) = 0$ and $M_{\pm}(t_{0+}) = -M^{\text{eq}} i e^{i\phi}$, and this holds until the beginning of the first gradient pulse, which transforms the magnetization into $m_Z(t_0 + \tau_{1-}) = 0$ and $M_{\pm}(t_0 + \tau_{1-}) = -M^{\text{eq}} i e^{i\phi} e^{-i\gamma G \tau_G z}$. With the present simplifications, the position of the first field gradient pulse in the τ_1 interval is immaterial. Immediately after the second rf pulse, the magnetization is given by

$$\begin{aligned} M_{\pm}(t_0 + \tau_{1+}) &= -M^{\text{eq}} \{ \text{Re}[i e^{i\phi} e^{-i\gamma G \tau_G z}] + i \cos \theta_1 \text{Im}[i e^{i\phi} e^{-i\gamma G \tau_G z}] \} \\ &= -\frac{1}{2} M^{\text{eq}} \{ (1 + \cos \theta_1) i e^{i\phi} e^{-i\gamma G \tau_G z} \\ &\quad - (1 - \cos \theta_1) i e^{-i\phi} e^{i\gamma G \tau_G z} \} \\ M_Z(t_0 + \tau_{1+}) &= -M^{\text{eq}} \sin \theta_1 \cos[\phi - \gamma G \tau_G z] \quad (54) \end{aligned}$$

Subsequently, the second gradient pulse multiplies $M_{\pm}$ by $e^{-i\gamma G \tau_G z}$, and the evolution under the dipolar field during the delay τ_2 by $e^{-i\gamma \mu_0 M^{\text{eq}} \tau_2 \cos[\phi - \gamma G \tau_G z]}$. Again, with the present simplifications, the position of the second gradient pulse in the τ_2 interval is immaterial. At acquisition time, which must be after the second gradient pulse if $n \neq 0$, $M_{\pm}$ is given by

$$\begin{aligned} M_{\pm}(t_0 + \tau_1 + \tau_2) &= -\frac{1}{2} M^{\text{eq}} \sum_{q=-\infty}^{+\infty} i^{-q} e^{-iq\phi} e^{-i\gamma G \tau_G z(n-q)} \\ &\times \{ [J_{q+1}(\omega_d \tau_2 \sin \theta_1) + J_{q-1}(\omega_d \tau_2 \sin \theta_1)] \\ &\quad + \cos \theta_1 [J_{q+1}(\omega_d \tau_2 \sin \theta_1) - J_{q-1}(\omega_d \tau_2 \sin \theta_1)] \} \quad (55) \end{aligned}$$

where $\omega_d = \gamma \mu_0 M^{\text{eq}}$, and the summation is over all integers q (note that n is not necessarily an integer). The last step in the calculation of the observed fid is an integral over the whole sample, i.e., a z integral over the thickness d of the flat disk. In a typical CRAZED situation, in which the first pulsed gradient winds the magnetization in a helix with a large number of turns $|\gamma G \tau_G d / 2\pi|$, the z integral of $e^{-i\gamma G \tau_G z(n-q)}$, when considered as a function of n , has a sharp maximum for $n = q$. This allows separate observation of each term in the summation over q in equation (55) by an appropriate choice of n in successive experiments. As shown by combining Figure 13 and equation (55), these signals are large and last for long times (provided that relaxation, molecular diffusion, and radiation damping are not too strong). The term $q = 0$, $n = 0$ (no second gradient pulse) in equation (55) is observable only if the second pulse is different from $\theta_1 = \pi/2$ because $J_1(u) + J_{-1}(u) = 0$. This term is particularly interesting because it does not depend upon the phase ϕ of the first rf pulse, hence it is also independent of any offset between the spectrometer frequency and the unperturbed spin NMR frequency (see, e.g., equation (49)). This behavior is strongly reminiscent of *intramolecular* zero-quantum coherences (which cannot exist in the present case of molecules bearing a single spin); in the ‘Warren’ formalism, the $n = 0 = q$ terms clearly originate from *intermolecular* zero-quantum coherences, and this concept was at the origin of the interest for such signals, and for important applications in imaging^{9,29} (not discussed

here) and in obtaining very high resolution spectra in external fields of moderate homogeneity.^{11,12}

We shall now discuss a simplified version of the HOMOGENIZED experiment proposed by the Warren group for this purpose. This requires extending the above calculations for the case of a mixture of two molecular species,⁷⁹ a and b , each bearing a single spin with different offsets $\delta\omega_a$ and $\delta\omega_b$ from the spectrometer reference frequency ω_{ref} . The discussion will be limited to the case where the difference between offsets is much larger than any dipolar frequency ω_d appearing in the problem, $|\delta\omega_a - \delta\omega_b| \gg |\omega_d|$, so that the spins a and b can be treated as ‘heteronuclear’ in the ‘secular’ simplification of the equations of motion (see Section 4.2.2; for the opposite case see Section 4.3.5).

Combining the notations and discussions in the paragraph ending in equation (49) with those of Section 4.3.2, and with the timing shown in Figure 16, the a and b magnetizations after the first gradient pulse but before the rf pulse at $t_0 + \tau_1$, are given by

$$\begin{aligned} M_{a\pm}(t_0 + \tau_1) &= -M_a^{\text{eq}} e^{i\phi} e^{i\delta\omega_a \tau_1} e^{-i\gamma G \tau_G z} \\ M_{b\pm}(t_0 + \tau_1) &= -M_b^{\text{eq}} e^{i\phi} e^{i\delta\omega_b \tau_1} e^{-i\gamma G \tau_G z} \\ M_{aZ}(t_0 + \tau_1) &= 0, \quad M_{bZ}(t_0 + \tau_1) = 0 \end{aligned} \quad (56)$$

and immediately after the rf pulse at $t_0 + \tau_1$, by

$$\begin{aligned} M_{a\pm}(t_0 + \tau_1) &= -\frac{1}{2} M_a^{\text{eq}} \{(1 + \cos \theta_1) i e^{i\phi} \\ &\times e^{i\delta\omega_a \tau_1} e^{-i\gamma G \tau_G z} - (1 - \cos \theta_1) i e^{-i\phi} e^{-i\delta\omega_a \tau_1} e^{i\gamma G \tau_G z}\} \\ M_{aZ}(t_0 + \tau_1) &= -M_a^{\text{eq}} \sin \theta_1 \cos[\phi - \gamma G \tau_G z + \delta\omega_a \tau_1] \end{aligned} \quad (57)$$

and similar relations for M_b obtained by permutation of the subscripts a and b . After the rf pulse at $t_0 + \tau_1$, and with the present drastic simplifications, M_{aZ} and M_{bZ} remain constant, the evolution of $M_{a\pm}$ is given by the product of three factors: (i) a factor $e^{-i\gamma G \tau_G z}$ from the second gradient pulse, (ii) a factor $e^{i\delta\omega_a \tau_2}$ from the offset, and (iii) a factor $e^{-i\gamma \mu_0 \tau_2 \sin \theta_1 \left\{ -M_{aZ}(t_0 + \tau_1) - \frac{2}{3} M_{bZ}(t_0 + \tau_1) \right\}}$ from the dipolar fields created by the a and b spins. The evolution of $M_{b\pm}$ is given by similar factors with permutation of a and b . With some algebra, one obtains, for acquisition times after the second gradient pulse,

$$\begin{aligned} M_{a\pm}(t_0 + \tau_1 + \tau_2) &= -\frac{1}{2} M_a^{\text{eq}} e^{i\delta\omega_a \tau_2} \sum_{p,q} \left\{ i^{p+q} e^{i\phi(p+q)} \right. \\ &\times e^{-i\gamma G \tau_G z(n+p+q)} e^{i(p\delta\omega_a + q\delta\omega_b)\tau_1} \\ &\times \left[(1 + \cos \theta_1) J_{p-1}(-\gamma \mu_0 \sin \theta_1 M_a^{\text{eq}} \tau_2) \right. \\ &\times J_q \left(-\gamma \mu_0 \sin \theta_1 \frac{2}{3} M_b^{\text{eq}} \tau_2 \right) \\ &+ \left[(1 - \cos \theta_1) J_{p+1}(-\gamma \mu_0 \sin \theta_1 M_a^{\text{eq}} \tau_2) \right. \\ &\times J_q \left(-\gamma \mu_0 \sin \theta_1 \frac{2}{3} M_b^{\text{eq}} \tau_2 \right) \left. \left. \right] \right\} \end{aligned} \quad (58)$$

and a similar relation for $M_{b\pm}$, where the summations over p and q range over all integers from $-\infty$ to $+\infty$.

In the perspective of high resolution spectra in fields of moderate homogeneity, the factor $e^{i(p\delta\omega_a + q\delta\omega_b)\tau_1}$ in equation (58) is very interesting in the cases $p = -q \neq 0$, for which it oscillates (as a function of τ_1) at the frequency *difference* between the a and b NMR lines (or multiples thereof). This difference is unaffected by small changes in external field. Of course, a 2D experiment (ω_1 associated with τ_1 , and ω_2 with τ_2 , both seen from the frame rotating at $\omega_{\text{ref}} \mathbf{1}_Z$) is required to study the τ_1 dependence of the signal, and the goal is to observe 2D peaks with very small width in the indirectly detected ω_1 direction.

For a pulsed gradient $G\tau_G$ which creates a magnetization helix with a large number of turns over the thickness of the sample, the $p = -q$ terms of equation (58) are efficiently selected by the choice of $n = 0$ (no gradient pulse after $t_0 + \tau_1$), and it is convenient to rewrite equation (58) in this particular case as

$$\begin{aligned} M_{a\pm}(t_0 + \tau_1 + \tau_2) &= -\frac{1}{2} M_a^{\text{eq}} e^{i\delta\omega_a \tau_2} \sum_{q=-\infty}^{+\infty} \left\{ e^{i\tau_1 q (\delta\omega_a - \delta\omega_b)} \right. \\ &\times J_q \left(-\gamma \mu_0 \sin \theta_1 \frac{2}{3} M_b^{\text{eq}} \tau_2 \right) \left[(1 + \cos \theta_1) J_{-q-1}(-\gamma \mu_0 \sin \theta_1 M_a^{\text{eq}} \tau_2) \right. \\ &+ \left. \left. (1 - \cos \theta_1) J_{-q+1}(-\gamma \mu_0 \sin \theta_1 M_a^{\text{eq}} \tau_2) \right] \right\} \end{aligned} \quad (59)$$

$$\begin{aligned} M_{b\pm}(t_0 + \tau_1 + \tau_2) &= -\frac{1}{2} M_b^{\text{eq}} e^{i\delta\omega_b \tau_2} \sum_{q=-\infty}^{+\infty} \left\{ e^{i\tau_1 q (\delta\omega_b - \delta\omega_a)} \right. \\ &\times J_q \left(-\gamma \mu_0 \sin \theta_1 \frac{2}{3} M_a^{\text{eq}} \tau_2 \right) \left[(1 + \cos \theta_1) J_{-q-1}(-\gamma \mu_0 \sin \theta_1 M_b^{\text{eq}} \tau_2) \right. \\ &+ \left. \left. (1 - \cos \theta_1) J_{-q+1}(-\gamma \mu_0 \sin \theta_1 M_b^{\text{eq}} \tau_2) \right] \right\} \end{aligned} \quad (60)$$

A simple and useful situation occurs when the a spins are abundant, hence cause large dipolar field effects, and the b spins are dilute. In this case, the Bessel function arguments involving $M_b^{\text{eq}} \tau_2$ remain much smaller than 1 (in absolute value) for any relevant value of τ_2 (i.e., for $\tau_2 < T_2$ where T_2 is the spin–spin relaxation time), hence the corresponding Bessel functions are well approximated by the first non-zero term of their power series expansion (see Figure 13).

The response due to $M_{b\pm}$ is proportional to M_b^{eq} and has a fast τ_2 dependence in $e^{i\delta\omega_b \tau_2}$, as expected. For this response, the term $q = 0$ is not interesting because it is independent of τ_1 , hence it gives a narrow but uninformative spectral contribution at $\omega_1 = 0$.

The term $q = 1$ has an interesting τ_1 dependence in $e^{i\tau_1 (\delta\omega_b - \delta\omega_a)}$, a contribution of $(1 - \cos \theta_1)$ arising from the Bessel function J_0 in the last term in equation (60), and an additional τ_2 dependence in $J_1(-\sin \theta_1 (2/3) \omega_{da} \tau_2)$ where $\omega_{da} = \gamma \mu_0 M_a^{\text{eq}}$ is the dipolar frequency of the abundant spins a alone. The contribution in J_{-2} is negligible for dilute spins b . All this generates a 2D peak at $\omega_1 = (\delta\omega_b - \delta\omega_a)$ and $\omega_2 = \delta\omega_b$, very narrow in the ω_1 direction and usually much broader in the ω_2 direction due to field inhomogeneities. The term $q = -1$ in $M_{b\pm}$ gives a similar peak at $\omega_1 = -(\delta\omega_b - \delta\omega_a)$ and $\omega_2 = \delta\omega_b$, with a magnitude proportional to $(1 + \cos \theta_1)$. The terms $|q| > 1$ give much smaller contributions when the spins b are diluted. The Warren group has shown that these remarkable peaks are very conspicuous under normal circumstances,⁷⁹ and can still be observed in

fields of rather poor homogeneity,^{11,12} provided that additional spin manipulations overcome the undesired effects of radiation damping, molecular diffusion, and field inhomogeneities during acquisition.

Also as expected, the response due to $M_{a\mp}$ has a fast τ_2 dependence in $e^{i\delta\omega_a\tau_2}$, and it is typically much larger because of the factor M_a^{eq} in equation (59). For this part of the response, the term $q = 0$ is equal to 0 when the rf pulses are both $\pi/2$ (see discussion after equation (55)), perhaps a favorable situation for actual experiments because large solvent signals are absent during acquisition while the relevant signals are close to maximum amplitude. The terms $|q| > 0$ no longer cancel for $\theta_1 = \pi/2$, but they give small contributions when the spins b are diluted.

By inspection of the above calculations, one can check that, for diluted b spins, the relevant signals during acquisition (the $q = \pm 1$ term in $M_{b\mp}$) arise from the b component of the $M_{\mp}$ transverse magnetization helices, progressively phase modulated by the dipolar field generated by the longitudinal magnetization grating of the abundant spins a . This process has strong analogies with the usual electronic demodulation of the (weak) fid signal by the (strong) reference signal at frequency $\omega_{\text{ref}}/2\pi$ of a coherent spectrometer, with the role of $\omega_{\text{ref}}/2\pi$ played, in the HOMOGENIZED experiment, by the NMR frequency $(\omega_{\text{ref}} + \delta\omega_a)/2\pi$ of the abundant spins in *exactly the same external field* in which the NMR frequency of the dilute spins is $(\omega_{\text{ref}} + \delta\omega_b)/2\pi$. With the above analogy, one immediately predicts that a mixture of various *diluted* spins generates a HOMOGENIZED spectrum which is the sum of the spectra for the separated diluted spins. More generally, the analogy indicates that for diluted polyatomic molecules with a complex NMR spectrum of the spins of the same species as the a spins, the HOMOGENIZED spectrum is quite similar to a standard COSY spectrum of the same molecules, with local demodulation using the frequency $(\omega_{\text{ref}} + \delta\omega_a)/2\pi$ and very narrow peaks in the ω_1 direction, and standard electronic demodulation using the frequency $\omega_{\text{ref}}/2\pi$ and broader peaks in the ω_2 direction.

4.3.4 The COSY Experiment

In echo experiments, the timing is set by the delay between the two pulses, and the main visible effect of relaxation is its influence on the magnitude of the various echoes. In COSY experiments, all delays contribute to the 2D spectra, and relaxation manifests itself not only in the size of the peaks, but also in their precise shape and position, as shown by Figures 17 and 18. As a preparation for the discussion of these features, we shall now briefly sketch the corresponding theory on the spin system already used at the end of Section 4.3.3: a mixture of spins a and b of the same species, bound on different molecules, with offsets $\delta\omega_a$ and $\delta\omega_b$ from the spectrometer reference frequency ω_{ref} such that $|\delta\omega_a - \delta\omega_b|$ is much larger than any dipolar field shift in the system.

All fields and magnetizations will be assumed to be uniform, and the shape and orientation of the ellipsoidal sample will be described by the parameter α_s (see equation (111)), which ranges from 1 for a pancake perpendicular to Z to $-(1/2)$ for a cylinder parallel to Z , through 0 for a sphere or a pancake at the magic angle. Radiation damping will be ignored and the a and b spins will be assumed to relax independently, with relaxation times T_{1a} , T_{2a} , T_{1b} , and T_{2b} . Under these

Figure 17 Absolute value COSY spectrum for a single NMR line with dipolar field effects, calculated for the sequence $\text{equil. } -[\pi/2, 0] - \tau_1 - [\pi/2, 0] - \tau_2 - \text{acq.}$. The simulation takes into account relaxation (with $T_1 = T_2$), a homogeneous dipolar field such that $T_2\delta\omega_d = 5.25$ (where $\delta\omega_d/2\pi$ is the frequency shift caused by the equilibrium magnetization) and an offset $\delta\omega$ of the NMR line chosen such that $T_2\delta\omega = 20$. Radiation damping has been ignored. In simplified models, the 2D peaks are expected at $\omega_2 = \delta\omega$ and $\omega_1 = n\delta\omega$, where n ranges over the integers; these frequencies are shown by the thick lines in the spectral plot

Figure 18 The same simulation as in Figure 17 is repeated 12 times for the sequence $\text{equil. } -[\pi/2, \phi] - \tau_1 - [\pi/2, 0] - \tau_2 - \text{acq.}$, with successive increments of ϕ by $2\pi/12$. A Fourier transform with respect to ϕ is performed on the set of data, separating the components of the COSY response according to their dependence in $e^{in\phi}$. The plots show the absolute value of these components

conditions, the equations of motion *between* the pulses are

$$\begin{aligned} \frac{\partial}{\partial t} M_{aZ}(t) &= -\frac{1}{T_{1a}} [M_{aZ}(t) - M_{aZ}^{\text{eq}}] \\ \frac{\partial}{\partial t} M_{a\mp}(t) &= -\frac{1}{T_{2a}} M_{a\mp}(t) + i\delta\omega_a M_{a\mp}(t) + i\gamma\mu_0\alpha_s \\ &\quad \times \left[M_{aZ}(t) + \frac{2}{3} M_{bZ}(t) \right] M_{a\mp}(t) \end{aligned} \quad (61)$$

and analogous equations for the b spins obtained by interchanging the subscripts a and b . In the absence of pulse

between t and $t + \tau$, the solution of these equations is

$$\begin{aligned} M_{aZ}(t + \tau) &= M_{aZ}^{\text{eq}} + [M_{aZ}(t) - M_{aZ}^{\text{eq}}]e^{-\tau/T_2a} \\ M_{a\pm}(t + \tau) &= M_{a\pm}(t)e^{-\tau/T_2a} e^{i\delta\omega_a\tau} e^{iK_a(t+\tau,t)} \end{aligned}$$

where

$$K_a(t + \tau, t) = \gamma\mu_0\alpha_s \int_{t'=t}^{t'+\tau} \left[M_{aZ}(t') + \frac{2}{3} M_{bZ}(t') \right] dt' \quad (62)$$

and analogous equations for the b spins.

The timing of Figure 16 is suitable for an elementary COSY experiment. By combining the known action of the hard rf pulses with equation (62), one can derive an analytical expression for the measured quantity $M_{a\pm}(t + \tau_1 + \tau_2) + M_{b\pm}(t + \tau_1 + \tau_2)$ at acquisition time, including a complete decomposition in terms depending upon ϕ as $e^{in\phi}$ for integer values of n (see Deville et al.⁸). This complicated expression is difficult to use directly, and it does not seem amenable to analytical Fourier or Laplace transform. The results shown in Figures 2 and 17 were obtained by numerical FFT of simulated data matrices.

Less accurate but directly usable analytical results can be obtained by ignoring relaxation. The derivation is almost the same as for equation (58), and the result for two $\pi/2$ pulses (i.e., $\theta_1 = \pi/2$) is

$$\begin{aligned} M_{a\pm}(t + \tau_1 + \tau_2) &= -\frac{1}{2} M_a^{\text{eq}} e^{i\delta\omega_a\tau_2} \\ &\times \sum_{p,q} \left\{ i^{p+q} e^{i(p+q)\phi} e^{i(p\delta\omega_a + q\delta\omega_b)\tau_1} [J_{p-1}(-\delta\omega_{d,a}\tau_2) \right. \\ &\left. + J_{p+1}(-\delta\omega_{d,a}\tau_2)] J_q \left(-\frac{2}{3} \delta\omega_{d,b}\tau_2 \right) \right\} \end{aligned}$$

where

$$\delta\omega_{d,a} = \gamma\mu_0\alpha_s M_a^{\text{eq}} \quad \text{and} \quad \delta\omega_{d,b} = \gamma\mu_0\alpha_s M_b^{\text{eq}} \quad (63)$$

and analogous expressions for the b spins. A rough estimate of the relative magnitude of the various peaks can be obtained by replacing τ_2 by T_2 in the arguments of the Bessel functions in equation (63).

As an example, consider the situation illustrated by Figure 2, with dilute (interesting) a spins and abundant (solvent) b spins, such that the argument $-\delta\omega_{d,a}\tau_2$ of J_{p-1} and J_{p+1} is always very small in equation (63), whereas the argument $-\delta\omega_{d,b}\tau_2$ of J_q has relevant absolute values up to 2 or more. The response at the acquisition frequency $\omega_2 = \delta\omega_a$ of the dilute spins, shown by equation (63), has large contributions only for $p + 1 = 0$ and $p - 1 = 0$ (see Figure 13), but over a range of values of q centered around 0. The terms ($p = \pm 1, q = 0$) are the expected peaks in the absence of dipolar field effects, other values of q give the conspicuous satellites shown in Figure 2, and other values of p give much weaker satellites, always in the indirectly detected ω_1 direction. The calculations can be extended for dilute molecules with multiple spins and a complex spectrum; in this case also, the main dipolar field effect is a decoration of each COSY peak of the dilute molecule by satellites in the ω_1 direction, separated by the b spins offset $\delta\omega_b$. Great care should be exercised in the interpretation of such spectra if conventional phase

cycling is used in the acquisition (or processing): the particular phase ϕ properties of the contributions for different orders $n = p + q$ often result in unexpected cancellations for some values of n . Any phase cycling used in data acquisition should also be incorporated in the corresponding simulations.

The multitude of additional 2D peaks caused by dipolar field effects is prone to ambiguity in assignment, hence a clear separation based on the $e^{i(p+q)\phi}$ factor in equation (63) is welcome. An efficient implementation of this separation is to perform each basic experiment (i.e., acquisition of a (τ_1, τ_2) matrix at constant ϕ in the present COSY case) for a succession of K equally spaced ϕ phases, $\phi(k) = k2\pi/K$, where the integer k ranges from 0 to $(K - 1)$, taking care to save all the data separately in computer memory. At this point, a Fourier transform with respect to the integer k separates the data in contributions from the individual values of $n = p + q$, provided that the number K of repetitions around the phase cycle is larger than the range of n over which appreciable contributions are present (otherwise, one encounters the usual folding problem). This procedure is much more efficient than the standard coaddition procedures because it provides a *complete* picture of the ϕ dependence of the data after a single phase cycle, a particularly important feature in exploratory experiments or in the presence of peaks of doubtful origin. The larger requirements of computer memory for this procedure are no longer a problem; modern software for 3D analysis makes the whole procedure quite simple to implement.⁸⁰

4.3.5 The Goldman–Desvaux Effect

The Goldman–Desvaux effect,⁶⁸ illustrated by Figure 19, is a dynamical manifestation of the *precessing* component of the dipolar field, which appears already in the simplest single rf pulse experiment (in homogeneous fields) when two (or more) NMR lines are so close together that their separation is not much larger than the total dipolar field shifts associated with both lines. We shall now briefly discuss this effect, using the notation and many simplifications of Sections 4.3.3 and 4.3.4, assuming homogeneous fields and two types of spins with almost the same NMR frequency.

The nuclear magnetization is a sum of components for the a and b spins, $\mathbf{M}(t) = \mathbf{M}_a(t) + \mathbf{M}_b(t)$, and the relevant part of the dipolar field is given by $\mathbf{B}_d^{\text{no ctp}} = -\mu_0 [M_Z(t)\mathbf{1}_Z - \frac{1}{3}\mathbf{M}(t)]$ for a flat sample perpendicular to Z [see equation (36)]. Ignoring relaxation, radiation damping, and rf fields, the equations of motion are

$$\left(\frac{d}{dt} \right)_{\text{rot}} \mathbf{M}_a(t) = \mathbf{M}_a(t) \times [\gamma \mathbf{B}_d^{\text{no ctp}} - \delta\omega_a \mathbf{1}_Z] \quad (64)$$

and a similar equation for $\mathbf{M}_b(t)$ obtained by permutation of the labels a and b . Qualitative discussions will be simplified by writing these equations in terms of rotating frame components (and performing obvious simplifications),

$$\begin{aligned} \frac{d}{dt} M_{a\bar{x}}(t) &= -\frac{\mu_0\gamma}{3} M_{aZ}(t) M_{b\bar{y}}(t) - M_{a\bar{y}}(t) \\ &\times \left\{ \delta\omega_a + \mu_0\gamma \left[M_{aZ}(t) + \frac{2}{3} M_{bZ}(t) \right] \right\} \end{aligned} \quad (65)$$

$$\begin{aligned} \frac{d}{dt} M_{a\bar{y}}(t) &= \frac{\mu_0\gamma}{3} M_{aZ}(t) M_{b\bar{x}}(t) + M_{a\bar{x}}(t) \\ &\times \left\{ \delta\omega_a + \mu_0\gamma \left[M_{aZ}(t) + \frac{2}{3} M_{bZ}(t) \right] \right\} \end{aligned} \quad (66)$$

Figure 19 The Goldman–Desvaux effect⁶⁸ for a mixture of independent a and b spins of equal concentrations. $\delta\omega_a$ and $\delta\omega_b$ are the offsets with respect to the spectrometer reference frequency. The spectra shown have been calculated as the ‘absorption’ part of the Fourier transform of the fid after a hard θ pulse applied to the equilibrium situation, for a dipolar field shift of each separate species ($|\gamma\mu_0 M_a^{\text{eq}}|$ for a flat sample perpendicular to Z) equal to the difference $|\delta\omega_b - \delta\omega_a|$ between the two unperturbed NMR frequencies. Relaxation and radiation damping were not included in the simulations, and the line widths result from a Gaussian apodisation. The overall shift of the spectrum as a function of θ is the effect demonstrated by Edzes⁷ on a single spin species. The Goldman–Desvaux effect is the θ -dependence of the difference in intensity and separation of the two lines, and the presence of (weak) satellites

$$\frac{d}{dt} M_{aZ}(t) = \frac{\mu_0\gamma}{3} [M_{a\bar{X}}(t)M_{b\bar{Y}}(t) - M_{a\bar{Y}}(t)M_{b\bar{X}}(t)] \quad (67)$$

and similar equations for the components of $\mathbf{M}_b(t)$. The unconventional spectral features shown by Figure 19 in addition to the overall θ -dependent shift, arise from the action, on each type of spin, of the precessing component of the dipolar field caused by the other type of spins.

Equation (67) shows that the longitudinal a magnetization is affected in this way whenever the transverse components of the a and b magnetizations are not parallel (this process is approximately periodic at the difference between the unperturbed NMR frequencies). Inspection confirms that the time derivatives of $M_{aZ}(t)$ and $M_{bZ}(t)$, due to the dipolar field, cancel exactly (as required by energy conservation). However, the oscillating magnetizations $M_{aZ}(t)$ and $M_{bZ}(t)$ appear separately in equations (65) and (66), where they cause a periodic phase modulation of $M_{a\bar{X}}(t)$ which generates for example, the sidebands shown in Figure 19. This mechanism acts also on the b spins, and is particularly active when the magnetization is mainly transverse. Another source of periodic phase modulation of $M_{a\bar{X}}(t)$ at the same frequency is the presence of a factor $M_{b\bar{Y}}(t)$ in equation (65) for the evolution of $M_{a\bar{X}}(t)$, which causes, for example, the appearance of a Fourier component of the a spins response at the b spins NMR frequency (and conversely for the b spins, with different sign and magnitude). This mechanism causes the differences in amplitude of the two main ‘absorption’ lines of the a, b mixture, and is particularly active when the magnetization is mainly longitudinal. Of course, the responses originating from the a and b spins cannot

be separated experimentally, but it is important to remember, in qualitative discussions of dipolar field effects, that each individual line reflects one aspect of the collective motion of the macroscopic a, b spin system and not the motion of a single type of spins. A similar situation occurs in ‘spectral clustering’ (see Section 6).

Goldman and Desvaux⁶⁸ have obtained a very useful analytical solution of equation (64) for the single pulse experiment, using approximations appropriate for weak (realistic) dipolar field effects. They have also demonstrated excellent quantitative agreement (without any adjustable parameter) between predictions and experimental results.

Realistic relaxation terms are easy to incorporate in equation (64), but this will not help finding ‘exact’ analytical solutions of the conventional type. Fortunately, it is very easy to generate numerical solutions of such a simple set of differential equations, for instance with a tool like *Mathematica*.

4.4 Quantum Calculations for all Spins and all Couplings Together

The ‘classical’ discussion of dipolar field effects in liquids can be presented quite convincingly in terms of a hydrodynamic description involving an independent spin system for each molecule in the sample and a classical average dipolar field generated by the average bulk nuclear magnetization (see Sections 2.2 and 4.1). However, when these effects were first observed in the perspective of multidimensional high resolution NMR, the surprise caused by the additional 2D peaks was such that some investigators felt that the classical formalism was unsuitable for their interpretation (or possibly wrong). Part of these initial worries could be settled by additional care in the use of the classical formalism (see, for example, Sections 2.3, 2.5 and last paragraph of 4.1), but others were more fundamental. For instance, it may seem strange to ignore correlations between distant spins for which the dipolar coupling manifests itself in dipolar field effects. Also, dipolar couplings at short distances cause relaxation, those at large distances are taken into account in the dipolar field; are some couplings at ‘moderate’ distance not forgotten or counted twice?

A first step towards improved understanding is to choose a more general presentation of the whole problem, in which all the spins in the sample are treated as a single quantum system of coupled objects. To avoid dissuasive complications, we shall continue to use a classical description for the electromagnetic field and for the positions of the atoms. In this introductory discussion, we shall examine the simplest system which exhibits dipolar field effects: an ensemble of equivalent spins, with a single spin on each molecule.

The individual spins will be labeled by lower case subscripts, $\mathbf{r}_j(t)$ is the position of spin j at time t , and the dipolar magnetic interaction between spins j and k is described by the Hamiltonian

$$\hat{H}_{jk}^{\text{dip}}(t) = -\frac{\mu_0}{4\pi} \frac{\gamma\hbar\{3[\hat{\mathbf{I}}_j \cdot \mathbf{1}_{j,k}(t)]\mathbf{1}_{j,k}(t) - \hat{\mathbf{I}}_j\}}{|\mathbf{r}_j(t) - \mathbf{r}_k(t)|^3} \cdot \gamma\hbar\hat{\mathbf{I}}_k \quad (68)$$

where $\mathbf{1}_{j,k}(t)$ is a unit vector pointing in the direction from j to k , the last dot product stands for a dot product in position space and a tensorial product of operators acting in the quantum state spaces of spins j and k , and $\hat{H}_{kj}^{\text{dip}}(t) = \hat{H}_{jk}^{\text{dip}}(t)$. The total

dipolar coupling between all spins in the sample is obtained by summing over all pairs,

$$\hat{H}_S^{\text{dip}}(t) = \sum_{j=1}^{N-1} \sum_{k=j+1}^N \hat{H}_{jk}^{\text{dip}}(t) \otimes \hat{1}_{S/jk} \quad (69)$$

where N is the total number of spins in the sample. The tensorial product with the unit operator $\hat{1}_{S/jk}$ for the state space of all spins except j and k is written explicitly in equation (69) to emphasize the fact that a sum of operators has a meaning only if the operators act in the same state space (the state space S for all spins in the sample, in this case). When no confusion seems possible, we shall follow the tradition by which the tensorial multiplication by the suitable unit operator is tacitly understood. To avoid ambiguities which are frequent in the literature, notably between density operators for a single spin or for the whole system, we shall systematically decorate every quantum operator with a subscript showing the smallest state space in which it is meaningful.

Ignoring the rf magnetic fields generated by the rf current in the sample coil, the Hamiltonian $\hat{H}_S(t)$ for the whole spin system is

$$\hat{H}_S(t) = \sum_{j=1}^N \{-\gamma \hbar \hat{\mathbf{I}}_j \cdot \mathbf{B}_0(\mathbf{r}_j, t)\} + \hat{H}_S^{\text{dip}}(t) \quad (70)$$

where $\mathbf{B}_0(\mathbf{r}, t)$ is the external magnetic field at position $\mathbf{r}$ and time t , and the von Neumann equation of motion for the density operator $\hat{\rho}_S(t)$ for the whole spin system is

$$i\hbar \frac{\partial}{\partial t} \hat{\rho}_S(t) = [\hat{H}_S(t) \hat{\rho}_S(t)] \quad (71)$$

Before discussing various methods which have been proposed to predict dipolar field effects on the basis of this equation of motion of formidable complexity, we shall briefly review some concepts which are useful for relating density operators for all spins in the sample with the more usual density operators for the spins of a single molecule.

The observables of direct interest are sums of terms involving very few spins (one spin for the total nuclear magnetic moment, two spins for the total coupling energy). The total nuclear magnetic moment is

$$\gamma \hat{\mathbf{I}}_S = \sum_{j=1}^N \gamma \hat{\mathbf{I}}_j \otimes \hat{1}_{S/j} \quad (72)$$

and the (quantum and statistical) average value of one of its terms is

$$\langle \gamma \hat{\mathbf{I}}_j \otimes \hat{1}_{S/j} \rangle(t) = \text{Tr}_S\{(\gamma \hat{\mathbf{I}}_j \otimes \hat{1}_{S/j}) \hat{\rho}_S(t)\} \quad (73)$$

where Tr_S is the trace over the state space S for all spins. One can take advantage of the particular properties of such observables by evaluating the trace over S in two successive steps: (i) first evaluate the partial trace $\text{Tr}_{S/j}$ over the states of all spins *except* j (this does not affect $\hat{\mathbf{I}}_j$, which acts only

on the spin j), and (ii) finally evaluate the trace Tr_j over the states of spin j alone,

$$\begin{aligned} \text{Tr}_S\{(\gamma \hat{\mathbf{I}}_j \otimes \hat{1}_{S/j}) \hat{\rho}_S(t)\} &= \text{Tr}_j\{\text{Tr}_{S/j}\{(\gamma \hat{\mathbf{I}}_j \otimes \hat{1}_{S/j}) \hat{\rho}_S(t)\}\} \\ &= \text{Tr}_j\{\gamma \hat{\mathbf{I}}_j \text{Tr}_{S/j}\{\hat{\rho}_S(t)\}\} = \text{Tr}_j\{\gamma \hat{\mathbf{I}}_j \hat{\rho}_j(t)\} \end{aligned}$$

where

$$\hat{\rho}_j(t) = \text{Tr}_{S/j}\{\hat{\rho}_S(t)\} \quad (74)$$

The reduced density operator $\hat{\rho}_j(t)$ acts in the state space j only, it has all the desirable properties of a density operator (Hermitian, $\text{Tr}_j\{\hat{\rho}_j(t)\} = 1$, all eigenvalues between 0 and 1), and it provides the complete information for evaluating the average value of any operator acting in the state space j . However, predicting the time evolution of $\hat{\rho}_j(t)$ from the equation of motion (71) for $\hat{\rho}_S(t)$ remains a formidable task. The formal manipulation of partial traces requires special care, as discussed in Appendix D of Ref.⁶⁹.

Another important issue is that of ‘correlations’, which will be used here in its usual meaning in statistical physics and probability theory (for more details, in the perspective of liquid NMR, see Appendix B of Ref.⁶⁹). If the two objects j and k are not correlated, then all joined distribution functions for properties of j and k are given by the product of the corresponding individual distribution functions, for instance,

$$\hat{\rho}_{jk}(t) = \hat{\rho}_j(t) \otimes \hat{\rho}_k(t) \quad \text{for } j \text{ and } k \text{ not correlated} \quad (75)$$

In general, objects which interact become correlated, and the correlation σ_{jk} is defined by the general relation

$$\hat{\rho}_{jk}(t) = \hat{\rho}_j(t) \otimes \hat{\rho}_k(t) + \sigma_{jk}(t) \quad (76)$$

in which the (reduced) density operators for the objects j and k are obtained from $\hat{\rho}_{jk}(t)$ by partial traces. These definitions are easily extended for any number of objects or spins. Hard pulses do not create or destroy correlations, they just ‘rotate’ the correlations in operator space.

4.4.1 Derivation of the Bloch–Redfield Equations

The Bloch–Redfield equations are obtained ‘from first principles’ (e.g., from equation (71)) by taking the fast molecular Brownian motion explicitly into account, and deriving an approximate kinetic equation of motion for the reduced density operator for the spins in a single molecule, averaged over all realizations of the Brownian motion. The derivation is usually presented with a single molecule in mind,⁴⁴ in the approximation of short correlation times for the molecular motion. With such an approach, dipolar field effects can only be introduced in the kinetic equation as an afterthought, as indicated in Section 2.2. However, it is also possible to start with a description including all spins in the sample and all dipolar couplings (see equation (70)). The main additional approximation which makes this more complete model tractable is to neglect any systematic buildup of correlations between spins on different molecules.⁷⁰ It is easy to support this approximation with heuristic arguments and heavily simplified models,⁶⁹ but its limits of validity have not been investigated in detail. When the model with all spins in the sample is treated carefully, the result is a kinetic equation of the Bloch–Redfield type,

with a dipolar field term which is exactly the term previously added ‘as an afterthought’. The derivation presented in Ref.⁶⁹ is explicitly extended to molecules carrying multiple spins and mixtures thereof, and does not use any approximation of high spin temperature or weak order, except in the last step leading to rates of relaxation *independent* of the average spin state. This reference assumes spatial homogeneity over the whole sample, for simplicity; Section 2.4 of the present article provides the necessary extension to spatially inhomogeneous situations, taking into account molecular diffusion and bulk flow.

4.4.2 A Rough but ‘Exactly Soluble’ Model

We shall now briefly discuss a rough model for which the calculations can be performed exactly on the density operator $\hat{\rho}_S(t)$ for N equivalent spins on different molecules, with dipolar interaction between every pair. This model sheds some light on the issue of correlations between spins on different molecules, and provides a pedagogical example of a mechanism by which a state-dependent NMR frequency can be derived from exact quantum mechanics with a time-independent Hamiltonian.

In a compact sample, each molecule ‘explores’ all regions of the sample, on average, over any duration larger than (d^2/D) , where d is the largest distance in the sample and D is the molecular diffusion coefficient; the relative position of two spins also ‘explores’ all possible values in the sample over the same duration. For water at room temperature and a maximum sample size of $d = 10 \mu\text{m}$, the characteristic duration (d^2/D) is less than 0.1 s and the number of protons N is still very large (on the order of 10^{13} , depending upon the shape). In this case, for simple experiments lasting on the order of 1 s, and in the absence of strong sources of spatial inhomogeneity (such as field gradients), a tempting approximation is to start the discussion by averaging the spin Hamiltonian of equation (70) over all positions in the sample. Of course, this throws away the fast fluctuations which cause relaxation, but the slow processes related to the dipolar field should survive.

The averaging of equation (70) is easy to perform for samples of ellipsoidal shape, with the same techniques as for the dipolar field. Not surprisingly, the average coupling vanishes for a spherical sample. For a flat sample perpendicular to Z , the averaged Hamiltonian is

$$\hat{H}_S = \sum_{j=1}^N \hbar \omega_0 \hat{I}_{jZ} + \hat{H}_S^{\text{av dip sec}}$$

where

$$\begin{aligned} \hat{H}_S^{\text{av dip sec}} &= \sum_{j=1}^{N-1} \sum_{k=j+1}^N \frac{\mu_0(\gamma \hbar)^2}{N} \frac{N}{V} \frac{1}{3} \\ &\times \left\{ 2\hat{I}_{jZ}\hat{I}_{kZ} - \frac{1}{2}(\hat{I}_{j+}\hat{I}_{k-} + \hat{I}_{j-}\hat{I}_{k+}) \right\} \end{aligned} \quad (77)$$

where Z points in the direction of $\mathbf{B}_0$, non-secular terms have been ignored in the coupling, and $\omega_0 = -\gamma \mathbf{B}_{0Z}$. As a result of this averaging, the Hamiltonian is time-independent, the positions of the spins are irrelevant, and each spin has the same weak coupling (proportional to $1/N$ if one keeps the

concentration N/V constant while changing the number of spins N) with every other spin. For arbitrary sample shapes, the averaged coupling has the same structure, with the factor $1/3$ replaced by a shape-dependent number.

In Appendix C of Ref.⁶⁹, the response of this model to a hard pulse is evaluated directly from an exact solution of the equation of motion for $\hat{\rho}_S(t)$, without the high temperature approximation. Many aspects of the spin dynamics are discussed in detail, including the issue of correlations between different spins. All conclusions confirm the results of the ‘classical’ approach, and the corresponding assumptions and approximations. It should be noted that Ref.⁶⁹ makes the further approximations of keeping only the terms in $\hat{I}_{jZ}\hat{I}_{kZ}$ in the coupling, and of neglecting the couplings in the expression of the initial thermal equilibrium. F. Henin has shown that these two approximations can be lifted without altering the general conclusions of the discussion (personal communication).

4.5 Suppression of Dipolar Field Effects

In many experiments, dipolar field effects appear as a nuisance and it would be desirable to suppress them, preferably without creating new artifacts or limitations. Various techniques have been proposed for this suppression, but none has been demonstrated, yet, in a realistic setting of high-resolution structural NMR.

A simple idea, with obvious limitations, is to avoid tipping any large nuclear magnetization during the experiment, e.g., by the use of deuterated solvents. This has the additional merit of solving the ‘solvent suppression’ problem.

In experiments without field gradients, one can use an ellipsoidal sample shape which gives a zero relevant dipolar field for a uniform nuclear magnetization. Examples of such shapes are the sphere, a long cylinder oriented at the magic angle, and a flat sample with a normal at the magic angle. The efficiency of this solution is very dependent upon a perfect sample shape and perfectly homogeneous fields $\mathbf{B}_0$ and $\mathbf{B}_1$.

In experiments involving field gradients, the gradients can be oriented at the magic angle so that the ‘modulated’ part of the magnetization generates a zero relevant dipolar field (except in a surface layer of thickness of the order of the wavelength of the modulation). The shape of the sample still has to be chosen carefully (see just above) to avoid the dipolar field generated by the average (‘unmodulated’) part of the magnetization.

Whenever a standard deuterium field-frequency lock is active during the experiment, the lock ‘tries’ to compensate for the longitudinal component of the dipolar field, at a rate limited by the averaging time constant of the lock system.²⁵ This scheme does not compensate for the transverse component of the dipolar field, which is particularly active on the solvent itself. It is also not active on the ‘modulated’ part of the dipolar field (generated by field gradients) or on any other spatial inhomogeneity.

Broekaert et al.²³ have demonstrated an active decoupling technique in which the strong offending solvent line is selectively irradiated on resonance, hence causing a precession of the large solvent magnetization around a fixed transverse direction in the appropriate rotating frame. For a fast enough precession, this effectively averages out the Z component of the dipolar field which is the important component for spins other than the solvent spins. In the experiment reported in

Ref.²³, the satellite lines of the acetone cross section shown in Figure 2 were effectively eliminated by a weak permanent DANTE irradiation of the water line, with acquisition during the ‘windows’ of the DANTE sequence. An advantage of this technique is that it acts locally on the solvent spins, irrespective of the homogeneity (or not) of the distribution of nuclear magnetization.

An even more radical scheme was proposed, also by Broekaert et al.,³¹ in which the whole sample is continuously rotated at the magic angle. The rate of rotation has to be large enough to average out to zero only that part of the dipolar couplings which has survived averaging by the molecular Brownian motion. As a result, MAS rotation at 100 Hz (or faster) would probably be satisfactory. Of course, this scheme limits the usable field gradients to being along the direction of the axis of rotation, presumably not a severe constraint.

4.6 Numerical Simulation Techniques

The analytical solutions, which are derived as an illustration for a number of examples in this article, should not create the illusion that many realistic problems in spin dynamics with collective effects can be handled completely in this way. Numerical calculations are usually required to obtain final predictions comparable to experiment, even in strongly simplified models. However, simulation techniques for position-dependent problems involving the dipolar field are still in a very primitive state of development.

The simplest problems arise for spatially homogeneous situations, in which one is confronted with sets of a small number of non-linear ordinary differential equations, even if dipolar field, relaxation, and radiation damping are taken into account. Powerful and convenient software packages, such as *Mathematica*, are available to solve such sets of equations (analytically or, if that fails, numerically) and to display the result in useful ways.

The next step concerns simple experiments using pulsed field gradients, in which a simple periodic distribution of magnetization with wave vector $\mathbf{q}$ is first created by the experimenter. If the overall shape of the sample is ellipsoidal, and edge effects can be neglected, the equations of motion can be Fourier transformed and the only wave vectors involved are given by $n\mathbf{q}$, where n is any integer (including 0).⁷¹ For dipolar field effects of moderate strength, it is sufficient to retain a very limited range of values of n , and this leads to a correspondingly limited set of non-linear differential equations. During the calculation, it is easy to check that the magnetization terms at the ends of the n range remain silent as expected.³⁹

The Warren group has proposed a new numerical method suitable for the study of general, bulk, three-dimensional phenomena involving the dipolar field.⁷² Their model describes the actual, continuous, distribution of magnetization by a set of discrete magnetic moments localized at each point of a three-dimensional, simple cubic, discretization lattice, inside a cubic basic cell (see lower part of Figure 20). Alternatively, a rectangular parallelepipedic lattice can be used, and also a rectangular parallelepipedic basic cell.

In setting up the equation of motion for the magnetization at each lattice point, no difficulty arises from local properties like relaxation and field offset, and radiation damping depends only on the total magnetization. The main problem is the evaluation of the dipolar field at each lattice point for each

Figure 20 2-dimensional sketch of the tacit implications of the 3-dimensional model used in the numerical simulation method of Enss et al.⁷² The greyed polygon in the basic cell symbolizes any spatial inhomogeneity (magnetization, offset, relaxation, coefficient of diffusion, ...)

different distribution of magnetization in the whole basic cell. A direct summation of the effects, on each localized moment, of all other localized moments, would require a prohibitive amount of calculation for any number of lattice points beyond a few hundred. If one limits the interactions to the pairs of localized moments actually in the basic cell, this procedure generates strong edge effects in the vicinity of the surface of the basic cell whenever a significant magnetization is present there. This is an undesirable feature when the basic cell is meant to describe the effects of local inhomogeneities in an otherwise larger object (as suggested by the upper part of Figure 20).

The very efficient solution proposed by Enss et al.⁷² is to use the simple relation in equation (36) between the magnetization $\mathbf{M}(\mathbf{r}, t)$ and the relevant part $\mathbf{B}_d^{\text{no crp}}(\mathbf{r}, t)$ of the dipolar field for simple periodic distributions of magnetization with zero average value. A fast Fourier transform (FFT) of the discrete description of the magnetization in the basic cell generates a description of this magnetization in terms of simple plane waves, equation (36) transforms this into the corresponding plane wave description of $\mathbf{B}_d^{\text{no crp}}(\mathbf{r}, t)$, and a final inverse FFT generates the desired $\mathbf{B}_d^{\text{no crp}}(\mathbf{r}, t)$, except for the contribution of the average magnetization (the $\mathbf{q} = 0$ component of the FFT of $\mathbf{M}(\mathbf{r}, t)$).

Let us temporarily ignore the problems at $\mathbf{q} = 0$ to concentrate on the fact that equation (36) is valid for periodic distributions in unbound space, and that the FFT algorithm implies a similar extension. As a consequence, the dipolar field evaluated by the above procedure is not that due to the magnetization in the basic cell only, but that generated by an infinite 3-dimensional repetition of the contents of the basic cell, as indicated in the top part of Figure 20. This situation should not cause further worries because the $\mathbf{q} \neq 0$ components of

$\mathbf{M}(\mathbf{r}, t)$ do not have the long distance influence typical of the $\mathbf{q} = 0$ component. However, one should keep in mind that the persistence in time of the (virtual) periodic array of similar basic cells implies that all relevant parameters of spin dynamics also must have this long range spatial periodicity. This may cause trouble in attempts to model ‘exactly’ the effects of persistent homogeneous field gradients.

Whenever the average (or total) magnetization in the basic cell is different from zero, this average magnetization is (virtually) extended to large distances by the periodic repetition discussed above. The overall self consistency of the model requires that the dipolar field, generated by this large scale uniform magnetization, should also be uniform. This, in turn, implies that the large scale shape of the NMR object should be an ellipsoid, as sketched in the top part of Figure 20, hence the $\mathbf{q} = 0$ component of the dipolar field can be evaluated from the corresponding component of the magnetization using equations (34)–(36) or (106), for instance. The uniform component of the dipolar field may be an irrelevant detail, for instance in studies of contrast in imaging, or an essential feature, as for dynamic stability.

When the concentration of spins and their coefficient of molecular diffusion are uniform throughout the basic cell, and diffusion proceeds freely between adjacent periodic repetitions of the basic cell, the diffusion contribution to the equations of motion is easily obtained in reciprocal space (see, for instance, equation (111)), and transformed back to configuration space by inverse FFT.⁷² For non-uniform situations, molecular diffusion can be modeled directly in configuration space as causing exchanges of magnetization between each pair of first neighbor localized magnetizations. Great care must be taken, in the case of non-uniform concentrations, to ensure a realistic description of molecular diffusion. With the algorithm of Ref.⁷², problems can be treated very easily on a desktop computer for spatial resolutions of $32 \times 32 \times 32$, and even significantly better. This scheme seems appropriate for spatial features (appreciably) larger than the pitch of the discretization lattice; for smaller features, the combined effects of multiple discretization artifacts should be carefully examined.

Unfortunately, the techniques described above do not (yet) offer satisfactory tools for situations in which the boundary of the sample plays an important role: spatial inhomogeneities on the scale of the size of the sample, non-ellipsoidal samples, unusual sample shapes (e.g., the $\cup$ shape mentioned in Section 6),...

5 DIPOLAR FIELD EFFECTS, THE ‘WARREN’ PRESENTATION

In this introductory text, specific examples will be limited to the simplest case which manifests dipolar field effects: a single type of spins 1/2, one spin per molecule.

5.1 Formal Introduction, Coherences, Interaction Representation

Let $\hat{A}$ be a Hermitian operator (whose role will be played later by $\hat{I}_Z$ or by the Hamiltonian) which is diagonalized by the orthonormal basis $\{|a_q\rangle\}$,

$$\hat{A}|a_q\rangle = a_q|a_q\rangle$$

where

$$\langle a_q|a_r\rangle = \delta_{q,r} \quad \text{and} \quad \sum_q |a_q\rangle\langle a_q| = \hat{1} \quad (78)$$

Now, we take any operator $\hat{B}$ (whose role will be played later by the density operator or parts of it), multiply it to the left and to the right by the closure relation for $\{|a_q\rangle\}$, and re-arrange terms,

$$\begin{aligned} \hat{B} &= \hat{1}\hat{B}\hat{1} = \left(\sum_q |a_q\rangle\langle a_q|\right) \hat{B} \left(\sum_r |a_r\rangle\langle a_r|\right) \\ &= \sum_{q,r} \langle a_q|\hat{B}|a_r\rangle |a_q\rangle\langle a_r| \end{aligned} \quad (79)$$

This expresses $\hat{B}$ as a linear combination of operators $|a_q\rangle\langle a_r|$ which have simple and convenient relations with $\hat{A}$. Indeed, inspection shows that

$$[\hat{A}, |a_q\rangle\langle a_r|] = (a_q - a_r)|a_q\rangle\langle a_r|$$

hence

$$e^{-i\xi\hat{A}}|a_q\rangle\langle a_r|e^{i\xi\hat{A}} = e^{-i\xi(a_q - a_r)}|a_q\rangle\langle a_r| \quad (80)$$

where ξ is any real constant such that $\xi\hat{A}$ is dimensionless. The operators $|a_q\rangle\langle a_r|$ also have the convenient properties of

$$\text{orthogonality: } \text{Tr}\{|a_q\rangle\langle a_r|\}^\dagger |a_s\rangle\langle a_t| = 0 \quad (81)$$

whenever $(q, r) \neq (s, t)$, and

$$\text{normalization: } \text{Tr}\{|a_q\rangle\langle a_r|\}^\dagger |a_q\rangle\langle a_r| = 1 \quad (82)$$

In the particular case of a single spin 1/2 labeled j , with the role of $\hat{A}$ played by $\hat{I}_{jZ}$ and the notation $\hat{I}_{jZ}|\pm\rangle_j = \pm 1/2|\pm\rangle_j$, we have, obviously, $|+\rangle_{jj}\langle -| = \hat{I}_{j+}$ and $|-\rangle_{jj}\langle +| = \hat{I}_{j-}$. In further calculations, it will be convenient to replace the two other operators, $|+\rangle_{jj}\langle +|$ and $|-\rangle_{jj}\langle -|$, which both commute with $\hat{I}_{jZ}$, with their more familiar combinations $\hat{I}_j = |+\rangle_{jj}\langle +| + |-\rangle_{jj}\langle -|$ and $\hat{I}_{jZ} = 1/2|+\rangle_{jj}\langle +| - 1/2|-\rangle_{jj}\langle -|$, in spite of the fact that $\hat{I}_j$ and $\hat{I}_{jZ}$ are not properly normalized. With this notation, the first line of equation (80) becomes

$$[\hat{I}_{jZ}, \hat{I}_{j\pm}] = \pm \hat{I}_{j\pm}, \quad [\hat{I}_{jZ}, \hat{I}_{jZ}] = 0 = [\hat{I}_{jZ}, \hat{I}_j] \quad (83)$$

and equation (1) for $\hat{\rho}_j(t)$ takes the form

$$\hat{\rho}_j(t) = \frac{1}{2}\{\hat{I}_j + 2\langle I_{j+}\rangle(t)\hat{I}_{j+} + 2\langle I_{j-}\rangle(t)\hat{I}_{j-} + 4\langle I_{jZ}\rangle(t)\hat{I}_{jZ}\} \quad (84)$$

where the average values are evaluated according to equation (7) and $\langle I_{j+}\rangle(t)$ is the complex conjugate of $\langle I_{j-}\rangle(t)$.

Similarly, the density operator $\hat{\rho}_{jk}$, for the two spins j and k , can be expressed as a linear combination of the 16 operators obtained successively by multiplication of each operator of the

list $\{\hat{I}_j, \hat{I}_{j+}, \hat{I}_{j-}, \hat{I}_{jZ}\}$ by each operator of the corresponding list for spin k ,

$$\begin{aligned}\hat{\rho}_{jk}(t) = & \frac{1}{4} \{\hat{I}_{jk} + 2\langle I_{j+} I_{k+} \rangle(t) \hat{I}_{j+} \hat{I}_{k+} + \dots \\ & + 2\langle I_{j+} I_{k-} \rangle(t) \hat{I}_{j+} \hat{I}_{k-} + 4\langle I_{j+} I_{kZ} \rangle(t) \hat{I}_{j+} \hat{I}_{kZ} + \dots \\ & + 2\langle I_{j-} I_{k+} \rangle(t) \hat{I}_{j-} \hat{I}_{k+} + 4\langle I_{j-} I_{k-} \rangle(t) \hat{I}_{j-} \hat{I}_{k-} + \dots \\ & + 4\langle I_{j-} I_{kZ} \rangle(t) \hat{I}_{j-} \hat{I}_{kZ} + 8\langle I_{jZ} I_{kZ} \rangle(t) \hat{I}_{jZ} \hat{I}_{kZ} + \dots \\ & + 16\langle I_{jZ} I_{kZ} \rangle(t) \hat{I}_{jZ} \hat{I}_{kZ}\} \quad (85)\end{aligned}$$

This procedure is easily extended for any number of spins.

A more conventional procedure for this type of decomposition of density operators for systems of spins 1/2 uses the (also not properly normalized) basis $\{\hat{I}_j, \hat{I}_{jX}, \hat{I}_{jY}, \hat{I}_{jZ}\}$ for each spin j , as indicated by equation (1). However, this basis contains the operators $\hat{I}_{jX}$ and $\hat{I}_{jY}$, each of which combines the coherence orders +1 and -1 (see below). The use of the basis $\{\hat{I}_j, \hat{I}_{j+}, \hat{I}_{j-}, \hat{I}_{jZ}\}$ avoids this mixture of coherence orders, and simplifies discussions in which the coherence order is a key feature.

Coherences are usually defined as off-diagonal elements of the density operator, and the corresponding diagonal elements are called populations. With this definition, coherences depend upon the basis used for their evaluation. The simplest situation arises when the motion of the system is governed by a time independent Hamiltonian $\hat{H}$ for which the eigenvalues and eigenstates are known, and one uses the eigenbasis of $\hat{H}$ to define the coherences. Equations (78)–(80) then lead to

$$\hat{H}|h_q\rangle = h_q|h_q\rangle, \quad \hat{\rho}(t) = \sum_{q,r} \langle h_q|\hat{\rho}(t)|h_r\rangle |h_q\rangle\langle h_r|$$

hence

$$\langle h_q|\hat{\rho}(t)|h_r\rangle = \langle h_q|\hat{\rho}(t_0)|h_r\rangle e^{i(t-t_0)(h_q-h_r)/\hbar} \quad (86)$$

where the subscripts q and r label the eigenvalues and eigenvectors of $\hat{H}$. During time evolution under $\hat{H}$, each coherence just oscillates at the corresponding Bohr frequency. However, time-dependent perturbations, like rf pulses, usually cause a major reorganization of the coherences.

In typical NMR situations (with spins of a single species), the Hamiltonian $\hat{H}$ for the spins in a single molecule can be decomposed as $\hat{H} = \hbar\omega_0 \sum_j \hat{I}_{jZ} + \hat{V}$, where the small term $\hat{V}$ describes chemical shifts and spin–spin couplings (suitably averaged over the molecular Brownian motion). For such small $\hat{V}$, it is sufficient to retain the part of $\hat{V}$ which is secular with respect to $\sum_j \hat{I}_{jZ}$, so that the eigenstates of $\hat{H}$ are also eigenstates of $\sum_j \hat{I}_{jZ}$,

$$\left(\sum_j \hat{I}_{jZ} \right) |h_q\rangle = n_q |h_q\rangle \quad (87)$$

where the n_q are integers (or half-integers for an odd number of half-integer spins). For any coherence $\langle h_q|\hat{\rho}(t)|h_r\rangle$, the integer $(n_q - n_r)$ is an essential parameter because it governs the behavior of the coherence with respect to the phase of rf pulses, and to changes in external magnetic field; it also gives the zero-th order approximation of the energy difference between

states q and r . The integer $(n_q - n_r)$ is the ‘order of coherence’ and the c-number $\langle h_q|\hat{\rho}(t)|h_r\rangle$ is called an ‘ $(n_q - n_r)$ -quantum coherence.’ The operators $|h_q\rangle\langle h_r|$ and $\langle h_q|\hat{\rho}(t)|h_r\rangle |h_q\rangle\langle h_r|$ are also called ‘ $(n_q - n_r)$ -quantum coherences.’ All these ideas are easily extended to the case of multiple spin species.

The present discussion of the ‘Warren’ presentation of the dipolar field effects will be based on a spin Hamiltonian of the type often used for solids,

$$\hat{H}_S = \sum_{j=1}^N \hbar(\omega_0 + \delta\omega_j) \hat{I}_{jZ} + \hat{H}_S^{\text{dipsec}} + \hat{P}_S(t)$$

where

$$\begin{aligned}\hat{H}_S^{\text{dipsec}} = & \sum_{i=1}^N \sum_{j=1(j \neq i)}^N \hbar D_{ij} \{3\hat{I}_{iZ}\hat{I}_{jZ} - \hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j\} \\ D_{ij} = & -\frac{1}{2} \frac{\mu_0}{4\pi} \frac{\gamma^2 \hbar}{|\mathbf{r}_i - \mathbf{r}_j|^3} \frac{3(\cos\theta_{ij})^2 - 1}{2} \quad (88)\end{aligned}$$

$\delta\omega_j$ is a small frequency offset, the non-secular part of the dipolar coupling has been ignored, $\hat{P}_S(t)$ describes rf pulses, and the D_{ij} are the same as in Ref.²¹. Discussions of spin dynamics will be simplified by the usual interaction representation based on the unitary transformation

$$\hat{W}_S(t) = \prod_{j=1}^N e^{-i\omega_0 \hat{I}_{jZ}(t-t_*)} \quad (89)$$

where t_* is an arbitrary reference date. The transformed versions of operators $\hat{A}_S(t)$ and evolution operators $\hat{U}_S(t_1, t_0)$ are given by

$$\begin{aligned}\hat{A}_S(t) = & \hat{W}_S^\dagger(t) \hat{A}_S(t) \hat{W}_S(t) \\ \hat{U}_S(t_1, t_0) = & \hat{W}_S^\dagger(t_1) \hat{U}_S(t_1, t_0) \hat{W}_S(t_0) \quad (90)\end{aligned}$$

the von Neumann equation of motion for $\hat{\rho}(t)$ is

$$i\hbar \frac{\partial}{\partial t} \hat{\rho}_S(t) = \left[\left(\sum_{j=1}^N \hbar \delta\omega_j \hat{I}_{jZ} + \hat{H}_S^{\text{dipsec}} + \hat{P}_S(t) \right), \hat{\rho}_S(t) \right] \quad (91)$$

and the average values of the components of the spin magnetization, as seen from the rotating frame of coordinates, are given by

$$\langle I_{j\pm} \rangle(t) = \text{Tr}_S \{ (\hat{I}_{j\pm})^\dagger \hat{\rho}(t) \}, \dots \quad (92)$$

Assuming that we can neglect the dipolar couplings (and the offsets) in the expression of the equilibrium density operator, $\hat{\rho}_S^{\text{eq}}$ is factorized in equilibrium density operators for the individual spins

$$\hat{\rho}_S^{\text{eq}} = \hat{\rho}_S^{\text{eq}} = \prod_{j=1}^N \hat{\rho}_j^{\text{eq}} = \prod_{j=1}^N \left\{ \frac{1}{2} (\hat{I}_j - \mathcal{J} \hat{I}_{jZ}) \right\}$$

where

$$\mathcal{J} = 2 \tanh \left(\frac{\hbar\omega_0}{2kT} \right) \approx \frac{\hbar\omega_0}{kT} \quad (93)$$

5.2 Intermolecular Multiple-quantum Coherences

Following the example of equation (85), the density operator $\hat{\rho}_S(t)$ for the system of N spins 1/2 can always be decomposed as²²

$$\hat{\rho}_S(t) = \sum_{\xi=1}^{4^N} k^{(\xi)} \langle A^{(\xi)} \rangle(t) \hat{A}^{(\xi)}$$

where

$$\begin{aligned} \langle A^{(\xi)} \rangle(t) &= \text{Tr}_S \{ \hat{A}^{(\xi)\dagger} \hat{\rho}_S(t) \} \\ k^{(\xi)} &= 1/\text{Tr}_S \{ \hat{A}^{(\xi)\dagger} \hat{A}^{(\xi)} \} \end{aligned}$$

and (orthogonality)

$$\text{Tr}_S \{ \hat{A}^{(\xi)\dagger} \hat{A}^{(\eta)} \} = (1/k^{(\xi)}) \delta_{\xi,\eta} \quad (94)$$

The $\hat{A}^{(\xi)}$ are products of one operator of the list $\{\hat{1}_j, \hat{I}_{j+}, \hat{I}_{j-}, \hat{I}_{jZ}\}$ for each spin j in the system, and the $k^{(\xi)}$ are not all unity because the operators $\hat{1}_j$ and $\hat{I}_{jZ}$ are not properly normalized. Each $\hat{A}^{(\xi)}$ has a well defined coherence order, equal to the number of single spin $\hat{I}_+$ minus that of $\hat{I}_-$ used to build $\hat{A}^{(\xi)}$. In the procedure proposed by the Warren group,^{19,21} the time evolution of the relevant observables is studied by solving the set of linear equations of motion of coherences involving progressively increasing numbers of spins (i.e., increasing numbers of spins contributing an operator other than $\hat{1}$ to the coherence),

$$\begin{aligned} \frac{\partial}{\partial t} \langle A^{(\xi)} \rangle(t) &= \text{Tr}_S \left\{ \hat{A}^{(\xi)\dagger} \frac{\partial}{\partial t} \hat{\rho}_S(t) \right\} \\ &= -\frac{i}{\hbar} \text{Tr}_S \left\{ \hat{A}^{(\xi)\dagger} \left[\left(\sum_{j=1}^N \hbar \delta \omega_j \hat{I}_{jZ} + \hat{H}_S^{\text{dip sec}} \right), \hat{\rho}_S(t) \right] \right\} \quad (95) \end{aligned}$$

where rf pulses have been ignored for simplicity. Due to the orthogonality of the coherences, the evaluation of the trace in equation (95) becomes trivial if one knows the coefficient of $\hat{A}^{(\xi)}$ in the expansion of the commutator in terms of coherences. The following simple relations, valid for spins 1/2, will be useful in further discussions,

$$\begin{aligned} [\hat{B}_q \hat{C}_r, \hat{D}_q \hat{E}_r] &= \hat{B}_q \hat{D}_q [\hat{C}_r, \hat{E}_r] + [\hat{B}_q, \hat{D}_q] \hat{E}_r \hat{C}_r \\ \hat{I}_{q\pm} \hat{I}_{qZ} &= \pm \frac{1}{2} \hat{I}_{q\pm}, \quad \hat{I}_{qZ} \hat{I}_{q\pm} = \mp \frac{1}{2} \hat{I}_{q\pm} \\ \hat{I}_{q+} \hat{I}_{q-} &= \frac{1}{2} \hat{1}_q + \hat{I}_{qZ}, \quad \hat{I}_{q-} \hat{I}_{q+} = \frac{1}{2} \hat{1}_q - \hat{I}_{qZ} \\ \left[\sum_{i,j} D_{ij} \hat{I}_{iZ} \hat{I}_{jZ}, \hat{I}_{q+} \right] &= 2 \sum_{i \neq q} D_{iq} \hat{I}_{iZ} \hat{I}_{q+} \\ \left[\sum_{i,j} D_{ij} \hat{I}_i \cdot \hat{I}_j, \hat{I}_{q+} \right] &= 2 \sum_{i \neq q} D_{iq} (\hat{I}_{iZ}, \hat{I}_{q+} - \hat{I}_{i+} \hat{I}_{qZ}) \\ \left[\sum_{i,j} D_{ij} \hat{I}_i \cdot \hat{I}_j, \hat{I}_{qZ} \right] &= \sum_{i \neq q} D_{iq} (\hat{I}_{i+} \hat{I}_{q-} - \hat{I}_{i-} \hat{I}_{q+}) \\ \left[\sum_{i,j} D_{ij} \hat{I}_i \cdot \hat{I}_j, \hat{I}_{qZ} \hat{I}_{rZ} \right] &= D_{qr} (\hat{I}_{q+} \hat{I}_{r-} - \hat{I}_{q-} \hat{I}_{r+}) + [3] \end{aligned}$$

$$\begin{aligned} \left[\sum_{i,j} D_{ij} \hat{I}_{iZ} \hat{I}_{jZ}, \hat{I}_{q+} \hat{I}_{rZ} \right] &= \frac{1}{2} D_{qr} \hat{I}_{q+} + [3] \\ \left[\sum_{i,j} D_{ij} \hat{I}_i \cdot \hat{I}_j, \hat{I}_{q+} \hat{I}_{rZ} \right] &= \frac{1}{2} D_{qr} (\hat{I}_{q+} - \hat{I}_{r+}) + [3] \\ \left[\sum_{i,j} D_{ij} \hat{I}_{iZ} \hat{I}_{jZ}, \hat{I}_{q+} \hat{I}_{r-} \right] &= [3] \\ \left[\sum_{i,j} D_{ij} \hat{I}_i \cdot \hat{I}_j, \hat{I}_{q+} \hat{I}_{r-} \right] &= D_{qr} (\hat{I}_{rZ} - \hat{I}_{qZ}) + [3] \\ \left[\sum_{i,j} D_{ij} \hat{I}_{iZ} \hat{I}_{jZ}, \hat{I}_{q+} \hat{I}_{r+} \right] &= [3] \\ \left[\sum_{i,j} D_{ij} \hat{I}_i \cdot \hat{I}_j, \hat{I}_{q+} \hat{I}_{r+} \right] &= [3] \\ \left[\sum_{i,j} D_{ij} \hat{I}_{iZ} \hat{I}_{jZ}, \hat{I}_{q+} \hat{I}_{rZ} \hat{I}_{pZ} \right] &= \frac{1}{2} D_{qr} \hat{I}_{q+} \hat{I}_{pZ} \\ &\quad + \frac{1}{2} D_{qp} \hat{I}_{q+} \hat{I}_{rZ} + [4] \\ \left[\sum_{i,j} D_{ij} \hat{I}_i \cdot \hat{I}_j, \hat{I}_{q+} \hat{I}_{rZ} \hat{I}_{pZ} \right] &= \frac{1}{2} D_{qr} (\hat{I}_{q+} - \hat{I}_{r+}) \hat{I}_{pZ} \\ &\quad + \frac{1}{2} D_{qp} (\hat{I}_{q+} - \hat{I}_{p+}) \hat{I}_{rZ} + [3] \\ \left[\sum_{i,j} D_{ij} \hat{I}_{iZ} \hat{I}_{jZ}, \hat{I}_{q+} \hat{I}_{r-} \hat{I}_{p+} \right] &= [3] \\ \left[\sum_{i,j} D_{ij} \hat{I}_i \cdot \hat{I}_j, \hat{I}_{q+} \hat{I}_{r-} \hat{I}_{p+} \right] &= D_{rq} \hat{I}_{p+} (\hat{I}_{rZ} - \hat{I}_{qZ}) \\ &\quad + D_{rp} \hat{I}_{q+} (\hat{I}_{rZ} - \hat{I}_{pZ}) + [3] \quad (96) \end{aligned}$$

where $[n]$ stands for additional terms involving at least n different spins. Two general features of such commutators of $\hat{H}_S^{\text{dip sec}}$ with any operator $\hat{A}$ are that (i) the order of coherence of the commutator is the same as that of $\hat{A}$, and (ii) the list of spins involved in the various terms of the commutator can be the same as that of $\hat{A}$, that of $\hat{A}$ with one spin removed, or that of $\hat{A}$ with one spin added.

Another set of useful relations describes the action of a hard rf pulse of tipping angle θ and phase ϕ on the single spin operators,

$$\begin{aligned} \hat{R}_j(\theta, \phi) \hat{I}_{jZ} \hat{R}_j^\dagger(\theta, \phi) &= i \frac{\sin \theta}{2} e^{-i\phi} \hat{I}_{j+} - i \frac{\sin \theta}{2} e^{i\phi} \hat{I}_{j-} + \cos \theta \hat{I}_{jZ}, \\ \hat{R}_j(\theta, \phi) \hat{I}_{j+} \hat{R}_j^\dagger(\theta, \phi) &= \frac{\cos \theta}{2} \hat{I}_{j+} - \frac{\cos \theta}{2} e^{2i\phi} \hat{I}_{j-} + \sin \theta e^{i\phi} \hat{I}_{jZ}, \\ \hat{R}_j(\theta, \phi) \hat{I}_{j-} \hat{R}_j^\dagger(\theta, \phi) &= -\frac{\cos \theta}{2} e^{-2i\phi} \hat{I}_{j+} + \frac{\cos \theta}{2} \hat{I}_{j-} + \sin \theta e^{-i\phi} \hat{I}_{jZ} \end{aligned} \quad (97)$$

where $\hat{R}_j(\theta, \phi) = e^{-i\phi \hat{I}_{jZ}} e^{-i\theta \hat{I}_{jX}} e^{i\phi \hat{I}_{jZ}}$ is the pulse operator for spin j in the interaction representation.

As a starting point for the discussion of the Warren procedure, consider the response to a hard θ pulse, in the X -direction of the rotating frame, applied to the equilibrium state given by equation (93). Immediately after the pulse, the density operator is still factorized, and is given by

$$\hat{\rho}_S(t_{0+}) = \prod_{j=1}^N \frac{1}{2} \left(\hat{1}_j - \frac{i}{2} \mathcal{J} \sin \theta (\hat{I}_{j+} - \hat{I}_{j-}) - \mathcal{J} \cos \theta \hat{I}_{jZ} \right) \quad (98)$$

Neglecting all offsets in a first round of discussion, we evaluate the time derivatives of $\langle I_{q\pm} \rangle(t)$ and $\langle I_{qZ} \rangle(t)$ at $t = t_{0+}$, using equations (95) and (96). The commutators with $\sum_{i,j} D_{ij} \hat{I}_i \cdot \hat{I}_j$ are antisymmetric for permutations of spin labels, hence they give total contributions of zero in the state given by equation (98) which is symmetric for these permutations. The commutators with $\sum_{i,j} D_{ij} \hat{I}_{iZ} \hat{I}_{jZ}$ give no contribution in $\hat{I}_{qZ}$, hence $d\langle I_{qZ} \rangle(t)/dt = 0$ at $t = t_{0+}$, and give a contribution in I_{q+} arising from the terms $(1/2)^N 8 \langle I_{q\pm} \rangle(t_{0+}) \langle I_{rZ} \rangle(t_{0+}) \hat{I}_{q+} \hat{I}_{rZ}$ in $\hat{\rho}_S(t_{0+})$, where $\langle I_{q\pm} \rangle(t_{0+}) = -\frac{i}{4} \mathcal{J} \sin \theta$ and $\langle I_{qZ} \rangle(t_{0+}) = -\frac{1}{4} \mathcal{J} \cos \theta$, hence

$$\left. \frac{\partial}{\partial t} \langle I_{q\pm} \rangle(t) \right|_{t=t_0} = -i \langle I_{q\pm} \rangle(t_{0+}) \sum_{r \neq q} 6D_{qr} \langle I_{rZ} \rangle(t_{0+}) \quad (99)$$

This is the time derivative which is expected at $t = t_{0+}$ if spin q precesses (in the rotating frame) *exactly* at the angular velocity caused by the average classical dipolar field, as given by equation (28) without averaging over molecular motion. The sum in equation (99) is relatively small because the large individual contributions from near-by spins tend to cancel on average, and one is left with distant contributions (depending upon the shape of the sample).

Note that the same dipolar field shift, which is predicted from a set of non-linear equations of motion for individual spins in the ‘classical’ presentation, is predicted here from a linear equation of motion for the system of all spins in the sample. In both cases, this effect appears at order 2 in a ‘systematic’ series expansion in powers of $(1/T)$ or $\mathcal{J}$.

At this point, it is instructive to evaluate the second time derivative of $\langle I_{q\pm} \rangle(t)$, still at $t = t_{0+}$, under the same conditions,

$$\left. \frac{\partial^2}{\partial t^2} \langle I_{q\pm} \rangle(t) \right|_{t=t_0} = \left(\frac{i}{\hbar} \right)^2 \text{Tr}_S \{ (\hat{I}_{q+})^\dagger [\hat{H}_S^{\text{dip sec}}, [\hat{H}_S^{\text{dip sec}}, \hat{\rho}_S(t_0)]] \} \quad (100)$$

Inspection of equation (96) show that terms $\hat{I}_{q+}$ in the double commutator originate from two types of terms in $\hat{\rho}_S(t_0)$: terms in $\hat{I}_{q+}$ and terms in $\hat{I}_{q+} \hat{I}_{rZ} \hat{I}_{pZ}$. The result is

$$\left. \frac{\partial^2}{\partial t^2} \langle I_{q\pm} \rangle(t) \right|_{t=t_0} = -\langle I_{q\pm} \rangle(t_{0+}) \left\{ 9 \sum_{r \neq q} D_{qr}^2 + 72 \sum_{r \neq q} \sum_{\substack{p \neq q \\ p > r}} D_{qr} D_{qp} \langle I_{rZ} \rangle(t_{0+}) \langle I_{pZ} \rangle(t_{0+}) \right\} \quad (101)$$

$$= -\langle I_{q\pm} \rangle(t_{0+}) \left\{ 9 \sum_{r \neq q} D_{qr}^2 (1 - 4 \langle I_{rZ} \rangle(t_{0+})^2) + \sum_{r \neq q} 6D_{qr} \langle I_{rZ} \rangle(t_{0+}) \sum_{p \neq q} 6D_{qp} \langle I_{pZ} \rangle(t_{0+}) \right\} \quad (102)$$

The product of two (equal) sums in equation (102) gives the acceleration expected for the precession indicated by equation (99). The much larger single sum in equation (102) is dominated by the positive contributions D_{qr}^2 for spins r in the immediate vicinity of spin q , and the contributions from distant spins are negligible because they are proportional to $|r_q - r_r|^{-6}$. This single sum is essentially the Van Vleck second moment for the rigid lattice, not a surprise for a model of immobile spins with dipolar couplings. However, the fid of such a model of a ‘frozen’ liquid usually lasts for less than 100 μ s, an intolerable feature for a model of liquids. In a liquid, the molecular Brownian motion very efficiently averages out to zero the effects of the strong couplings between near-by spins, hence suppressing the fast decay of the fid typical of solids. However, this motional averaging has negligible effects on distant couplings, hence it does not affect the dipolar field effects.

All this provides a strong motivation for the solution proposed by the Warren group in the first publication²⁰ on the quantum model described here: ignore the dipolar couplings between near-by spins by setting $D_{ij} = 0$ for all pairs for which $|\mathbf{r}_i - \mathbf{r}_j| < r_0$, with r_0 chosen large enough to avoid visible solid-like broadening of the lines, and smaller than the distance scale of the spatial inhomogeneity of the average spin magnetization during the experiment. As shown by the Warren group, this usually leaves a lot of leeway for the choice of r_0 , and the predictions are independent of the value of r_0 chosen. In some publications,²¹ the cutoff distance r_0 is discussed in terms of a ‘coherent interaction time’ for each pair of molecules in the liquid. The use of this heuristic notion is not necessary, and I feel that it undermines the overall soundness of the model without leading to new conclusions.

Let us now come back to the mechanism which causes the fast decay of the fid when all D_{ij} are taken into account. At $t = t_{0+}$, the density operator $\hat{\rho}_S(t_{0+})$ is factorized and we have $\langle I_{q\pm} \rangle(t_{0+}) \sim \mathcal{J}$ and $\langle I_{q\pm} I_{rZ} \rangle(t_{0+}) \sim \mathcal{J}^2$. The first step, described by the inner commutator in equation (100), acts on $\hat{I}_{q+}$ to generate coherences $\langle I_{q\pm} I_{rZ} \rangle \sim D_{qr} \mathcal{J}$. The second step, described by the outer commutator, acts on these coherences to generate a coherence $\langle I_{q\pm} \rangle \sim \sum_{r \neq q} D_{qr}^2 \mathcal{J}$ which describes the fast decay. The intermediate coherence $\langle I_{q\pm} I_{rZ} \rangle$ is obviously not factorized because it does not have the same $\mathcal{J}$ and D dependences as the product of $\langle I_{q\pm} \rangle \sim \mathcal{J}$ and $\langle I_{rZ} \rangle \sim \mathcal{J}$, hence this corresponds to the growth of two-spin *correlations* involving spin q and all other spins r . If we ignore couplings at short distances, the remaining correlations are small and, to a very good approximation, have no effect whatsoever on the evolution of the observed quantities $\langle I_{q\pm} \rangle$ and $\langle I_{rZ} \rangle$.

In summary, in this particular case, the neglect of couplings at short distances makes quantities of the type $\sum_{r \neq q} D_{qr}^2$ completely negligible, and avoids the generation of *intermolecular correlations* in $\hat{\rho}_S$ which would cause observable effects. Warren and co-workers²¹ have shown that this conclusion is

general. Hence, the factorized part of $\hat{\rho}_S$ is sufficient for all practical purposes of NMR, quantities of the type $\sum_{r \neq q} D_{qr}^2$ can safely be ignored in detailed calculations, and this implies that one can also ignore all contributions arising from terms in the expansion of commutators with $\hat{H}_S^{\text{dip sec}}$ which ‘add’ one spin. These properties simplify the calculations enough to make them tractable and confirm the validity of the factorization approximation for $\hat{\rho}_S(t)$ used in the derivation of the ‘classical’ procedure. In this way, the two methods appear as strictly equivalent for all situations in which the molecular Brownian motion is not an active participant (causing relaxation and macroscopic molecular diffusion).

A less formal, but more detailed discussion of intermolecular multiple quantum coherences in liquids, together with a complete calculation for the CRAZED experiment, can be found in Ref.⁷³.

5.3 Equivalence Between the ‘Classical’ and ‘Warren’ Predictions

This equivalence can be seen in a particularly useful way by coming back to the evaluation of the time derivatives of the average values $\langle I_{q+}(t) \rangle$ and $\langle I_{qZ}(t) \rangle$ at any time t , taking into account only the factorized part of $\hat{\rho}_S(t)$. The calculation will be carried out for a single type of spins 1/2, but it will include offsets and spatial inhomogeneities. By combining equations (83), (88), (91), (95), and (96), without the simplifications used for equation (99) we obtain

$$\begin{aligned} \frac{\partial}{\partial t} \langle I_{q+}(t) \rangle &= -i \delta \omega_q \langle I_{q+}(t) \rangle - i \langle I_{q+}(t) \rangle \sum_{r \neq q} 6 D_{qr} \langle I_{rZ}(t) \rangle \\ &+ i \left\{ \langle I_{q+}(t) \rangle \sum_{r \neq q} 2 D_{qr} \langle I_{rZ}(t) \rangle \right. \\ &\left. - \langle I_{qZ}(t) \rangle \sum_{r \neq q} 2 D_{qr} \langle I_{r+}(t) \rangle \right\} \end{aligned} \quad (103)$$

$$\begin{aligned} \frac{\partial}{\partial t} \langle I_{qZ}(t) \rangle &= -i \langle I_{q-}(t) \rangle \sum_{r \neq q} 2 D_{qr} \langle I_{r+}(t) \rangle \\ &+ i \langle I_{q+}(t) \rangle \sum_{r \neq q} 2 D_{qr} \langle I_{r-}(t) \rangle \end{aligned} \quad (104)$$

In spite of a different notation, this is exactly the generalized Bloch equation (3) for spin q seen in the rotating frame, with an offset $\delta \omega_q$ and a dipolar field given by equation (33), but without relaxation and without rf current in the coil.

In the classical procedure, one considers the Bloch equations as a set of coupled nonlinear differential equations for the three components of the average magnetic moment of each individual spin, i.e., the functions of time explicitly written in equation (103) and (104), a total of $3N$ real variables (here, N real and N complex variables). When a solution has been worked out, all coherences involving a single spin are known as a function of time, hence all higher order coherences can be easily evaluated from the factorization property of $\hat{\rho}_S(t)$. However, there is usually little incentive to do this.

In the Warren procedure, one starts from the same set of equations (103) and (104) for the time derivatives of the average components of the magnetic moments of individual

spins, but one considers it as a (small) subset of the much larger set of equations of motion (95) for all coherences in the spin system. With this viewpoint, the equations are linear, but the number of equations and (real) unknowns has grown to $4^N - 1$. In the approximations appropriate for liquid NMR, all relevant multiple spin coherences remain factorized in the corresponding single spin coherences. Hence, if one should choose to describe the spin state in terms of single spin coherences only, the multiple spin coherences would be expressed as products of single spin coherences, and this would introduce the non-linearities which are directly visible in the classical procedure. The Warren procedure takes the other tack, and starts from an initial situation (at time t_{ini}) for which all coherences are known: immediately after a hard rf pulse applied to the thermal equilibrium situation (for instance, equation (98)), or after some tractable evolution after which all coherences are still known. The next step is to express the observable quantities like $\langle I_{q+}(t) \rangle$ as a series expansion in powers of the delay $t - t_{\text{ini}}$,

$$\langle I_{q+}(t) \rangle = \langle I_{q+}(t_{\text{ini}}) \rangle + \sum_{v=1}^{\infty} \frac{1}{v!} (t - t_{\text{ini}})^v \frac{\partial^v}{\partial t^v} \langle I_{q+}(t) \rangle \Big|_{t=t_{\text{ini}}}$$

where

$$\frac{\partial^v}{\partial t^v} \langle I_{q+}(t) \rangle \Big|_{t=t_{\text{ini}}} = \text{Tr}_S \left\{ \left(\hat{I}_{q+} \right)^\dagger \left[\overbrace{\hat{K}_S, \dots, \hat{K}_S}^v, \hat{\rho}_S(t_{\text{ini}}) \right] \dots \right\}$$

and

$$\hat{K}_S = \sum_{j=1}^N \hbar \delta \omega_j \hat{I}_{jZ} + \hat{H}_S^{\text{dip sec}} \quad (105)$$

The ‘Warren’ procedure is particularly useful in the frequent case of weak dipolar field effects, for which $\mathcal{J}$ is a small parameter, because the initial coherences involving n spins are proportional to $\mathcal{J}^n$ and decrease rapidly for increasing n . The analogy with the usual discussion of *intramolecular* q -quantum coherences in terms of product operators indicates that the observed effects of order q in multiple spin echoes, CRAZED experiments, COSY spectra, ..., arise from the evolution of intermolecular q -quantum coherences during the delay τ_1 between the two rf pulses. Hence, when these effects are small, they arise essentially from q -quantum coherences involving the smallest possible number of spins (which is also $|q|$, except when $q = 0$). These $|q|$ -spins, q -quantum coherences are transformed by the second rf pulse into combinations of various $|q|$ -spins coherences, of which only $|q|$ -spins, 1-quantum coherences contribute to the time derivative of order $|q|$ after $|q|$ commutations with $\hat{H}_S^{\text{dip sec}}$. A wide choice of detailed calculations of this type can be found in publications of the Warren group²¹ and others.⁶⁶ For strong dipolar field effects, many more coherences have to be taken into account and the Warren procedure becomes extremely clumsy, unfortunately.

Most quantitative predictions of dipolar field effects are strongly dependent upon relaxation, and relaxation is not a built-in feature of the original ‘Warren’ procedure, so that it has to be introduced ‘by hand’ as an afterthought. This is easily justified by using the equivalence with the classical procedure

which automatically includes relaxation.⁶⁹ Molecular diffusion is much more difficult to handle, and no reliable method has been proposed yet for its incorporation in the Warren procedure.

6 SPECTRAL CLUSTERING AND DYNAMIC INSTABILITY

For obvious reasons of simplicity and efficiency, many NMR experiments are planned and modeled with homogeneous fields, homogeneous distributions of nuclear magnetization (and a sample shape leading to a homogeneous dipolar field). In experiments using field gradients (usually pulsed), homogeneous distributions of magnetization and dipolar field are replaced by multiple turn helical and grating-like distributions with direction and pitch under the direct control of the experimenter. The calculations show that such *perfectly* regular situations remain perfectly regular in the presence of dipolar field effects.

In this section, we shall discuss two types of unexpected consequences of small deviations from these 'well controlled' distributions, both due to the dynamical effects of the rotating component of the dipolar field:¹³ spectral clustering and dynamical instabilities.

6.1 Spectral Clustering

Spectral clustering was first observed in cryogenic experiments, which offer the favorable combination of slow relaxation and large dipolar fields due to large nuclear polarizations. Particularly clear results were obtained by the Nacher group on dilute solutions of hyperpolarized ³He in ⁴He at lattice temperatures of the order of 0.2 K,^{74–76} and later on hyperpolarized liquid ¹²⁹Xe.⁷⁷ In these experiments, the sample is contained in a capillary tube in the shape of a U, with a constant external magnetic field parallel to the straight arms of the U. With this geometry, the 'equilibrium' dipolar field varies continuously from $+2B_d$ in the vertical arms to $-B_d$ at the bottom of the U; hence one naively expects an absorption spectrum (i.e., the Fourier transform of the response to a small pulse of transverse magnetic field) with the corresponding continuous shape, resembling a powder pattern in solids. What is actually observed is a set of very sharp and well separated lines in a pattern for which the naive expectation looks like an envelope. As shown by the Nacher group, this set of sharp lines, which they associate with the 'magnetic modes' of the sample, is predicted whenever one takes into account the dipolar couplings between the slices along the capillary. Semi-quantitative agreement is even obtained with such a simplistic model as a regular necklace of 48 equal classical spins, in the shape of a U or a circle, with dipolar couplings between first neighbors or between all spins.

Figure 21 shows the result of a numerical simulation of spectral clustering under circumstances more familiar in high-resolution NMR: a compact sample and a small B_0 inhomogeneity. If the nuclei on which a small rf pulse is applied generate a small dipolar field (e.g., dilute nuclei), the Fourier transform of the fid will faithfully show the overall inhomogeneity over the sample, and this may serve as indicator for further shimming. In contradistinction, for abundant nuclei generating maximum dipolar field shifts comparable to the

Figure 21 The usual expectation is that a B_0 inhomogeneity causes a corresponding line broadening (top spectrum). Spectral clustering is the process by which, for small pulses, this broadening is suppressed by the dynamic effect of the dipolar field (bottom spectra). The figure shows the absorption component of the Fourier transform of the response to a very small rf pulse, as a function of frequency, for a 'single NMR line'. The spectra are marked by the ratio $\omega_d/\omega_{\text{inhom width}}$, where $\omega_d = \gamma\mu_0 M^{\text{eq}}$ is the typical maximum dipolar field shift and $\omega_{\text{inhom width}}$ is the line width due to the external field inhomogeneity. The large tick is at the same frequency in all seven spectra. For this numerical simulation, the B_0 field inhomogeneity is a $\wedge\wedge\wedge$ -function of the Z-coordinate and the overall shape of the sample is spherical. Eight layers of spins are present over each region of increase or decrease of the external field (changing this number to 16 or 32 does not significantly alter the result), the width of individual lines is artificial. Relaxation and radiation damping have been ignored

inhomogeneity over the sample, the response to a small pulse is dominated by a single sharp line and does not clearly reflect the inhomogeneity any more. This should not be mistaken for an actual elimination or compensation of the inhomogeneity, it is a dynamic mechanism acting only on the strong (usually solvent) line and not on the weak (usually interesting) lines from dilute molecules in the same sample.

In the numerical simulations, the situation shown by Figure 21 persists for tipping angles up to about 0.2 radian; for larger tipping angles and ratios $|\omega_d/\omega_{\text{inhom width}}|$ above 1 or 2, the 'spectra' become broad and complex, and dynamic instabilities set in for tipping angles larger than about 0.7 radian. The corresponding effects have been observed in cryogenic experiments,⁷⁷ but the lack of satisfactory equipment for the elimination of radiation damping has prevented clear observations under ordinary NMR conditions (as far as I know).

6.2 Dynamic Instabilities Caused by the Dipolar Field

Even in the best spectrometer, the regular 'well controlled' distributions of magnetization which are the aim of the experimenter and the starting point of standard NMR predictions, are approximations which ignore such 'imperfections' as edge effects, minor field inhomogeneities, equilibrium fluctuations, etc. Common sense suggests that, if the imperfections are small, their overall influence on the experimental outcomes will also be small. Fortunately, this is what happens whenever collective effects are negligible. However, the dipolar field mediates interactions between the bulk nuclear magnetizations at different places in the sample, and this raises the question of the fate of (even small) deviations from the perfectly regular

distribution of magnetization. In the case of a helical distribution of magnetization, for which the fid signal is ideally zero, a similar question arises about the effects of radiation damping; this part of the discussion will be deferred to Section 6.3.

In general, after a small pulse applied to the equilibrium situation, the very small deviations just oscillate as a function of time, hence they are harmless. On the contrary, after a large pulse (typically between about $\pi/4$ and $3\pi/4$), some of the deviations grow exponentially with time, with characteristic doubling delay as short as $1/\omega_d$. Such instabilities rapidly cause major spin turbulence and an irrecoverable loss of NMR signal.

We shall now discuss a slightly extended version of an example presented in Ref.¹³, in which the issue of stability is easy to treat analytically. In this model, all spins are equivalent, all external fields are homogeneous, radiation damping is ignored, and the shape of the sample is such that a homogeneous magnetization $\mathbf{M}_{av}(t)$ generates a dipolar field $\mathbf{B}_{d,av}(t)$ which is also homogeneous inside the sample. After removal of the counter-rotating parts, the relevant part of this dipolar field is given by [see equations (34) to (36)]

$$\mathbf{B}_{d,av}^{no\ crp}(t) = -\frac{\mu_0}{3} \left[\frac{3(\cos \theta_s)^2 - 1}{2} \right] [3M_{avZ}(t)\mathbf{1}_Z - \mathbf{M}_{av}(t)] \quad (106)$$

where θ_s is the angle between Z and the normal to the plane for a flat sample, and suitably chosen values of θ_s can simulate other shapes and orientations (for instance $\theta_s = \arccos(1/\sqrt{3})$ simulates a sphere). The deviations from $\mathbf{M}_{av}(t)$ will be described as a superposition of plane wave distributions of magnetization of the type $\mathbf{m}_q(t)e^{iq \cdot \mathbf{r}}$. If the distribution of magnetization $\mathbf{m}_q(t)e^{iq \cdot \mathbf{r}}$ should extend over all space, it would generate a dipolar field with a relevant part given by

$$\mathbf{B}_{d,q}^{no\ crp}(\mathbf{r}, t) = -\frac{\mu_0}{3} \left[\frac{3(\cos \theta_q)^2 - 1}{2} \right] e^{iq \cdot \mathbf{r}} [3m_{qZ}(t)\mathbf{1}_Z - \mathbf{m}_q(t)] \quad (107)$$

For large vectors $\mathbf{q}$, for which the spatial wavelength $2\pi/|q|$ is much shorter than the smaller axis of the sample, equation (107) remains a good approximation for the positions $\mathbf{r}$ inside the sample at distances from the surface (much) larger than $2\pi/|q|$. We shall limit the discussion to such large vectors $\mathbf{q}$, and neglect the surface layer.

If the magnetization is exactly homogeneous, the equation of motion, written in the frame of coordinates rotating at the angular velocity $-\gamma\mathbf{B}_0$ is

$$\begin{aligned} \left(\frac{d}{dt} \right)_{\text{rot}} \mathbf{M}_{av}(t) &= \mathbf{M}_{av}(t) \times \gamma \mathbf{B}_{d,av}^{no\ crp}(t) \\ &= \mathbf{M}_{av}(t) \times (-\omega_{d,av}) \end{aligned}$$

where

$$\omega_{d,av} = \frac{\gamma\mu_0}{3} \left[\frac{3(\cos \theta_s)^2 - 1}{2} \right] 3M_{avZ}(t)\mathbf{1}_Z \quad (108)$$

This describes an additional (slow) rotation, also around Z , due to the dipolar field generated by the average magnetization $\mathbf{M}_{av}(t)$. If relaxation is neglected, $\omega_{d,av}$ is constant.

We can now express the total magnetization $\mathbf{M}(\mathbf{r}, t)$ as a spatial Fourier series (perhaps with periodic boundary conditions over a parallelepiped surrounding the sample),

$$\mathbf{M}(\mathbf{r}, t) = \mathbf{M}_{av}(t) + \sum_{\mathbf{q} \neq 0} \mathbf{m}_q(t) e^{iq \cdot \mathbf{r}} \quad (109)$$

where $\mathbf{m}_q(t) = (\mathbf{m}_{-q}(t))^*$ to satisfy the reality condition for $\mathbf{M}(\mathbf{r}, t)$. The equation of motion for $\mathbf{M}(\mathbf{r}, t)$ is

$$\begin{aligned} \left(\frac{d}{dt} \right)_{\text{rot}} \mathbf{M}(\mathbf{r}, t) &= \mathbf{M}(\mathbf{r}, t) \times \left\{ \mathbf{B}_{d,av}^{no\ crp}(t) + \sum_{\mathbf{q} \neq 0} \mathbf{B}_{d,q}^{no\ crp}(\mathbf{r}, t) \right\} \\ &\quad - \sum_{\mathbf{q} \neq 0} Dq^2 \mathbf{m}_q(t) e^{iq \cdot \mathbf{r}} \end{aligned} \quad (110)$$

where D is the coefficient of molecular diffusion, and relaxation has been ignored. As a first step in the discussion of linear stability, equations (106), (107), and (109) are substituted in equation (110) and only the terms of order 0 and 1 in the small quantities $\mathbf{m}_q(t)$ are retained. The terms of order 0 just reproduce equation (108). It is worth noting that this is no longer true when one retains the terms of order 2 in the small quantities, which provide the mechanism by which large irregularities strongly attenuate the observed fid. The only position dependences left in the terms of order 1 are then a single factor $e^{iq \cdot \mathbf{r}}$ in the summation over $\mathbf{q}$ in the left-hand side, and a single term $e^{iq' \cdot \mathbf{r}}$ in the summations over $\mathbf{q}'$ in the right-hand side; hence, a single equality results for each separate wave vector $\mathbf{q}$,

$$\begin{aligned} \left(\frac{d}{dt} \right)_{\text{rot}} \mathbf{m}_q(t) &= \mathbf{m}_q(t) \times \left(\frac{-\gamma\mu_0}{3} \right) \alpha_s 3M_{avZ}(t)\mathbf{1}_Z \\ &\quad + \mathbf{M}_{av}(t) \times \left(\frac{-\gamma\mu_0}{3} \right) \{ \alpha_q 3m_{qZ}(t)\mathbf{1}_Z \\ &\quad + [\alpha_s - \alpha_q] \mathbf{m}_q(t) \} - Dq^2 \mathbf{m}_q(t) \end{aligned}$$

where

$$\alpha_s = \left[\frac{3(\cos \theta_s)^2 - 1}{2} \right] \quad \text{and} \quad \alpha_q = \left[\frac{3(\cos \theta_q)^2 - 1}{2} \right] \quad (111)$$

The systematic rotation of all magnetization vectors at the 'additional' angular velocity $\omega_{d,av}$ is conveniently taken into account by using an appropriate frame of coordinates rotA rotating at the angular velocity $\omega_{d,av}$ with respect to the frame rot . Taking into account the effects of molecular diffusion, we can re-write equation (111) as

$$\begin{aligned} \left(\frac{d}{dt} \right)_{\text{rotA}} \{ \mathbf{m}_q(t) e^{Dq^2(t-t_0)} \} &= \mathbf{M}_{av}(t) \times \left(\frac{-\gamma\mu_0}{3} \right) \\ &\quad \times \{ \alpha_q 3m_{qZ}(t)\mathbf{1}_Z + [\alpha_s - \alpha_q] \mathbf{m}_q(t) \} \end{aligned} \quad (112)$$

This leads to an eigenvalue problem involving the 3-dimensional vector $\mathbf{m}_q(t)$. The solution is of the form

$$\mathbf{m}_q(t) = \sum_{g=1}^3 k_{q,g}(t_0) \tilde{\mathbf{m}}_{q,g}(t) e^{\lambda_{q,g}(t-t_0)} e^{-Dq^2(t-t_0)} \quad (113)$$

where g labels the eigenvectors, the $k_{q,g}(t_0)$ are complex constants depending upon the state at time t_0 , the eigenvectors $\tilde{\mathbf{m}}_{q,g}(t)$ are immobile in the rotating frame rotA (and normalized if convenient), and the $\lambda_{q,g}$ are the eigenvalues in the absence of diffusion. If we now substitute one of the terms of the summation of equation (113) in equation (112), we obtain a standard eigenvector problem for the Cartesian components of $\tilde{\mathbf{m}}_{q,g}$,

$$\lambda_{q,g} \tilde{\mathbf{m}}_{q,g} = \mathbf{M}_{\text{av}} \times \left(\frac{-\gamma\mu_0}{3} \right) \{ \alpha_q 3\tilde{\mathbf{m}}_{q,gZ} \mathbf{1}_Z + [\alpha_s - \alpha_q] \tilde{\mathbf{m}}_{q,g} \} \quad (114)$$

If we choose X and Y coordinates such that $\mathbf{M}_{\text{av}}$ is in the XZ -plane, the eigenvectors of equation (114) are given by

eigenvalue λ_q	eigenvector $\{\tilde{m}_{qX}, \tilde{m}_{qY}, \tilde{m}_{qZ}\}$,
0	$\left\{ -\frac{2\alpha_q + \alpha_s}{\alpha_q - \alpha_s} \frac{M_{\text{av}X}}{M_{\text{av}Z}}, 0, 1 \right\}$
$\sqrt{\Delta} \frac{\gamma\mu_0}{3}$	$\left\{ -\frac{M_{\text{av}Z}}{M_{\text{av}X}}, \frac{\sqrt{\Delta}}{(\alpha_q - \alpha_s)M_{\text{av}X}}, 1 \right\}$
$-\sqrt{\Delta} \frac{\gamma\mu_0}{3}$	$\left\{ -\frac{M_{\text{av}Z}}{M_{\text{av}X}}, \frac{-\sqrt{\Delta}}{(\alpha_q - \alpha_s)M_{\text{av}X}}, 1 \right\}$

where

$$\Delta = (\alpha_q - \alpha_s)(2\alpha_q + \alpha_s)M_{\text{av}X}^2 - (\alpha_q - \alpha_s)^2 M_{\text{av}Z}^2 \quad (115)$$

Equation (113) shows that the time evolution of the components of the actual spin magnetization $\mathbf{m}_q(t)$ is governed by eigenvalues $\lambda_{q,g} - Dq^2$, in which molecular diffusion contributes an additional damping proportional to q^2 . In a first round of discussion, we shall ignore diffusion effects. Under these conditions, the eigenvalue 0 corresponds to a constant, hence harmless, component of the small deviations from uniformity, and the general behavior of the two other components is governed by the sign of Δ . For $\Delta < 0$, these two components oscillate as a function of time, hence they are also harmless. On the contrary, for $\Delta > 0$, one of the components grows exponentially with time and will soon contribute to spin turbulence (provided that it is not damped by relaxation and diffusion). A necessary condition for $\Delta > 0$, independent of the ratio $M_{\text{av}X}/M_{\text{av}Z}$, is that $(\alpha_q - \alpha_s)(2\alpha_q + \alpha_s) > 0$. Figure 22 shows the region in which this condition holds.

An important property of the instability eigenvectors (see equation (115)) is that they have non-zero components in the transverse direction and in the Z -direction. As a result, instability creates a very complicated spatial distribution of transverse and longitudinal magnetization, and this situation persists when spin turbulence sets in.

For a spherical sample, $\alpha_s = 0$, instability is present for all orientations of $\mathbf{q}$ (except the magic angle), and equation (115) shows that this instability sets in whenever the angle between $\mathbf{M}_{\text{av}}$ and the transverse plane is smaller than the magic angle. More details about this case are given in Ref.¹³, where it is also shown that, for water at 298 K and a proton NMR frequency of 600 MHz, the maximum growth rate of instabilities is about 7.2 s^{-1} and all instabilities are suppressed by diffusion for wavelengths $2\pi/q$ shorter than about 0.11 mm.

A particular situation occurs for a flat sample perpendicular to Z (i.e., $\alpha_s = 1$), for which no instability is predicted. As soon as the sample is slightly tilted, α_s decreases below 1,

Figure 22 Stability (or not) of small magnetization inhomogeneities of wave vector $\mathbf{q}$ in a homogeneous background. The quantities α_s and α_q are defined under equation (111). When the direction of $\mathbf{q}$ varies between Z and transverse, α_q varies from 1 to $-1/2$ ($\alpha_q = 0$ for $\mathbf{q}$ at the magic angle). For flat samples, α_s similarly depends upon the orientation of the pancake; for any ellipsoidal shape, α_s is also between 1 and $-1/2$, with $\alpha_s = 0$ for a sphere. The situation is unconditionally stable in the gray region; for every point in the white region, there is a range of orientations of the average (background) magnetization $\mathbf{M}_{\text{av}}$ for which instability occurs

hence instabilities occur (over a wide range of orientations of $\mathbf{M}_{\text{av}}$ for $\mathbf{q}$ pointing close to Z , and only for $\mathbf{M}_{\text{av}}$ close to the transverse plane for $\mathbf{q}$ close to the transverse plane). For such a slight tilt, the predicted rates of growth of the instabilities are quite small.

All the detailed analytical predictions presented here derive from equation (111), which is a linear approximation valid for small deviations from the uniform distribution $\mathbf{M}_{\text{av}}(t)$. In the present model, these small deviations have a zero total magnetization over the whole sample, hence they do not contribute to the fid signal. As a result, the dynamic instabilities give rise to directly observable effects only when they have grown enough to violate the linear approximation and cause non-linear effects. No convenient analytical methods are available to treat these non-linearities, so that one has to solve equation (110) numerically with initial conditions simulating small inhomogeneities. The numerical solutions show that (i) the fid is unaffected during an initial induction delay, while the growing inhomogeneities are still small (as expected from the analytical results), (ii) when the fastest growing inhomogeneities become comparable to the initial magnetization, the fid is abruptly affected and rapidly decays, usually after some large oscillations. Due to the difficulty of performing realistic numerical simulations, it is not yet clear which details of part (ii) of the above scenario are intrinsic properties of the non-linear spin dynamics, and which may be numerical artifacts.

Presumably, the analytical method used above for homogeneous situations can be extended to the helical distributions of magnetization created, e.g., by a pulsed field gradient applied soon after the initial rf pulse in an otherwise homogeneous case. In the mean time, numerical simulations have indicated that helical distributions behave much in the same way as their homogeneous counterparts, with the angle between the pulsed

field gradient and Z playing the role of θ_s in the homogeneous case (see equation (111)). For instance, a pulsed field gradient in the Z direction protects against instability, whereas a pulsed field gradient at the magic angle does not.⁷⁸

I have performed numerical investigations of the issue of dynamical stability on a variety of other models. The conclusion is that instability is a general feature of spin dynamics with dipolar field effects, at least when the bulk magnetization points closer to the transverse plane than to the Z direction. Exceptions (like the flat sample perpendicular to Z) are very rare (the suggestion made in Ref.¹³ that instability would be restricted to three-dimensional models was the result of looking at oversimplified cases).

6.3 Dynamic Instabilities Caused by Radiation Damping and the Dipolar Field

Recently, the Warren group¹⁴ has discovered an important new type of instability, caused by the joint action of radiation damping and the dipolar field. The example studied by these authors involves a single NMR line, homogeneous external fields (except for a pulsed field gradient), and an initial situation created from equilibrium by a hard $\pi/2$ pulse followed by a pulsed field gradient in the Z direction, chosen such as to create a magnetization helix with a large number of turns in the sample, hence a very small fid signal immediately after this preparation.

The discussion at the end of Section 6.2 indicates that this initial situation is stable (although marginally) in the presence of *only* dipolar field effects. In the presence of *only* radiation damping, this situation is also 'marginally stable' in the sense that any small (total) transverse magnetization will cause a correspondingly slow tipping of the local magnetization at every point in the sample. The outcome of this motion strongly depends upon the small (total) Z magnetization.

The new result, demonstrated by numerical simulations as well as in actual experiments, is that the simultaneous action of radiation damping and the dipolar field turns the combination of marginal stabilities described above into strong instability. Some extensions of these results are given in Ref.⁷⁸ As an example, the total transverse magnetization grows exponentially, at a rate intermediate between the characteristic rate for maximum radiation damping and that for maximum dipolar field effects. In typical experiments on water, the transverse magnetization reached a value close to 10 % of the equilibrium magnetization in less than half a second. The experiments have also shown that the results are exceedingly sensitive to details such as weak temperature gradients and delay since a magnet fill.

The Warren group notes that the new results may provide a clear explanation for the unexpected failure of a number of tempting water suppression schemes. This should give additional motivation for the spectrometer manufacturers to provide efficient and versatile instrumentation for the electronic control of radiation damping.

1 INTRODUCTION

In nuclear magnetic resonance (NMR), the magnetic interaction between the nuclear magnetic dipole moment and the magnetic field $\mathbf{B}_0$ determines the nuclear spin energy levels. Nuclear spin interactions with the chemical structures in the local environment cause small shifts of the energy levels. Brownian molecular motions cause this local structure to fluctuate and as a result cause the energy levels to be time dependent. The frequency component of energy level fluctuation at the frequency difference between two energy levels induces nuclear spin transitions between the energy levels. The rate of such transitions depends on the intensity of the nuclear spin energy at the nuclear spin transition frequency. These transitions couple the spin system to the kinetic energy of the molecular system, enabling the spin system to reach thermal equilibrium (i.e. to relax). The relaxation times are inversely proportional to the transition rates. Therefore, we can use NMR relaxation time measurements to study molecular motions in liquids.

In the case of spin- $\frac{1}{2}$ nuclei, the spin interactions include magnetic interactions of the nuclear magnetic moment with the local magnetic field. The local magnetic field depends on the distance and position relative to neighboring nuclear spins and unpaired electrons, and on the effective local fields generated by the chemical shielding due to the surrounding electrons. Nuclei of spin $> \frac{1}{2}$ have an additional interaction, the electric

interaction between the nuclear quadrupole moment and the surrounding electric charges. Both interactions depend on the length of the vector that joins the nucleus to the interacting entity and on the orientation of this interaction vector in the magnetic field $\mathbf{B}_0$. Such interactions are the mechanism by which the energy of the nuclear spins is coupled to the molecular system.

To illustrate the relationship between Brownian motion and NMR relaxation, we consider the cases of magnetic dipolar interaction between two identical spin- $\frac{1}{2}$ nuclei and of electric quadrupolar interaction of a spin 1 nucleus with an electric charge ze . In both instances, the relaxation times are given¹ by the expressions:

$$1/T_1 = H[J_1(\omega_0) + J_2(2\omega_0)] \quad (1)$$

$$1/T_2 = \frac{1}{4}H[J_0(0) + 10J_1(\omega_0) + J_2(2\omega_0)] \quad (2)$$

where T_1 is the spin-lattice relaxation time, T_2 is the transverse of spin-spin relaxation time, and ω_0 is the angular Larmor frequency. These equations apply in the motionally narrowed limit (see **Relaxation Theory: Density Matrix Formulation**) which is appropriate for liquids.

In deriving these relationships, we express the time dependencies of the nuclear spin interactions $\mathcal{H}(t)$ in terms of the interaction constants H and the time correlation functions $\langle F_h(t)F_h^*(t + \tau) \rangle$ in which the $F_h(t)$ terms are the spatial parts of the time-dependent nuclear spin interactions and the $\langle \rangle$ brackets denote ensemble average. The $J_h(\omega)$ terms are Fourier intensities (or spectral densities) of the time correlation functions at the angular frequency ω as given by

$$J_h(\omega) = \int_{-\infty}^{+\infty} \langle F_h(t)F_h^*(t + \tau) \rangle \exp(i\omega\tau) d\tau \quad (3)$$

where $i = (-1)^{\frac{1}{2}}$ and the asterisk denotes the complex conjugate. The interaction constants are $H = (9/8)\gamma^4\hbar^2$ for magnetic dipole-dipole interaction between two identical atomic nuclei and $H = (9/8)e^4Q^2z^2\hbar^2$ for the electric quadrupolar interaction. The physical quantities are: γ , the nuclear magnetogyric ratio; $\hbar$, Planck's constant divided by 2π ; e , the unit electric charge; z , the number of unit charges in the electric charge; and Q , the nuclear quadrupole moment. For both interactions, the $F_h(t)$ terms are related to the second-order spherical harmonics as given by:

$$F_0(t) = r(t)^{-3}[3\cos^2\theta(t) - 1] \quad (4a)$$

$$F_1(t) = r(t)^{-3}\{\sin\theta(t)\cos\theta(t)\exp[i\phi(t)]\} \quad (4b)$$

$$F_2(t) = r(t)^{-3}\{\sin^2\theta(t)\exp[2i\phi(t)]\} \quad (4c)$$

in which $r(t)$ is the length of the vector connecting the nucleus with the interacting unit, and $\theta(t)$ and $\phi(t)$ are the polar and azimuthal angles that describe the orientation of this vector in the laboratory rectangular coordinate system S (magnetic field $\mathbf{B}_0$ of the NMR spectrometer).

Different motions of molecules in liquids cause r , θ , and ϕ to be time dependent. We classify them as rotational and translational. The translational motions cause the molecules to move in three-dimensional space. The rotational motions cause

an axis in the molecule to change in orientation with respect to the axes of the fixed three-dimensional laboratory rectangular coordinate system. Many molecules contain chemical groups that can rotate with respect to the rest of the molecule. Methyl groups that reorient about the methyl threefold symmetry axis comprise a common example of molecular internal motion.

We commonly designate relaxation interactions as *intra-molecular* or *intermolecular*, depending on whether the entity that interacts with the nucleus is part of the same molecule. This designation is related to the above classification of molecular motions. For a completely rigid molecule (Section 3), the intramolecular relaxation results only from the time dependences of θ and ϕ because r is constant. Then, we may remove r from equations (3) and (4) absorb it into a redefined H (i.e. H'), and redefine the $F_h(t)$:

$$F_0(t) = 3 \cos^2 \theta(t) - 1 \quad (5a)$$

$$F_1(t) = \sin \theta(t) \cos \theta(t) \exp[i\phi(t)] \quad (5b)$$

$$F_2(t) = \sin^2 \theta(t) \exp[2i\phi(t)] \quad (5c)$$

For magnetic dipolar relaxation of two identical nuclei with spin- $\frac{1}{2}$, $H' = (9/8)\gamma^4 \hbar^2 r^{-6}$. For quadrupolar relaxation of a nucleus with spin 1, $H' = (9/8)e^4 Q^2 z^2 \hbar^2 r^{-6}$. Here, if all the electric charges result in a nuclear quadrupolar interaction with zero asymmetry parameter, $H' = (9/8)\pi^2 \chi^2$. The same statement applies to intragroup relaxation of nuclei in a rigid group that rotates within an otherwise rigid ellipsoid (Section 4), such as a methyl group that rotates about its threefold symmetry axis that is fixed to the ellipsoid. However, intramolecular magnetic dipolar relaxation between a nucleus of such a rotating group and a nucleus on the remainder of the ellipsoid (Section 5) is more complex. Besides θ and ϕ , r also is time dependent. For intermolecular magnetic dipolar relaxation (Section 7), r , θ , and ϕ are all time dependent. A mathematical description of the correlation function is especially complex. It depends on the translational diffusion of the molecules and on the rotational motions of the molecule. We emphasize intramolecular NMR relaxation in this article and briefly treat intermolecular relaxation in Section 7.

As the NMR relaxation times are related to the molecular motions through the correlation function and the spectral densities, we need relationships between these quantities to analyze the relaxation times of liquids in terms of molecular motions. It is customary to invoke specific models of molecular motions and formulate correlation functions from these models. There are many different models that are based on different starting points and perturbations from them. Some are based on a quantum mechanical formulation and some are treated from the viewpoint of classical mechanics. No single, tractable model that describes all liquids has been found.

2 REMARKS ON MODELS OF MOLECULAR REORIENTATION

Molecules in the gaseous state undergo vibrational and rotational motions and exist in discrete vibrational-rotation energy levels with discrete frequencies. Molecular collisions cause transitions between the energy states and broaden the energy levels. In a condensed phase, such as a liquid

or a solid, the ‘collisions’ between molecules occur much more frequently and the kinetic and potential energies of the different molecules are much more closely coupled. Consequently, we cannot calculate the correlation functions that are effective in NMR relaxation from the motions of isolated, noninteracting molecules. Rothschild² has presented a comprehensive, detailed account of the theoretical and experimental knowledge of the rotational and vibrational motions of small, nearly spherical molecules in liquids.

Many different models of molecular reorientation have been discussed. It is beyond the scope of this article to review these models in detail because the literature is extensive (see *Spin-Rotation Relaxation Theory*). One approach is to start from an assembly of freely rotating molecules, as in a dilute gas. There are different ways of introducing the effects of the surrounding molecules. One way is to have collisions that introduce sudden or instantaneous changes in molecular angular momentum. Another way is to examine the potential energy of the molecule as a function of orientation. If the potential energy is independent of orientation, the molecule experiences no torques and rotates freely. The correlation function is that for an assembly of freely rotating molecules. If the potential energy does depend on orientation, the molecule experiences torques that depend on the molecular shape and on the shape, configuration, motions (‘collisions’), and distances of the neighboring molecules. These torques quench or change the molecular rotation. The effective molecular shape could be that of a spherical top, a symmetric top, or a completely asymmetric rotor. The molecule might experience a constant torque or a torque that is significant only when the neighboring molecules attain specific configurations. In such approaches, the rotational inertia of the molecule is important in deciding the mathematical form of the correlation function.

Another approach is to assume that the environment of the molecule sets up an energy barrier that the molecule must surmount to rotate into an orientation in which its interaction energy with its neighbors is the next minimum. While in this potential well, the molecule undergoes low-amplitude rotational oscillations. A ‘large’ change in orientation occurs when a transition from one potential well to another takes place. The molecule is stationary except for occasional jumps to a different orientation. Some consider the jump to be instantaneous and others consider the jump velocity to be the rms average molecular rotational velocity obtained from kinetic energy considerations.

Clearly the rotational motion of molecules in liquids is a many-body problem and, to calculate the correlation functions, we must introduce approximate methods. We can view Brownian rotational motion as a random walk in coordinate space in which the molecular orientations are defined relative to a motionless laboratory coordinate system. Diffusion-type equations correctly describe the observed rms displacements after many random steps have taken place. The length of the step is an important parameter if solutions of diffusion-type equations are to be used to calculate the correlation functions. The average length of the step must be small compared with the correlation distance of the orientational function. Because the orientational functions undergo large changes with a one-radian change in orientation, the step must be much smaller than one radian.

The Debye theory³ is a widely used model of molecular reorientation. The molecule is assumed to be a rigid sphere that

undergoes isotropic reorientations by infinitesimal rotations caused by thermal collisions with other molecules. Because the reorientation occurs by infinitesimal rotations, isotropic rotational diffusion motion is obtained. The rotational diffusion coefficient is related through Stokes's law to the viscosity of the fluid. This approach was used by Bloembergen, Purcell, and Pound⁴ in their pioneering work on NMR relaxation.

Perrin⁵ has developed an anisotropic model of molecular reorientation. The molecule reorients like a rigid ellipsoid that undergoes rotational diffusion by infinitesimal rotations about the different ellipsoid axes at different rates. Although the diffusion approximation may not be an exact model and molecules are not completely rigid, it does provide a reasonably reliable model for many liquids. Also, use of it yields equations that are well suited for straightforward data reduction. In the following sections, we assume that molecules are rigid bodies that follow the Perrin model and that internal motion is described by rigid groups that rotate about an axis that is fixed to the rigid body. This internal rotation is independent of the ellipsoid reorientation. Some consequences of vibrations and oscillations of the otherwise rigid bodies are noted in Section 8.1.

3 CORRELATION FUNCTIONS FOR A RIGID, COMPLETELY ASYMMETRIC ELLIPSOID

In formulating the spatial orientational correlation functions of nuclei in a completely asymmetric ellipsoid, it is convenient to express the $F_h(t)$ in terms of the direction cosines l , m , and n of the nuclear interaction vector with respect to the X , Y , and Z axes, respectively, of the laboratory coordinate system S . Rotational Brownian motions cause these direction cosines to fluctuate. The coordinate system S is fixed in space with its Z axis in the direction of $\mathbf{B}_0$. Using the definitions $l = \sin \theta \cos \phi$, $m = \sin \theta \sin \phi$, and $n = \cos \theta$, the $F_h(t)$ terms, as given by equation (5) in which r is constant, are:

$$F_0(t) = 1 - 3n^2 \quad (6a)$$

$$F_1(t) = (l + im)n \quad (6b)$$

$$F_2(t) = (l + im)^2 \quad (6c)$$

To include the fluctuations of these direction cosines, we use two additional rectangular coordinate systems. The first is S_0 , a stationary reference frame, to describe the rotational motion of the ellipsoid. The other coordinate system is S' which is fixed to the ellipsoid and oriented such that the X' , Y' , and Z' axes of S' always coincide with the three major axes of the ellipsoid. We reference the direction cosines of the relaxation interaction vector in the ellipsoid directly to S' . At time t , these direction cosines are denoted by l' , m' , and n' . When there is no internal motion, the direction cosines always have these values. However, to allow for internal motion in later equations, we let l'' , m'' , and n'' be the respective direction cosines at the later time $t + \tau$.

We assume that all of the ellipsoids are equivalent. Since we are dealing with liquids, at any instant t there is a random

orientation distribution of ellipsoids. Let us choose a particular ellipsoid. We orient S_0 of this ellipsoid so that, at time t , S_0 coincides with S' and the Euler angles $(\phi_0, \theta_0, \psi_0)$ that describe the orientation of S' in S_0 are all zero. Since S_0 is stationary and S' is fixed to the ellipsoid, rotational Brownian motion of the ellipsoid causes ϕ_0 , θ_0 , and ψ_0 to become nonzero. The direction cosines of the relaxation interaction vector in S_0 at $t + \tau \geq 0$ are given by the following transformation that involves the change in the Euler angles of S' in S_0 :

$$\begin{pmatrix} l_0 \\ m_0 \\ n_0 \end{pmatrix} = \begin{pmatrix} c_{11} & c_{12} & c_{13} \\ c_{21} & c_{22} & c_{23} \\ c_{31} & c_{32} & c_{33} \end{pmatrix} \begin{pmatrix} l'' \\ m'' \\ n'' \end{pmatrix} \quad (7)$$

where

$$\left. \begin{aligned} c_{11} &= \cos \psi \cos \phi - \cos \theta \sin \phi \sin \psi \\ c_{12} &= -\sin \psi \cos \phi - \cos \theta \sin \phi \cos \psi \\ c_{13} &= \sin \theta \sin \phi \\ c_{21} &= \cos \psi \sin \phi + \cos \theta \cos \phi \sin \psi \\ c_{22} &= -\sin \psi \sin \phi + \cos \theta \cos \phi \cos \psi \\ c_{23} &= -\sin \theta \cos \phi \\ c_{31} &= \sin \theta \sin \psi \\ c_{32} &= \sin \theta \cos \psi \\ c_{33} &= \cos \theta \end{aligned} \right\} \quad (8)$$

In this definition of the transformation matrix elements, the subscript of the Euler angles has been omitted for simplicity. Finally, the direction cosines of the interaction vector in S are given by the following transformation in Euler angles (ϕ, θ, ψ) that describe the orientation of S_0 in S :

$$\begin{pmatrix} l \\ m \\ n \end{pmatrix} = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{pmatrix} \begin{pmatrix} l_0 \\ m_0 \\ n_0 \end{pmatrix} \quad (9)$$

where the definitions of the a_{ij} are analogous to those of the c_{ij} in equation (8). We use the transformations shown in equations (7) and (9) to evaluate the functions $F_h(t + \tau)$ for $\tau \geq 0$. The initial conditions imply that $c_{ij}(t) = \delta_{ij}$ (the delta function). Consequently, the initial values at time t are:

$$F_0(t) = 1 - 3(a_{31}l' + a_{32}m' + a_{33}n')^2 \quad (10a)$$

$$F_1(t) = (A_1l' + A_2m' + A_3n')(a_{31}l' + a_{32}m' + a_{33}n') \quad (10b)$$

$$F_2(t) = (A_1l' + A_2m' + A_3n')^2 \quad (10c)$$

where

$$A_1 = a_{11} + ia_{21} \quad (11a)$$

$$A_2 = a_{12} + ia_{22} \quad (11b)$$

$$A_3 = a_{13} + ia_{23} \quad (11c)$$

Because molecular orientations in a liquid are random, there is a random distribution of orientations of S_0 in S . The c_{ij} in all the S_0 are equivalent at all times $t + \tau \geq t$. The rotational Brownian motion of the ellipsoid causes the c_{ij} to be time dependent. Suppose $\Delta\alpha$, $\Delta\beta$, and $\Delta\gamma$ are the angular displacements of the ellipsoid about the X' , Y' , and Z' axes, respectively, of S' due to the Brownian motion. We assume that the elementary angular displacements are sufficiently small (see Section 8.2) so that the angular displacements during time τ are given by rotational diffusion relationships that involve rotational diffusion coefficients R_i as:

$$\langle(\Delta\alpha)^2\rangle = 2R_1\tau \quad (12a)$$

$$\langle(\Delta\beta)^2\rangle = 2R_2\tau \quad (12b)$$

$$\langle(\Delta\gamma)^2\rangle = 2R_3\tau \quad (12c)$$

and the motions are statistically independent, e.g., $\langle\Delta\alpha\Delta\beta\rangle = 0$. Internal motion within the ellipsoids, when it occurs, causes the direction cosines l'' , m'' , and n'' to be time dependent. Because we assume that the internal motion is statistically independent of the Brownian motion of the ellipsoid, we average separately over the two types of motion to obtain the final correlation functions. For each S_0 , and for a given set of intramolecular parameters, the $F_h(t)$ in the correlation function is a time independent multiplication factor and the autocorrelation function becomes:

$$\langle F_h(t)F_h^*(t+\tau) \rangle_{S_0} = F_h(t)\langle F_h^*(t+\tau) \rangle_{S_0} \quad (13)$$

In the calculation of the rotational Brownian motion parts of $\langle F_h^*(t+\tau) \rangle_{S_0}$, we find for each S_0 a sum of terms that are proportional to squares and products of the c_{ij} that appear in the transformation shown in equation (8). To calculate these terms, we use the time dependent probability density $P(\phi_0, \theta_0, \psi_0; \tau)$ for S' to be in orientation $(\phi_0, \theta_0, \psi_0)$ in S_0 at time $t + \tau$. This probability density is described⁶ by the partial differential equation:

$$\partial P(\phi_0, \theta_0, \psi_0; \tau) / \partial \tau = \Lambda P(\phi_0, \theta_0, \psi_0; \tau) \quad (14)$$

where the operator Λ is given by:

$$\begin{aligned} \Lambda = & (R_1 \cos^2 \psi_0 + R_2 \sin^2 \psi_0) \left(\frac{\partial^2}{\partial \theta_0^2} \right) \\ & + (R_1 \sin^2 \psi_0 + R_2 \cos^2 \psi_0) \left(\cot \theta_0 \frac{\partial}{\partial \theta_0} + \frac{1}{\sin^2 \theta_0} \frac{\partial^2}{\partial \phi_0^2} \right. \\ & \left. + \cot^2 \theta_0 \frac{\partial^2}{\partial \psi_0^2} - \frac{2 \cot \theta_0}{\sin \theta_0} \frac{\partial^2}{\partial \phi_0 \partial \psi_0} \right) \quad (15) \\ & + 2(R_1 - R_2) \frac{\cos \psi_0 \sin \psi_0}{\sin \theta_0} \left(\frac{\partial^2}{\partial \theta_0 \partial \phi_0} - \cos \phi_0 \frac{\partial^2}{\partial \theta_0 \partial \psi_0} \right) \\ & + \frac{1 + \cos^2 \theta_0}{2 \sin \theta_0} \frac{\partial}{\partial \psi_0} - \cot \theta_0 \frac{\partial}{\partial \phi_0} \Big) \\ & + R_3 \frac{\partial^2}{\partial \psi_0^2} \end{aligned}$$

The properties of Λ are such that the time differential $\langle f \rangle$, the average value of any function f of the orientation of the ellipsoid, is given by the relationship

$$d\langle f \rangle / d\tau = \langle \Lambda f \rangle \quad (16)$$

The application of equation (15) yields:

$$\Lambda(c_{jj}c_{kk} + c_{jk}c_{kj}) = -(4R_i + R_j + R_k)(c_{jj}c_{kk} + c_{jk}c_{kj}) \quad (17)$$

$$\Lambda c_{ri}^2 = -2(R_j + R_k)c_{ri}^2 + 2R_j c_{rk}^2 + 2R_k c_{rj}^2 \quad (18)$$

where the indices i , j , and k are all different. With the condition $c_{ij} = \delta_{ij}$ (i.e. the delta function) when $\tau = 0$, the application of equations (16) yields the average values:

$$\langle c_{jj}c_{kk} + c_{jk}c_{kj} \rangle = \exp[-(4R_i + R_j + R_k)\tau] \quad (19)$$

The application of equations (16) and (18) in deriving the average values of the c_{ri}^2 yields three first-order linear differential equations that are related because $\sum_i c_{ri}^2 = 1$. The average values are:

$$\langle c_{ii}^2 \rangle = \left(\frac{1}{3}\right) + \left(\frac{1}{6}\right)(2 + \delta_i) \exp(-\tau/\tau_-) + \left(\frac{1}{6}\right)(2 - \delta_i) \exp(-\tau/\tau_+) \quad (20)$$

$$\langle c_{jk}^2 \rangle = \left(\frac{1}{3}\right) - \left(\frac{1}{6}\right)(1 - \delta_i) \exp(-\tau/\tau_-) - \left(\frac{1}{6}\right)(1 + \delta_i) \exp(-\tau/\tau_+) \quad (21)$$

where

$$\delta_i = (R_i - R)/(R^2 - L^2)^{1/2} \quad (22)$$

$$1/\tau_{\pm} = 6[R \pm (R^2 - L^2)^{1/2}] \quad (23)$$

in which

$$R = \left(\frac{1}{3}\right)(R_1 + R_2 + R_3) \quad (24)$$

$$L^2 = \left(\frac{1}{3}\right)(R_1 R_2 + R_1 R_3 + R_2 R_3) \quad (25)$$

The final result, after averaging over all S_0 , is⁷

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle = & \left(\frac{1}{2}\right)K_h \langle C_+ \exp(-|\tau|/\tau_+) + C_- \exp(-|\tau|/\tau_-) \\ & + C_1 \exp(-|\tau|/\tau_1) + C_2 \exp(-|\tau|/\tau_2) \\ & + C_3 \exp(-|\tau|/\tau_3) \rangle_{av} \end{aligned} \quad (26)$$

in which

$$K_0 = \frac{4}{5} \quad (27a)$$

$$K_1 = \frac{2}{1} \quad (27b)$$

$$K_2 = \frac{8}{15} \quad (27c)$$

$$C_B = C_1 + C_2 = 6n'n''(m'm'' + l'l'') \quad (33b)$$

$$1/\tau_1 = 4R_1 + R_2 + R_3 \quad (28a)$$

$$C_C = C_- + C_3 = \left(\frac{3}{2}\right)(l'^2 - m'^2)(l''^2 - m''^2) + 6l'l''m'm'' \quad (33c)$$

$$1/\tau_2 = 4R_2 + R_1 + R_3 \quad (28b)$$

$$1/\tau_3 = 4R_3 + R_1 + R_2 \quad (28c)$$

The operation $\langle \cdots \rangle_{av}$ on the right-hand side of equations (26) and (31) signifies the final average over molecular internal motions that introduce additional time dependencies into the correlation function. If there are no internal motions and the ellipsoid is rigid, this final averaging procedure is unnecessary. In this case, l'', m'', n'' are equal to l', m', n' , respectively.

The correlation functions for a rigid, completely asymmetric ellipsoid are then

$$C_+ = d - e \quad (29a)$$

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle = & \left(\frac{1}{2}\right)K_h[C_+ \exp(-|\tau|/\tau_+) + C_- \exp(-|\tau|/\tau_-) \\ & + C_1 \exp(-|\tau|/\tau_1) + C_2 \exp(-|\tau|/\tau_2) \\ & + C_3 \exp(-|\tau|/\tau_3)] \end{aligned} \quad (34)$$

$$C_- = d + e \quad (29b)$$

$$C_1 = 6m'n'm''n'' \quad (29c)$$

It is useful to note that $C_+ + C_- + C_1 + C_2 + C_3 = 2$. For a sphere, $R_1 = R_2 = R_3 = R_s$, where R_s is the rotational diffusion constant for the sphere and all of the correlation times are equal to the well-known result $\tau_c = 1/6R_s$.

Similarly, the correlation functions for a rigid, axially symmetric ellipsoid are

$$C_2 = 6l'n'l''n'' \quad (29d)$$

$$C_3 = 6l'm'l''m'' \quad (29e)$$

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle = & \left(\frac{1}{2}\right)K_h[C_A \exp(-|\tau|/\tau_A) \\ & + C_B \exp(-|\tau|/\tau_B) + C_C \exp(-|\tau|/\tau_C)] \end{aligned} \quad (35)$$

in which

$$d = \left(\frac{1}{2}\right)[3(l'^2l''^2 + m'^2m''^2 + n'^2n''^2) - 1] \quad (30a)$$

$$\begin{aligned} e = & \left(\frac{1}{2}\right)[\delta_1(l'^2l''^2 + m'^2m''^2 + n'^2m''^2) \\ & + \delta_2(m'^2m''^2 + l'^2n''^2 + n'^2l''^2) \\ & + \delta_3(n'^2n''^2 + l'^2m''^2 + m'^2l''^2)] \end{aligned} \quad (30b)$$

In this case, the C_i simplify to:

$$C_A = \left(\frac{1}{2}\right)(1 - 3n'^2)^2 \quad (36a)$$

$$C_B = 6n'^2(1 - n'^2) \quad (36b)$$

$$C_C = \left(\frac{3}{2}\right)(1 - n'^2)^2 \quad (36c)$$

Frequently, the shape of a molecule approximates an axially symmetric ellipsoid. In this case, given by $R_1 = R_2$, the correlation function in equation (26) is simplified to

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle = & \left(\frac{1}{2}\right)K_h[C_A \exp(-|\tau|/\tau_A) \\ & + C_B \exp(-|\tau|/\tau_B) + C_C \exp(-|\tau|/\tau_C)]_{av} \end{aligned} \quad (31)$$

where

$$1/\tau_A = 6R_2 \quad (32a)$$

$$1/\tau_B = 5R_2 + R_3 \quad (32b)$$

$$1/\tau_C = 2R_2 + 4R_3 \quad (32c)$$

$$C_A = C_+ = \left(\frac{1}{2}\right)(1 - 3n'^2)(1 - 3n''^2) \quad (33a)$$

Note that the correlation functions are independent of l' and m' . The $J_h(\omega)$ depend only on the angle between the nuclear interaction vector and the motional symmetry axis.

The rotational correlation function is a sum of five (or three) simple exponential decay functions. This functional form is a consequence of the assumption of rotational diffusion that involves only infinitesimally small rotational steps.

4 CORRELATION FUNCTIONS FOR AXIALLY SYMMETRIC ELLIPSOIDS WITH INTERNAL MOTION

When the nuclear interaction vector reorients independently inside the ellipsoid, the direction cosines l' , m' , and n' of the interaction vector with respect to the rectangular coordinate system S' of the ellipsoid are time dependent and time dependent averaging on the right-hand side of equation (31)

must be performed to obtain the correlation functions. Because the internal rotational motion is independent of the rotational motions of the ellipsoid, we must evaluate the separate correlation functions (i.e. the C_i) in equation (33). To do this, it is convenient to express the internal motion in terms of spherical polar coordinates in S' . The relaxation vector rotates about the z' axis with a constant polar angle Δ and a time dependent azimuthal angle $\phi'(t)$. In the case of a methyl group, the z' axis is the threefold symmetry axis. The z' axis makes a constant angle α with the Z' symmetry axis of the ellipsoid. In the coordinate system of the ellipsoid,

$$C_A = \left(\frac{1}{2}\right)[1 - 3\cos^2\theta(t)][1 - 3\cos^2\theta(t + \tau)] \quad (37a)$$

$$C_B = \left(\frac{3}{2}\right)\langle \sin 2\theta(t) \exp[i\phi(t)] \sin 2\theta(t + \tau) \times \exp[-i\phi(t + \tau)] \rangle \quad (37b)$$

$$C_C = \left(\frac{3}{2}\right)\langle \sin^2\theta(t) \exp[2i\phi(t)] \sin^2\theta(t + \tau) \times \exp[-2i\phi(t + \tau)] \rangle \quad (37c)$$

where $\theta(t)$ and $\phi(t)$ are the time dependent polar and azimuthal angles of the interaction vector in S' .

The quantities in brackets are products of spherical harmonics; the C_i can be expressed in terms of the constant angles α and Δ and of the time dependent angle $\phi'(t)$ by using the transformation formulas for spherical harmonics. The result of setting $\phi''(\tau) = \phi'(t + \tau) - \phi'(t)$ and averaging over the random distribution at time t is⁸

$$C_A = C_{A1} + C_{A2}\langle \cos \phi''(\tau) \rangle + C_{A3}\langle \cos 2\phi''(\tau) \rangle \quad (38a)$$

$$C_{A1} = \left(\frac{1}{8}\right)(1 - 3\cos^2\alpha)^2(1 - 3\cos^2\Delta)^2 \quad (38b)$$

$$C_{A2} = \left(\frac{9}{16}\right)\sin^2 2\alpha \sin^2 2\Delta \quad (38c)$$

$$C_{A3} = \left(\frac{9}{16}\right)\sin^4 \Delta \sin^4 \alpha \quad (38d)$$

$$C_B = C_{B1} + C_{B2}\langle \cos \phi''(\tau) \rangle + C_{B3}\langle \cos 2\phi''(\tau) \rangle \quad (39a)$$

$$C_{B1} = \left(\frac{3}{8}\right)\sin^2 2\alpha(3\cos^2\Delta - 1)^2 \quad (39b)$$

$$C_{B2} = \left(\frac{3}{4}\right)(\cos^2 2\alpha + \cos^2 \alpha)\sin^2 2\Delta \quad (39c)$$

$$C_{B3} = \left(\frac{3}{4}\right)[\sin^2 \alpha + \left(\frac{1}{4}\right)\sin^2 2\alpha]\sin^4 \Delta \quad (39d)$$

$$C_C = C_{C1} + C_{C2}\langle \cos \phi''(\tau) \rangle + C_{C3}\langle \cos 2\phi''(\tau) \rangle \quad (40a)$$

$$C_{C1} = \left(\frac{3}{8}\right)\sin^4 \alpha(3\cos^2\Delta - 1)^2 \quad (40b)$$

$$C_{C2} = \left(\frac{3}{4}\right)[\sin^2 \alpha + \left(\frac{1}{4}\right)\sin^2 2\alpha]\sin^2 2\Delta \quad (40c)$$

$$C_{C3} = \left(\frac{3}{16}\right)[(1 + \cos^2 \alpha)^2 + 4\cos^2 \alpha]\sin^4 \Delta \quad (40d)$$

Each of the three coefficients C_A , C_B , and C_C consists of a time-independent term (subscripted 1) and two terms that are time dependent because of the internal motion.

The internal motion determines the time dependence of $\phi''(\tau)$. One model for the time dependence is that of a terminal methyl group in an n -paraffin molecule in the s -*trans* configuration. Because there are three equivalent positions of the methyl group, the allowed values of $\phi''(\tau)$ are 0° , 120° , and 240° . Here, the internal motion occurs by random jumping of the methyl group from any of these equivalent positions to either of the two adjacent positions at an average rate of $(3\tau_{ci})^{-1}$. With this type of motion,⁹ we have

$$\langle \cos \phi''(\tau) \rangle = \langle \cos 2\phi''(\tau) \rangle = \exp(-|\tau|/\tau_{ci}) \quad (41)$$

so that

$$C_A = C_{A1} + (C_{A2} + C_{A3})\exp(-|\tau|/\tau_{ci}) \quad (42a)$$

$$C_B = C_{B1} + (C_{B2} + C_{B3})\exp(-|\tau|/\tau_{ci}) \quad (42b)$$

$$C_C = C_{C1} + (C_{C2} + C_{C3})\exp(-|\tau|/\tau_{ci}) \quad (42c)$$

As a result of this type of internal motion, the correlation function contains the three additional correlation times

$$1/\tau_{A23} = 6R_2 + 1/\tau_{ci} \quad (43a)$$

$$1/\tau_{B23} = 5R_2 + R_3 + 1/\tau_{ci} \quad (43b)$$

$$1/\tau_{C23} = 2R_2 + 4R_3 + 1/\tau_{ci} \quad (43c)$$

Another model of internal motion is a stochastic diffusion process among a very large number of equilibrium positions that are uniformly distributed from $\phi' = 0$ to 2π such that $\langle \phi''^2 \rangle = 2R_i\tau$, where R_i is the internal rotational diffusion coefficient. With this model⁹ of internal motion,

$$\langle \cos \phi''(\tau) \rangle = \exp(-R_i|\tau|) \quad (44a)$$

$$\langle \cos 2\phi''(\tau) \rangle = \exp(-4R_i|\tau|) \quad (44b)$$

so that

$$C_A = C_{A1} + C_{A2}\exp(-R_i|\tau|) + C_{A3}\exp(-4R_i|\tau|) \quad (45a)$$

$$C_B = C_{B1} + C_{B2}\exp(-R_i|\tau|) + C_{B3}\exp(-4R_i|\tau|) \quad (45b)$$

$$C_C = C_{C1} + C_{C2}\exp(-R_i|\tau|) + C_{C3}\exp(-4R_i|\tau|) \quad (45c)$$

giving the six new correlation times

$$1/\tau_{A2} = 6R_2 + R_i \quad (46a)$$

$$1/\tau_{A3} = 6R_2 + 4R_i \quad (46b)$$

$$1/\tau_{B2} = 5R_2 + R_3 + R_i \quad (46c)$$

$$1/\tau_{B3} = 5R_2 + R_3 + 4R_i \quad (46d)$$

$$1/\tau_{C2} = 2R_2 + 4R_3 + R_i \quad (46e)$$

$$1/\tau_{C3} = 2R_2 + 4R_3 + 4R_i \quad (46f)$$

Frequently, the internal rotation axis lies along the symmetry axis of the ellipsoid so that $\alpha = 0$ in equations (38)–(40). Consequently, the value of many of these equations is zero and the correlation function is⁷

$$\langle F_h(t)F_h^*(t + \tau) \rangle = \left(\frac{1}{2}\right)K_h[A \exp(-|\tau|/\tau'_A) + B \exp(-|\tau|/\tau'_B) + C \exp(-|\tau|/\tau'_C)] \quad (47)$$

in which

$$A = \left(\frac{1}{2}\right)(1 - 3 \cos^2 \Delta)^2 \quad (48a)$$

$$B = \left(\frac{3}{2}\right) \sin^2 2\Delta \quad (48b)$$

$$C = \left(\frac{3}{2}\right) \sin^4 \Delta \quad (48c)$$

For the internal jump model,

$$1/\tau'_A = 1/\tau_A = 6R_2 \quad (49a)$$

$$1/\tau'_B = 5R_2 + R_3 + \tau_{ci} \quad (49b)$$

$$1/\tau'_C = 2R_2 + 4R_3 + \tau_{ci} \quad (49c)$$

For the internal rotational diffusion model,

$$1/\tau'_A = 1/\tau_A = 6R_2 \quad (50a)$$

$$1/\tau'_B = 5R_2 + R_3 + R_i \quad (50b)$$

$$1/\tau'_C = 2R_2 + 4R_3 + 4R_i \quad (50c)$$

Generally, the correlation function of a nonspherical molecule that reorients at different rates about different molecular axes depends on many external and internal molecular motions. We can use NMR relaxation time measurements on nuclei that have different nuclear interaction vector orientations in the molecule to give information on the internal and external molecular motions.

5 CORRELATION FUNCTIONS FOR INTERGROUP MAGNETIC DIPOLAR RELAXATION WITH INTERNAL MOTION

In intramolecular magnetic dipolar relaxation between a nucleus of a rotating group and a nucleus on the remainder of the molecule, the length as well as the orientation of the nuclear interaction vector is time dependent. Consequently, we use the $F_h(t)$ as defined in equation (4). To restrict the calculation of the correlation function to simple but useful cases, we assume the following geometry.¹⁰ The two nuclei rotate in parallel planes about the same perpendicular axis. The planes are separated by the distance b and the radii of rotation are a and c . This geometry describes the magnetic dipolar interaction between protons in different methyl groups in ethane, protons on neighboring carbon atoms in n -paraffins, methyl and ring protons in toluene, fluorine nuclei and protons in benzotrifluoride, etc.

Let us assume that the molecule is an axially symmetric ellipsoid and that the internal rotation axis is parallel to the ellipsoid symmetry axis. Because the internal motion causes simultaneous changes in the orientation and length of the internuclear vector, the correlation function is an extension of equations (31)–(33) to include a time dependent r .

$$\langle F_h(t)F_h^*(t + \tau) \rangle = \left(\frac{1}{2}\right)K_h \langle C_{Ar} \exp(-|\tau|/\tau_A) + C_{Br}(-|\tau|/\tau_B) + C_{Cr} \exp(-|\tau|/\tau_C) \rangle_{av} \quad (51)$$

where

$$1/\tau_A = 6R_2 \quad (52a)$$

$$1/\tau_B = 5R_2 + R_3 \quad (52b)$$

$$1/\tau_C = 2R_2 + 4R_3 \quad (52c)$$

$$C_{Ar} = \left(\frac{1}{2}\right)(1 - 3n'^2)(1 - 3n''^2)r'^{-3}r''^{-3} \quad (53a)$$

$$C_{Br} = 6n'n''(m'm'' + l'l'')r'^{-3}r''^{-3} \quad (53b)$$

$$C_{Cr} = \left[\left(\frac{3}{2}\right)(l'^2 - m'^2)(l''^2 - m''^2) + 6l'l''m'm''\right]r'^{-3}r''^{-3} \quad (53c)$$

The operation $\langle \dots \rangle_{av}$ on the right-hand side of equation (51) signifies the final average over the internal motions. These motions are statistically independent from the rotational motions of the ellipsoid. The values at time t are l' , m' , n' , and r' , and those at the later time $t + \tau$ are l'' , m'' , n'' , and r'' .

r'' . In terms of the geometry of the problem, the C quantities are:

$$C_{Ar} = \left(\frac{1}{2}\right)r'^{-5}r''^{-5}\{(a^2 + c^2 - 2b^2)^2 - 2(a^3c + ac^3 - 2ab^2c) \\ \times [\cos(\phi'_1 - \phi'_2) + \cos(\phi''_1 - \phi''_2)] \\ + 4a^2c^2 \cos(\phi'_1 - \phi'_2) \cos(\phi''_1 - \phi''_2)\} \quad (54a)$$

$$C_{Br} = 6r'^{-5}r''^{-5}b^2\{c^2 \cos(\phi'_1 - \phi''_1) + a^2 \cos(\phi'_2 - \phi''_2) \\ - ac[\cos(\phi'_1 - \phi''_2) + \cos(\phi'_2 - \phi''_1)]\} \quad (54b)$$

$$C_{Cr} = \left(\frac{3}{2}\right)r'^{-5}r''^{-5}\{c^4 \cos(2\phi'_1 - 2\phi''_1) + a^4 \cos(2\phi'_2 - 2\phi''_2) \\ + 4a^2c^2 \cos(\phi'_1 + \phi'_2 - \phi''_1 - \phi''_2) \\ + a^2c^2[\cos(2\phi'_1 - 2\phi''_2) + \cos(2\phi'_2 - 2\phi''_1)] \\ - 2ac^3[\cos(2\phi'_1 - \phi''_1 - \phi''_2) + \cos(\phi'_1 + \phi'_2 - 2\phi''_1)] \\ - 2a^3c[\cos(2\phi'_2 - \phi''_1 - \phi''_2) + \cos(\phi'_1 + \phi'_2 - 2\phi''_2)]\} \quad (54c)$$

in which ϕ'_1 and ϕ'_2 are the azimuthal angles of the nuclei at time t and ϕ''_1 and ϕ''_2 are the angles at time $t + \tau$.

Calculating the time dependent average values $\langle C_{ir} \rangle$ involves integrals of functions that approach the complete elliptic integrals at long τ values if $(\phi'_1 - \phi''_1)$ and $(\phi'_2 - \phi''_2)$ are allowed to have all values from 0 to 2π . The calculation is greatly simplified with the model in which one nucleus occupies three positions 120° apart and the other nucleus occupies three similar positions that are staggered with respect to those of the former nucleus. Here, there are only two different values of r , as given by the expressions:

$$r_1^2 = a^2 + b^2 + c^2 + 2ac \quad (55a)$$

$$r_s^2 = a^2 + b^2 + c^2 - ac \quad (55b)$$

If each nucleus independently and randomly jumps among its three positions, the $\langle C_{ir} \rangle$ are

$$\langle C_{Ar} \rangle = C_{a1} + C_{a2} \exp[-|\tau|(1/\tau_1 + 1/\tau_2)] \quad (56a)$$

$$\langle C_{Br} \rangle = C_{b1} \exp[-|\tau|/\tau_1] + C_{b2} \exp[-|\tau|/\tau_2] \\ + C_{b3} \exp[-|\tau|(1/\tau_1 + 1/\tau_2)] \quad (56b)$$

$$\langle C_{Cr} \rangle = C_{c1} \exp[-|\tau|/\tau_1] + C_{c2} \exp[-|\tau|/\tau_2] \\ + C_{c3} \exp[-|\tau|(1/\tau_1 + 1/\tau_2)] \quad (56c)$$

where

$$C_{a1} = \left(\frac{1}{18}\right)[(a^2 + c^2 - 2b^2)^2 Q_1 + 4a^2c^2 Q_2 \\ - 4(a^3c + ac^3 - 2ab^2c) Q_3] \quad (57a)$$

$$C_{a2} = \left(\frac{1}{9}\right)[(a^2 + c^2 - 2b^2)^2 Q_2 + a^2c^2 Q_5 \\ - 2(a^3c + ac^3 - 2ab^2c) Q_4] \quad (57b)$$

$$C_{b1} = \left(\frac{2}{3}\right)b^2(c^2 Q_1 + a^2 Q_2 - 2ac Q_3) \quad (57c)$$

$$C_{b2} = \left(\frac{2}{3}\right)b^2(c^2 Q_2 + a^2 Q_1 - 2ac Q_3) \quad (57d)$$

$$C_{b3} = \left(\frac{2}{3}\right)b^2(a + c)^2 Q_2 \quad (57e)$$

$$C_{c1} = \left(\frac{1}{6}\right)(c^4 Q_1 + a^4 Q_2 + 6a^2c^2 Q_6 - 4ac^3 Q_3 + 4a^3c Q_2) \quad (57f)$$

$$C_{c2} = \left(\frac{1}{6}\right)(c^4 Q_2 + a^4 Q_1 + 6a^2c^2 Q_6 + 4ac^3 Q_2 - 4a^3c Q_3) \quad (57g)$$

$$C_{c3} = \left(\frac{1}{6}\right)(c^4 Q_2 + a^4 Q_2 + 6a^2c^2 Q_7 - 4ac^3 Q_3 - 4a^3c Q_3) \quad (57h)$$

in which

$$Q_1 = 4r_s^{-10} + r_1^{-10} + 4r_s^{-5}r_1^{-5} \quad (58a)$$

$$Q_2 = r_s^{-10} + r_1^{-10} - 2r_s^{-5}r_1^{-5} \quad (58b)$$

$$Q_3 = 2r_s^{-10} - r_1^{-10} - r_s^{-5}r_1^{-5} \quad (58c)$$

$$Q_4 = r_s^{-10} - 2r_1^{-10} + r_s^{-5}r_1^{-5} \quad (58d)$$

$$Q_5 = r_s^{-10} + 4r_1^{-10} + 4r_s^{-5}r_1^{-5} \quad (58e)$$

$$Q_6 = r_1^{-10} - r_s^{-5}r_1^{-5} \quad (58f)$$

$$Q_7 = 3r_s^{-10} + r_1^{-10} + 2r_s^{-5}r_1^{-5} \quad (58g)$$

The correlation time of internal motion of the nucleus associated with ϕ_1 and c is τ_1 and that of the nucleus associated with ϕ_2 and a is τ_2 .

The final correlation times are given by:

$$1/\tau_{a1} = 1/\tau_A = 6R_2 \quad (59a)$$

$$1/\tau_{a2} = 6R_2 + 1/\tau_1 + 1/\tau_2 \quad (59b)$$

$$1/\tau_{b1} = 5R_2 + R_3 + 1/\tau_1 \quad (59c)$$

$$1/\tau_{b2} = 5R_2 + R_3 + 1/\tau_2 \quad (59d)$$

$$1/\tau_{b3} = 5R_2 + R_3 + 1/\tau_1 + 1/\tau_2 \quad (59e)$$

$$1/\tau_{c1} = 2R_2 + 4R_3 + 1/\tau_1 \quad (59f)$$

$$1/\tau_{c2} = 2R_2 + 4R_3 + 1/\tau_2 \quad (59g)$$

$$1/\tau_{c3} = 2R_2 + 4R_3 + 1/\tau_1 + 1/\tau_2 \quad (59h)$$

Use of this simple model of internal motion with magnetic dipolar relaxation interaction increases the number of correlation times for the axially symmetric ellipsoid from three to eight. If the internal rotational axis were not parallel to the ellipsoid symmetry axis, then more than eight correlation times would result. Even in this simple case, many simplifications occur if the molecule rotates with spherical symmetry, if $\tau_1 = \tau_2$, or if either of the two nuclei does not rotate internally.

Examination of the sum of the eight coefficients given by equation (57) reveals insight into the effects of internal motion. This sum is $(4/3)r_s^{-6} + (2/3)r_l^{-6}$, which is twice the weighted average of r^{-6} . The corresponding sum for a rigid molecule, obtained from the sum of equation (53) when the single-primed and double primed quantities are equal, is $2r^{-6}$. The effect of the internal motion, then, is to split r^{-6} into several terms. Most of these terms have shorter correlation times than for a rigid molecule. One of the terms is independent of the internal motion and it gives rise to the ‘order parameter’ that represents a kind of order in a large, flexible molecule.

6 ‘MODEL-FREE’ CORRELATION FUNCTIONS FOR FLEXIBLE MACROMOLECULES

Modern applications of NMR include the use of relaxation time measurements to investigate the dynamics of flexible macromolecules, such as polymers, lipids, and proteins (see *Protein Dynamics from NMR Relaxation*), in solution. Clearly, the correlation function for such systems is extremely complex because many different correlation times and associated preexponential factors are involved in its formulation. In addition, we must assume structural and dynamical models to make the formulation. Even with such a formulation, the typical NMR relaxation time measurement does not allow for the experimental evaluation of all the parameters that are in the assumed models.

We can use the expressions presented in this article with various assumed dynamics and structures to formulate the correlation functions for a complex flexible molecule and compute values of relaxation times. We can use these values to validate simplified expressions for the spectral density to figure out (a) what is the unique information in a set of relaxation time data and (b) how can we extract this information from the data?

Such simplified expressions are called^{11–13} ‘model-free’ because the analysis of relaxation time data using these

expressions does not require the adoption of a physical model. However, the derivation and productive use of these expressions do require the assumption of certain limiting cases. The description of the motion of the flexible macromolecule is that of overall reorientation of the molecular framework and internal motions within this framework that are independent of the reorientation of the framework. To illustrate this approach, we factor equation (47) as

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle &= (\tfrac{1}{2})K_h[\exp(-|\tau|/\tau_{ov})] \\ &\quad \times [A + B \exp(-|\tau|/\tau_{i1}) + C \exp(-|\tau|/\tau_{i2})] \end{aligned} \quad (60)$$

in which $A + B + C = 2$. When the internal motion is rotational diffusion, for example, the correlation times are:

$$1/\tau_{ov} = 1/\tau_A = 6R_2 \quad (61a)$$

$$1/\tau_{i1} = -R_2 + R_3 + R_i \quad (61b)$$

$$1/\tau_{i2} = -4R_2 + 4R_3 + 4R_i \quad (61c)$$

We can view equation (60) as the product of a correlation function $C_{ov}(\tau)$ that depends only on overall motion, and a correlation function $C_{in}(\tau)$ that contains a constant term and terms that involve the internal motion, so that

$$\langle F_h(t)F_h^*(t+\tau) \rangle = K_h C_{ov}(\tau) C_{in}(\tau) \quad (62)$$

where

$$C_{ov}(\tau) = \exp(-|\tau|/\tau_{ov}) \quad (63a)$$

$$C_{in}(\tau) = (\tfrac{1}{2})[A + B \exp(-|\tau|/\tau_{i1}) + C \exp(-|\tau|/\tau_{i2})] \quad (63b)$$

The model-free approach is to approximate $C_{in}(\tau)$ as

$$C_{in}(\tau) = \zeta^2 + (1 - \zeta^2) \exp(-|\tau|/\tau_{eff}) \quad (64)$$

where ζ is called an order parameter, equal to $(A/2)^{1/2}$ in the present example, and τ_{eff} is an effective correlation time as given by the definition:

$$\tau_{eff} = (1 - \zeta^2)^{-1} \int_0^\infty [C_{in}(\tau) - \zeta^2] d\tau \quad (65)$$

When the internal motions are rapid so that $2\omega_0/R_i \ll 1$, use of this definition in the spectral density function provides an excellent approximation.

In considering the consequences of the fluctuations of internuclear separation on magnetic dipolar relaxation that are

caused by the internal motion, we can use equations (56)–(59) to factor equation (51) as

$$\begin{aligned} \langle F_h(t) F_h^*(t + \tau) \rangle &= \left(\frac{1}{2}\right) K_h [\exp(-|\tau|/\tau_{ov})] \\ &\times [C_{a1} + C_{a2} \exp(-|\tau|/\tau_{i1}) \\ &+ C_{b1} \exp(-|\tau|/\tau_{i2}) + C_{b2} \exp(-|\tau|/\tau_{i3}) \\ &+ C_{b3} \exp(-|\tau|/\tau_{i4}) + C_{c1} \exp(-|\tau|/\tau_{i5}) \\ &+ C_{c2} \exp(-|\tau|/\tau_{i6}) + C_{c3} \exp(-|\tau|/\tau_{i7})] \end{aligned} \quad (66)$$

in which

$$1/\tau_{ov} = 6R_2 \quad (67a)$$

$$1/\tau_{i1} = 1/\tau_1 + 1/\tau_2 \quad (67b)$$

$$1/\tau_{i2} = -R_2 + R_3 + 1/\tau_1 \quad (67c)$$

$$1/\tau_{i3} = -R_2 + R_3 + 1/\tau_2 \quad (67d)$$

$$1/\tau_{i4} = -R_2 + R_3 + 1/\tau_1 + 1/\tau_2 \quad (67e)$$

$$1/\tau_{i5} = -4R_2 + 4R_3 + 1/\tau_1 \quad (67f)$$

$$1/\tau_{i6} = -4R_2 + 4R_3 + 1/\tau_2 \quad (67g)$$

$$1/\tau_{i7} = -4R_2 + 4R_3 + 1/\tau_1 + 1/\tau_2 \quad (67h)$$

The analogous order parameter ζ_r for internal motion with equation (62) is similarly defined by:

$$C_{in}(\tau) = \zeta_r^2 + (1 - \zeta_r^2) \exp(-|\tau|/\tau_{er}) \quad (68)$$

in which ζ_r is equal to $(C_{a1}/2)^{1/2}$ and τ_{er} is the effective correlation time that is defined in the same fashion as τ_{eff} .

When the internal motions are rapid compared with the overall molecular reorientation rate and obey the condition $2\omega_0/R_i \ll 1$, the correlation function is the sum of two terms. One of these terms involves the overall correlation time and the other term involves the effective correlation time that depends on the internal motions. The term that is dependent on the overall molecular motion is weighted by the order parameter.

7 CORRELATION FUNCTIONS FOR INTERMOLECULAR MAGNETIC DIPOLAR RELAXATION

Magnetic dipolar NMR relaxation between nuclei of different molecules is an important relaxation mechanism that depends on Brownian motion. The values of r , θ , and ϕ are time dependent because of translational diffusion of the molecular centers and rotation of the molecules about their centers. If the interacting nuclei are at the centers of spherical molecules, the correlation functions can be calculated¹ from classical diffusion theory. The correlation function is¹

$$\begin{aligned} \langle F_h(t) F_h^*(t + \tau) \rangle &= \frac{\alpha_h N}{d^3} \\ &\times \int_0^\infty [J_{3/2}(u)]^2 \exp\left[-\left(\frac{2D}{d^2} u^2 \tau\right)\right] \frac{du}{u} \end{aligned} \quad (69)$$

where N is the number of nuclear spins per cm^3 , D is the translational diffusion coefficient, d is the minimum distance of approach between nuclei on different molecules, $J_{3/2}$ is a Bessel function, α_h is a numerical factor that depends on h , and u is a dummy integration parameter. The spectral energy densities are then

$$J_h(\omega) = \frac{\alpha_h N}{dD} \int_0^\infty [J_{3/2}(u)]^2 \frac{u du}{u^4 + \omega^2 \tau^2} \quad (70)$$

where $\tau = d^2/2D$. The effects on $J_h(\omega)$ in the case of off-center nuclei¹⁴ depend on the ratio τ/τ_c and they are not insignificant.

8 EXPERIMENTAL AND THEORETICAL CORRELATION TIMES OF RIGID MOLECULES

8.1 Evaluation of Correlation Times from NMR Relaxation Data

We can express the correlation functions in the preceding sections of this article (except for Section 7) as the following sum of exponential functions:

$$\langle F_h(t) F_h^*(t + \tau) \rangle = \left(\frac{1}{2}\right) \langle F_h(t) F_h^*(t) \rangle \sum_j C_j \exp(-|\tau|/\tau_{cj}) \quad (71)$$

in which $\sum_j C_j = 2$. The values of the correlation times τ_{cj} depend on the rates of molecular motions, and the number and values of the C_j depend on the details of molecular structure and motion. Because equation (71) is a sum of exponential functions, the spectral densities $J_h(\omega)$ in equation (3) are given by the sum of Lorentzian functions

$$J_h(\omega) = \langle F_h(t) F_h^*(t) \rangle \sum_j C_j [\tau_{cj}/(1 + \omega^2 \tau_{cj}^2)] \quad (72)$$

Note that the spectral densities for intermolecular magnetic dipolar relaxation in Section 7 are not sums of Lorentzian functions because equation (69) is not a sum of exponential functions.

The models presented in the preceding sections do not explicitly include various motions, such as high frequency, small amplitude bond stretching vibrations, as well as torsional oscillations about temporary equilibrium positions that change because of Brownian motion. The inclusion of such motions would increase the number of terms in equations (71) and (72) and could decrease the spectral density. If the decrease in spectral density is significant, the application of the preceding models to relaxation time data could lead to inconsistencies of interpretation. In the case of magnetic dipolar relaxation of CH_3 groups, the predicted decrease due to torsional oscillations agrees¹⁵ with experiment.

The study of Brownian motions by means of NMR relaxation time measurements involves the evaluation of the τ_{cj} from $J_h(\omega)$ values that are obtained from the measured relaxation times. These relaxation times should be from different nuclei that have different orientations of relaxation interaction vector with respect to the various axes of the ellipsoidal molecule.

There can be an ambiguity in evaluating correlation times from relaxation data, especially for large molecules with relatively small R_i values. Because the function $\tau_{cj}/(1 + \omega^2\tau_{cj}^2)$ is at its maximum value $1/\omega$ at $\omega\tau_{cj} = 1$, there is an ambiguity of τ_{cj} values when the 'experimental' value of $\tau_{cj}/(1 + \omega^2\tau_{cj}^2)$ is less than $1/\omega$. This ambiguity does not occur if, for example, all of the τ_{cj} values are small compared to $1/\omega$. In ordinary NMR spectrometers, this condition is met for nonviscous liquids. For example, $2\omega_0\tau_c \approx 0.05$ for protons in liquid water at 0 °C in a 750 MHz NMR spectrometer. Clearly, the simplest circumstance is a rigid, spherical molecule of a nonviscous liquid so that there is only one correlation time. We can compare the correlation time obtained from the analysis of the NMR relaxation time to the value that is predicted from liquid properties and molecular parameters.

8.2 Relationship of Rotational Correlation Times to Brownian Motion

In the preceding sections of this article, the correlation functions for a rigid ellipsoid are expressed in terms of the rotational diffusion coefficients R_i . The R_i values can be determined from the analysis of the proper relaxation time measurements. The next step is to relate the R_i to Brownian motion in the liquid. Molecules in the liquid undergo random collisions with other molecules. Perrin's exquisitely detailed description of the translational and rotational motion of an ellipsoid that is immersed in a liquid and experiencing collisions with the liquid molecules⁵ is useful in establishing this relationship.

It is assumed that the average action of molecular collisions on the ellipsoid gives rise to the friction of viscosity. Fluctuations of these collisions produce impulses of torque that affect the rotation of the ellipsoid. These impulses couple the rotational kinetic energy of the ellipsoid to the kinetic energy of its surroundings so that thermodynamic equilibrium obtains and the average kinetic energy for each degree of freedom is

equal to $kT/2$, where T is the absolute temperature of the fluid and k is Boltzmann's constant.

Let ω_1, ω_2 , and ω_3 be the angular velocities of the ellipsoid about the X, Y , and Z axes and I_1, I_2 and I_3 be the moments of inertia about these axes, respectively. Similarly, let α_1, α_2 , and α_3 be small rotation angles about these axes. In the following discussion, designate the subscripts 1, 2, and 3 as the subscript i . If K is the kinetic energy of the particle, the angular momenta λ_i are the partial derivatives of K with respect to the angular velocities ω_i :

$$\lambda_i = \partial K / \partial \omega_i \quad (73)$$

At each instant, the collisions with the surrounding molecules produce a torque L_i about the respective ellipsoid axes. Each L_i is the sum of the frictional torque $-C_i\omega_i$ that results from viscosity and a variable torque Γ_i that is caused by fluctuations of the collisions. This torque causes changes in angular momenta as given by

$$d\lambda_i/dt = -C_i\omega_i + \Gamma_i \quad (74)$$

We take time intervals Δt that are sufficiently great so that there is almost complete statistical independence of the angular displacements that are produced by torque Γ_i during two consecutive time intervals, and nevertheless, sufficiently small so that the rotation during each interval is very small. If α_i are the very small angles that are needed to describe the changes in orientation from its initial position to its orientation at the end of time interval Δt , to a first approximation the angular velocities are

$$\omega_i = d\alpha_i/dt \quad (75)$$

Under these conditions, the angular displacements that result from successive impulses due to the thermal motions of the liquid are independent and simply additive. If we divide the time interval Δt into very small successive intervals δt , the variable couple Γ_i communicates to the ellipsoid an impulse $\mathcal{L}_i$ that is the integral of Γ_i over the interval δt ,

$$\mathcal{L}_i = \int_0^{\delta t} \Gamma_i dt \quad (76)$$

Also, to calculate the net angular displacement that results from these impulses, it suffices to calculate the displacement that results from each impulse, assuming action on the initially immobile particle, and take the sum of these small displacements as if they are not superposed in time.

Because $\omega_i = d\alpha_i/dt$ and $d\lambda_i/dt = -C_i\omega_i + \Gamma_i$

$$d\lambda_i/dt = -C_i(d\alpha_i/dt) + \Gamma_i \quad (77)$$

Integration between the initial time t_0 and the final time t gives:

$$\lambda_i - \lambda_{i0} = -C_i(\alpha_i - \alpha_{i0}) + \int_{t_0}^t \Gamma_i dt \quad (78)$$

The ellipsoid is assumed to be immobile at time t_0 so that $\lambda_0 = 0$. If the torque Γ_i acts on the particle only during the time interval δt ,

$$\lambda_i = -C_i(\alpha_i - \alpha_{i0}) + \mathcal{L}_i \quad (79)$$

If t is large enough so that the particle is now practically stopped due to the friction, the rotational displacement of the particle that results from the total of the angular impulses $\mathcal{L}$ is

$$\delta\alpha_i = \mathcal{L}_i/C_i \quad (80)$$

The displacement does not depend on the moments of inertia, I_i ; it depends only on the coefficients of friction C_i . However, this result is true only if the preceding approximations are justified by the smallness of the angular displacements.

If the time interval Δt is sufficiently great, the displacement is that which results from the n successive intervals δt that compose it. If the intervals δt are not too small, the successive corresponding impulses are nearly statistically independent, and the net angular displacement $\Delta\alpha_i$ over time Δt is given by:

$$\langle \Delta\alpha_i^2 \rangle = (1/C_i^2) \sum_k \langle \mathcal{L}_{ik}^2 \rangle = n \langle \mathcal{L}_i^2 \rangle / C_i^2 \quad (81)$$

because the average values for time intervals of the same duration δt are equal. Also, the average values of cross terms $\Delta\alpha_i \Delta\alpha_j$ are zero.

The average values of the $\Delta\alpha_i^2$ quantities can be found by noting that the impulses received by the particle maintain statistically a state of agitation that corresponds to the average kinetic energy that, from the equipartition theorem of statistical mechanics, is given by:

$$\langle \lambda_i \omega_i \rangle = kT \quad (82)$$

If the time interval δt is sufficiently small so that the rotational velocity ω_i is nearly constant, integration of equation (74) over δt gives:

$$\lambda_i' = \lambda_i - C_i \omega_i \delta t + \mathcal{L}_i \quad (83)$$

where λ_i and λ_i' are angular momenta at the beginning and end of the interval δt . After squaring and taking the average,

$$\begin{aligned} \langle \lambda_i'^2 \rangle = & \langle \lambda_i^2 \rangle + C_i^2 \langle \omega_i^2 \rangle \delta t^2 + \langle \mathcal{L}_i^2 \rangle \\ & - 2C_i \langle \lambda_i \omega_i \rangle \delta t + 2\langle \lambda_i \mathcal{L}_i \rangle - 2C_i \langle \omega_i \mathcal{L}_i \rangle \delta t \end{aligned} \quad (84)$$

Several characteristics allow us to simplify this expression. Since the system is in steady-state conditions, $\langle \lambda_i'^2 \rangle = \langle \lambda_i^2 \rangle$. The impulses $\mathcal{L}_i$ do not depend directly on the angular velocities, and the intervals δt are assumed to be sufficiently long in order than the impulses may be independent of the previous impulses that have influenced the angular velocities. Therefore, the average values of products of impulses and angular velocities and of products of impulses and angular momenta are null. Finally, the terms in δt^2 are negligible. Equation (84) then reduces to:

$$\langle \mathcal{L}_i^2 \rangle = 2C_i \langle \lambda_i \omega_i \rangle \delta t \quad (85)$$

and use of equation (82) gives the relation:

$$\langle \mathcal{L}_i^2 \rangle = 2C_i kT \delta t \quad (86)$$

Then, because $n\delta t = \Delta t$ equation (81) gives:

$$\langle \Delta\alpha_i^2 \rangle = 2(kT/C_i) \Delta t \quad (87)$$

and $\Delta\alpha_i$ changes with time as described by the rotational diffusion coefficient

$$R_i = kT/C_i \quad (88)$$

In an analogous fashion, Einstein¹⁶ considered the translational Brownian motion of colloidal particles and showed that the translational diffusion coefficient D in an infinitely dilute solution is given by the equation:

$$D = kT/f \quad (89)$$

where f is the frictional coefficient of the particle.

8.3 Relationships between Friction Coefficients and Properties of Molecules and Liquids

8.3.1 Hydrodynamic Models

The strategy to evaluate the C_i and f friction coefficients for *molecules* in ordinary liquids is not completely straightforward. Usually, the results of classical hydrodynamics are used. Stokes¹⁷ considered the special case of the motion of a macroscopic spherical particle of radius a moving with uniform velocity in a continuous fluid (i.e. infinitesimally small particles) of viscosity η . He assumed that the moving sphere carries along with it, *with no slippage*, the layer of fluid in contact with it (i.e. the surface of the sphere is 'wetted' by the fluid medium). Parenthetically, using this assumption avoids the problems of evaluating the friction coefficient between two different materials, the surface of the smooth sphere and the adjacent surface of the fluid medium. Using classical hydrodynamical principles, such as perfect streamline flow, etc., he showed that the translational movement of the sphere is impeded by the sum of two forces: (1) the force ($=4\pi\eta a$) due to pressure built up in front of it, and (2) a frictional force ($=2\pi\eta a$) parallel to its surface. Then, the friction coefficient f_0 is given by

$$f_0 = 6\pi\eta a \quad (90)$$

Einstein¹⁶ noted that *if* one can assume that this equation applies to spherical *molecules* of radius a , the resulting value of the molecular diffusion coefficient is given by the equation

$$D = kT/6\pi\eta a \quad (91)$$

which is known as the Stokes–Einstein equation. This relationship has been experimentally verified many times for particles whose size can be measured directly, including latex particles of only 1300 Å radius in water. The increase in size

due to the monolayer of water molecules is negligible for spheres of such size.

For the case of a sphere rotating uniformly in the continuous medium, the Stokes approach gives the rotational friction coefficient

$$C_i = 8\pi\eta a^3 \quad (92)$$

Following Einstein's lead in assuming that the translational friction coefficient of a molecule obeys the classical hydrodynamic formulation, Debye³ made the analogous assumption that the rotational motion of a spherical molecule is described by rotational diffusion with the classical rotational friction coefficient given above.

Edwardes extended Stokes's calculation of the single rotational friction coefficient of a rotating sphere to evaluate the three friction coefficients for an asymmetric ellipsoid rotating in a continuous fluid. The results, as corrected by Perrin,⁵ are:

$$C_1 = 16\pi\eta(b^2 + c^2)/[3(b^2Q + c^2R)] \quad (93a)$$

$$C_2 = 16\pi\eta(c^2 + a^2)/[3(c^2R + a^2P)] \quad (93b)$$

$$C_3 = 16\pi\eta(a^2 + b^2)/[3(a^2P + b^2Q)] \quad (93c)$$

where a , b , and c are the X' , Y' , and Z' semi-axes of the ellipsoid, and P , Q and R are the elliptic integrals

$$P = \int_0^\infty (a^2 + s)^{-3/2}(b^2 + s)^{-1/2}(c^2 + s)^{-1/2} ds \quad (94a)$$

$$Q = \int_0^\infty (b^2 + s)^{-3/2}(a^2 + s)^{-1/2}(c^2 + s)^{-1/2} ds \quad (94b)$$

$$R = \int_0^\infty (c^2 + s)^{-3/2}(a^2 + s)^{-1/2}(b^2 + s)^{-1/2} ds \quad (94c)$$

These quantities are related by the equations:

$$P + Q + R = 2/(abc) \quad (95)$$

$$a^2P + b^2Q + c^2R = S \quad (96)$$

where

$$S = \int_0^\infty [(a^2 + s)(b^2 + s)(c^2 + s)]^{-1/2} ds \quad (97)$$

For the axially symmetric ellipsoid, with $a = b$ so that $R_1 = R_2$, the C_i simplify to

$$C_1 = C_2 = 32\pi\eta(c^4 - b^4)/\{3[(2c^2 - b^2)S - 2c]\} \quad (98a)$$

$$C_3 = 32\pi\eta b^2(c^2 - b^2)/[3(2c - b^2S)] \quad (98b)$$

Also, for $b > c$,

$$S = 2(b^2 - c^2)^{-1/2} \tan^{-1}[(b^2 - c^2)^{1/2}/c] \quad (99a)$$

and for $b < c$,

$$S = 2(c^2 - b^2)^{-1/2} \ln\{[c + (c^2 - b^2)^{1/2}]/b\} \quad (99b)$$

For a sphere, where $a = b = c$, all the C_i are equal to $8\pi\eta a^3$.

The relationships given above can be used to calculate the NMR correlation times for rigid molecules of a variety of shapes. Generally, for pure liquids and for solutes in solutions in which the solute molecules are not large compared to the solvent molecules, the calculated correlation times are approximately an order of magnitude greater than the values obtained from analysis of NMR relaxation time data. The discrepancy is especially great for small, nearly spherical molecules. Also, the calculated translational diffusion coefficients for such systems are significantly smaller than measured D values.¹⁸

8.3.2 Gierer–Wirtz Microviscosity Factor

Two difficulties will arise from use of these hydrodynamic friction coefficients. One difficulty is uncertainty of the size of small molecules. Because of the free space between molecules in a liquid, it is not sufficient to equate the molecular volume to the molar volume divided by Avogadro's number. For example, a crystal made up of closely packed spheres is 26% empty volume. Accordingly, 74% of the above molecular volume is commonly used in calculating the molecular radius for rotational correlation time estimates. Several other methods are described¹⁸ for use in the Stokes–Einstein equation. However, using any realistic method of calculating molecular size does not solve the problem. The inclusion of a 'wetting' or 'sticking' layer of molecules would make the situation worse, because even smaller molecular volumes are generally needed to fit the experimental results to equations (91) and (92).

Another problem is that the molecule of interest is surrounded by particles of comparable size instead of a continuous fluid of infinitesimally small particles. Gierer and Wirtz¹⁹ estimated the rotational and translational friction coefficients of a 'solute' sphere surrounded by 'solvent' spheres by formulating the liquid viscosity in terms of the kinetics of the spheres. They regard the given molecule of interest to be a sphere of radius r and the surrounding molecules to be spheres of radius r_1 . The surrounding molecules form spherical layers, each of thickness $2r_1$, around the given molecule. If this central molecule is set rotating about the z axis with angular velocity ω , each layer will eventually acquire an angular velocity because of the friction between layers. In the steady state, the m th layer will have angular velocity ω_m . At equilibrium the total torque acting on the m th layer will be equal to the resistive torque on the central molecule, which is zero. The rotational friction coefficient for the central molecule is given by

$$C_s = 8\pi\eta r^3 f_r \quad (100)$$

where

$$f_r = \frac{\rho}{6} \left[\sum_m (1 + 2m\rho)^{-4} \right]^{-1} \approx \left[6\rho + \frac{1}{(1 + \rho)^3} \right]^{-1} \quad (101)$$

in which f_r is the rotational ‘microviscosity factor’, the summation is from $m = 0$ to $m = \infty$, and $\rho = r_l/r$. For translational motion, the Stokes–Einstein friction coefficient is multiplied by the microviscosity factor

$$f_t = [(3/2)\rho + 1/(1 + \rho)]^{-1} \quad (102)$$

The value for pure liquids is $f_r = 0.164$. Use of these microviscosity correction factors gives correlation times and diffusion coefficients that are generally close to experimental values when the assumed molecular volume is 0.74 times the molar volume divided by Avogadro’s number. However, when ρ differs from unity, the experimental f_r depends more strongly on ρ than equation (101) predicts. Generally, $\rho \neq 1$ for molecules in solutions.

8.3.3 Mutual Viscosity Formulation

The preceding calculations of the friction coefficient $\mathcal{C}_i$ use the viscosity of the fluid. This usage represents a deficiency of approach. As discussed by Hill,²⁰ every molecule in a pure liquid is surrounded by molecules of the same kind and the interactions between these like molecules determine both the liquid viscosity η and the friction coefficient $\mathcal{C}_i$. Despite the particular argument by which η and $\mathcal{C}_i$ are related, it is expected that they will vary in a similar manner from one substance to another. But in a dilute solution, η is determined almost entirely by the interactions between the solvent molecules while $\mathcal{C}_i$ is determined almost entirely by interactions between the solute and solvent molecules. Therefore, there is no reason to expect a general, simple relationship between η and $\mathcal{C}_i$ for solutions of different substances. To obtain an improved relationship, it is necessary to consider more closely the interactions that determine these quantities.

In the Andrade theory of liquid viscosity, the molecules in a liquid are regarded as vibrating with a frequency ν about equilibrium positions that change slowly with time. The transfer of momentum that occurs in a viscous liquid between layers moving with different velocities is due to temporary unions or collisions of adjacent molecules. These unions occur at the extremes of each vibrational swing so that, for an infinitesimal time, the two molecules move as one. Hill²⁰ applied this approach to a mixture of two liquids and found that the viscosity η_m of the mixture is:

$$\eta_m = f_A^2 \eta_A \sigma_A / \sigma_m + f_B^2 \eta_B \sigma_B / \sigma_m + 2 f_A f_B \eta_{AB} \sigma_{AB} / \sigma_m \quad (103)$$

where η_A and η_B are the viscosities of the pure liquids A and B, η_{AB} is the ‘mutual viscosity’, σ_A and σ_B are the average distances between molecules in the liquids A and B, σ_m is the average distance between molecules in the mixture, and σ_{AB} is the mean distance between a molecule of type A and

an adjacent molecule of type B in the mixture. The resultant value of $\mathcal{C}_s$ for a molecule of type B is:

$$\begin{aligned} \mathcal{C}_s = & 6 f_A \{ [(I_{AB} I_B) / (I_{AB} + I_B)] \\ & \times [(m_A + m_B) / (m_A m_B)] \} \eta_{AB} \sigma_{AB} \\ & + 3(3 - \sqrt{2}) f_B \{ [(I_{BB} I_B) / (I_{BB} + I_B)] \\ & \times [(m_B + m_B) / (m_B m_B)] \} \eta_B \sigma_B \end{aligned} \quad (104)$$

where I_B is the moment of inertia of a type B molecule, m is the mass of a molecule, and I_{AB} is the moment of inertia of molecule A about the center of mass of molecule B at the instant of collision. For a pure liquid ($f_B = 1$), the results are nearly the same as the Gierer and Wirtz approach, but for an infinitely dilute solution ($f_A = 1$), the viscosity is the mutual viscosity η_{AB} instead of the solvent viscosity. This approach explains²⁰ the different correlation times, found from dielectric relaxation measurements, for one solute in a variety of solvents having the same viscosity and for the relatively short correlation times found for solutes in high viscosity solvents.

In studies of the dielectric relaxation times of molecules of a wide range of size in solution, the use of equation (92) gives friction coefficients that agree²¹ with experiment when the molecular volume is at least three times that of the solvent molecule. Furthermore, the Hill theory is inferior for large solute molecules but it is superior for small solute molecules. Therefore, use of the rotational friction coefficients that are given in equations (92)–(99) to evaluate the correlation times for rotational diffusion of ellipsoids should provide a good approximation for large molecules in a solvent of small molecules.

8.4 Deficiencies of Viscosity/Rotational Diffusion Models

Since the earliest studies on molecular reorientational phenomena by nuclear magnetic relaxation, many have attempted to find a fundamental connection between orientational correlation times and macroscopic viscosity. Macroscopic viscosity, or shear viscosity, is defined as the resistance to shear if a thin liquid layer is moved (‘sheared’) between parallel plates. The physical dimension of viscosity is force times time divided by area. This tells us that we deal with momentum transfer. The momentum transfer tries to equalize the velocities of the moving layers. As indicated in Section 8.3.1, the hydrodynamic boundary conditions for the viscosity dependence of the orientational function of a spherical molecule have been defined in terms of a ‘rough sphere’; the surface of the reorienting molecule entrains its neighbors. A perfectly slipping sphere would have zero viscosity. On the other hand, we know that, on the molecular level, interactions take place through impulsive collisions between only a few neighbors. It is therefore not surprising that such a macroscopic rough sphere model overestimates $\mathcal{C}_s$. The microviscosity and mutual viscosity approaches are different attempts to formulate relationships that retain the idea of smooth spheres that, nevertheless, have surface friction. The situation is simpler for systems of small molecules of ellipsoidal shape since their reorientational motion displaces their neighbors; the rotational motion of a perfectly slipping ellipsoid would show a viscosity dependence.

The NMR relaxation behavior of several pure liquids of small molecules provides instructive cases. When the

molecules are rigid, all of the rotational diffusion models described above predict that the correlation times are directly proportional to the quantity η/T . However, this relationship is not always obeyed. Perdeuterobenzene provides a good example of this behavior. The temperature dependence of the deuteron T_1 value obeys²² an Arrhenius equation with an apparent activation energy $E_a = 7.78 \text{ kJ mol}^{-1}$. On the other hand, the temperature dependence of η/T is much greater; an Arrhenius equation is obeyed, but with $E_a = 13.05 \text{ kJ mol}^{-1}$. Besides varying temperature, the viscosity can be adjusted by changing the pressure on the liquid. The pressure dependence of the benzene viscosity²³ is described by an activation volume of $20.5 \text{ cm}^3 \text{ mol}^{-1}$. The pressure dependence of the deuteron T_1 of perdeuterobenzene is much less,²⁴ described by an activation volume of only $0.44 \text{ cm}^3 \text{ mol}^{-1}$. On the other hand, the pressure dependence of the translational diffusion coefficient of benzene²⁵ obeys an activation volume of $20.0 \text{ cm}^3 \text{ mol}^{-1}$, nearly identical to that of the viscosity. This means that the translational frictional coefficient is directly coupled to the viscosity, but the effective rotational friction coefficient is largely decoupled from the viscosity.

Acetonitrile, CH_3CN ,²⁶ is another instructive case. In the temperature range from 20°C to 50°C , the temperature dependence of η/T obeys an Arrhenius equation with $E_a = 8.66 \text{ kJ mol}^{-1}$. This molecule has an electric dipole moment that is parallel to the C–N axis of the molecule and the ^{14}N nucleus experiences an electric quadrupole interaction in the same direction. The temperature dependence of the dielectric relaxation time ($E_a = 8.28 \text{ kJ mol}^{-1}$) and of the ^{14}N T_1 (7.9 kJ mol^{-1}) are nearly equal to the above value for η/T . This shows that the rotational friction coefficient for reorientation of the C–N molecular axis at a given temperature is directly proportional to the viscosity. Also, the microviscosity model of Gierer and Wirtz,

$$\tau_c \equiv V\eta/6kT \quad (105)$$

where V is the molecular volume, yields at room temperature $\tau_c = 0.89 \times 10^{-12} \text{ s}$. This value is close (81%) to the value found from the ^{14}N measurements of T_1 . The deuteron T_1 values of CD_3CN , however, have a smaller temperature dependence with $E_a = 5.73 \text{ kJ mol}^{-1}$. This temperature dependence behavior shows that the rotational friction coefficient of the C–N axis of the molecule is directly proportional to the viscosity but that of the other molecular axes is relatively uncoupled from the viscosity. Also, at 25°C , the effective deuteron correlation time is $0.340 \times 10^{-12} \text{ s}$, which is much smaller than the value $1.104 \times 10^{-12} \text{ s}$ for ^{14}N . Evidently, the molecular reorientation rate about the C–N axis is much greater than that about an axis that is perpendicular to the C–N direction. If the molecule reorients like a rigid axially symmetric ellipsoid, use of equations (32) and (34)–(36) gives $R_3 = 10.35 \times R_2$. Also, the temperature dependence of R_3 is small, described by an Arrhenius equation with $E_a = 3.05 \text{ kJ mol}^{-1}$.

Toluene provides another informative case²⁷ of motions of small molecules. The temperature dependence of η/T is well described by an Arrhenius equation with $E_a = 11.51 \text{ kJ mol}^{-1}$. This value is larger than that of the T_1 of the ring deuterons of perdeuterotoluene (8.20 kJ mol^{-1}) and that of the methyl group deuterons of perdeuterotoluene (5.77 kJ mol^{-1}). Toluene has a

small electric dipole moment ($0.3\text{--}0.4 \text{ D}$) that is parallel to the methyl group symmetry axis. The dielectric relaxation time is approximately three times the NMR correlation time of the ring deuterons and its temperature dependence is essentially the same as that of this correlation time. Also, the T_1 values of the *ortho* and *para* ring deuterons are apparently equal. These dielectric and NMR relaxation results indicate that the ring of the toluene molecule reorients approximately like a sphere with $R_1 = R_2 = R_3$. However, the observation that the activation energy for the dielectric and NMR relaxation times is significantly smaller than that of η/T suggests that the molecular rotational friction coefficients of the ring are not directly related to the liquid viscosity.

Another significant observation is that the methyl deuterons have a much longer T_1 than the ring deuterons (4.88 s compared with 0.943 s). This longer T_1 and the smaller activation energy mean that the methyl group of the toluene molecule is internally reorienting rapidly about its symmetry axis. The intramolecular energy barrier to internal rotation of the methyl group in molecules such as toluene is very small, only $0.059 \text{ kJ mol}^{-1}$,²⁸ especially in comparison with the hinderance from interactions with neighboring molecules. Here, reorientation of the methyl group about its symmetry axis is completely independent from the reorientation of the remainder of the molecule, and the terms involving R_3 in equations (49) and (50) are omitted. Analysis²⁷ of the data using the ‘internal’ rotational diffusion model gives an apparent activation energy of 3.47 kJ mol^{-1} . Use of the ‘internal’ 120° jump model gives a similar value, 3.89 kJ mol^{-1} . Many other molecules have rapid internal reorientation of the methyl group, including methanol, acetone, acetic anhydride, ethanol, acetic acid, *t*-butanol, *p*-xylene, and acetophenone.

The rapid reorientation of the methyl group about its symmetry axis, the low values of apparent activation energy of this motion, and the decoupling of the rotational friction coefficient of benzene from the liquid viscosity may show that the model of rotational diffusion of a rigid ellipsoid may provide an incomplete description of molecular rotation of small molecules.

Relationships among viscosity, molecular reorientational motions, and molecular translational diffusion depend on the physical model that is assumed in the derivation. The Stokes–Einstein–Debye–Perrin model is based on the idea of particles surrounded by a continuous medium that is characterized by viscosity. The Gierer–Wirtz and Hill methods assume that the molecule of interest is surrounded by other particles and use specific physical models of interactions of spheres to interrelate the quantities. In all models, the system is at thermal equilibrium and subject to the general laws of thermodynamics and statistical mechanics. Different models may be appropriate for different molecular liquids. Steric considerations and the NMR observation²⁹ that benzene molecules rotate in the solid state suggest that liquid benzene molecules could rotate much faster about the C_6 molecular symmetry axis than about a C_2 axis. Such C_6 rotation requires less accommodation of the surrounding molecules than is required by a C_2 rotation. Similarly, for such molecules as toluene and acetonitrile, the rotation of a methyl group about its C_3 symmetry axis requires less accommodation by the surroundings than the rotation of the symmetry axis itself. Because the viscosity is likely to reflect the motions

that experience the greatest hindrances, the above C_6 and C_3 rotations could be largely uncoupled from the liquid viscosity. However, these rotations need not be completely free or frictionless. For example, the electric dipole moments of the individual C–H or C–D bonds could interact with the fluctuating local electric dipole fields due to the nearby molecules and hinder this motion.

9 CORRELATION FUNCTIONS FOR A 'NEARLY-FREE' ROTOR ATTACHED TO AN ELLIPSOID

The rotational diffusion model is a limiting case of the Langevin model. The internally reorienting part of the molecule may be treated as a classical rigid rotor that rotates about one axis. This rotational problem is analogous³⁰ to the case of translational motion.³¹ The distribution of rotational angular velocities follows the Boltzmann energy distribution law. The angular frequency ω of a rotor changes in time as described by

$$d\omega/dt = -[\xi\omega + F(t)]/I \quad (106)$$

where ξ is a rotational friction coefficient, I is the moment of inertia, and $F(t)$ is a randomly fluctuating torque. The fluctuating part is an instantaneous angular velocity independent, statistically defined force (its autocorrelation function decays much faster than that of the angular frequency) that causes random changes in the angular frequency. The value of the rotational angle $\phi''(\tau)$ of a rotor with initial angular velocity ω_i obeys a normal Gaussian distribution with a mean value

$$\langle\phi''(\tau)\rangle = \omega_i(I/\xi)\{1 - \exp[-(\xi/I)\tau]\} \quad (107)$$

When ξ is small, the value of $\langle\phi''(\tau)\rangle$ is $\omega_i\tau$. The averages $\langle\cos\phi''(\tau)\rangle$ and $\langle\cos 2\phi''(\tau)\rangle$ that appear in equations (38)–(40), obtained by a final averaging over the distribution of ω_i values, are:

$$\langle\cos\phi''(\tau)\rangle = \exp\{-(IkT/\xi^2)[\xi\tau/I + \exp(-\xi\tau/I) - 1]\} \quad (108a)$$

$$\langle\cos 2\phi''(\tau)\rangle = \exp\{-4(IkT/\xi^2)[\xi\tau/I + \exp(-\xi\tau/I) - 1]\} \quad (108b)$$

When the rotational friction coefficient is sufficiently great, we obtain an exponentially decaying function in τ as given in equation (44) with $R_i = kT/\xi$. This is the rotational diffusion limit. However, when the friction coefficient is sufficiently small, at short τ values we obtain exponentially decaying functions in τ^2 as given by

$$\langle\cos\phi''(\tau)\rangle = \exp[-(kT/2I)\tau^2] \quad (109a)$$

$$\langle\cos 2\phi''(\tau)\rangle = \exp[-(2kT/I)\tau^2] \quad (109b)$$

In this limit, the average values are independent of the friction coefficient and inertial effects dominate. The rotational

motions are decoupled from the viscosity of the liquid. The temperature dependencies predicted for these limiting cases are greatly different. Because the friction coefficient is likely to decrease with an increase in temperature, the temperature dependence in the rotational diffusion limit is expected to be much greater than in the inertial limit.

Although the temperature dependence may be used as a criterion between the applicability of these models, the value of R_i obtained from data analysis with the average angular velocity $(kT/I)^{1/2}$ provides another criterion. The rotational diffusion case may apply when the time required for the internal orientation to change by one radian calculated from the value of R_i obtained from data analysis, $(1/2R_i)$, is large compared to the time required by free rotation, $(I/kT)^{1/2}$. The motion of the methyl groups (CD_3) at room temperature falls between these two limits.²⁷ Further information about methyl group reorientation is available as follows. Equation (108) shows that I/ξ is the time constant for frictional changes in the rotational velocity of the CD_3 rotor. The quantity $(kT/I)^{1/2}$ is the average rotational angular velocity. The product of these two quantities, $(IkT/\xi^2)^{1/2}$, is the number of radians through which the CD_3 group rotates before its angular velocity changes appreciably. For the CD_3 groups of perdeuterotoluene at 298 K, this angle is 16° . This value is too large for rigorous application of the rotational diffusion model. Nevertheless, it is sufficiently small so that this model provides a convenient mathematical form for data analysis.

The experimental correlation times for many small rigid molecules in pure liquids and solutions obey a linear relationship with the liquid viscosity but have a nonzero intercept at zero viscosity. The intercept yields a correlation time² that appears to equal the time interval $(2\pi/9)(I/kT)^{1/2}$. This is the time required for a freely rotating molecule to turn through an angle of 41° , the angle for the correlation function of a second-order Legendre polynomial to drop to $1/e$ of its original (at $\tau = 0$) value. This result, which also shows that the correlation time is not directly proportional to viscosity at constant temperature, provides another indication that rotational diffusion may not accurately describe the motions of small molecules and the inertial effects are important in the rotational motions of small liquid molecules.

10 SCRUTINY OF THE MATHEMATICAL FORM OF CORRELATION FUNCTIONS

Realistically, at short enough times molecular collisions have not yet occurred and, consequently, molecular motion is purely kinetic. Because of this, the real correlation function has no first-order term in τ (it has zero slope at $\tau = 0$). Consequently, the rotational diffusion model fails with the first-order term and the spectral density derived from it is in error. We cannot use it to give a credible description of the details of molecular motion, especially for small molecules, since it is invalid for initial time intervals where the correlation function is least 'scrambled' by complicated orientation–collision events. This is dramatically shown by the nonexponential infrared and Raman spectral correlation functions² obtained in measurements on small molecules. NMR relaxation measurements made over a range

of frequencies do not reveal this dramatic behavior because the spectral density at ordinary Larmor frequencies is merely the integral of the correlation function. However, at sufficiently 'high' Larmor frequencies, the Lorentzian spectral density equation would not be obeyed. When this happens, and if the Larmor frequency is varied on both sides of the ' T_1 minimum', serious errors could occur if we interpret the relaxation data by use of the Lorentzian spectral density equation.

When the angle of free rotation is very large, the correlation functions derived for rotational diffusion of an asymmetric ellipsoid are no longer a reasonable approximation. In the spirit of Brownian rotational motion that is based on the Langevin equation in Section 9, the correlation functions for a rotating sphere with three degrees of rotational freedom are given by:

$$\langle F_h(t)F_h^*(t+\tau) \rangle = \langle F_h(t)F_h^*(t) \rangle \exp\{-6(IkT/C_s^2) \times [C_s\tau/I + \exp(-C_s\tau/I) - 1]\} \quad (110)$$

At long times, this function decays exponentially with time. At very short times, the results for a freely rotating sphere are obtained. At 'low' frequencies a plot of spectral density vs. friction coefficient C_s has a nonzero intercept equal to $(\pi/12)^{1/2}(I/kT)^{1/2}$. The spectral density function at high frequencies would deviate significantly from a Lorentzian function. When the friction is very large so that $C_s\tau/I \gg 1$, we obtain from equation (110) the results for rotational diffusion of a sphere.

There is a wide variety of correlations between NMR spectral densities of liquid molecules and macroscopic liquid properties such as viscosity. These correlations are sensitive to molecular size and intermolecular interactions. The spectral densities of large molecules appear to obey rotational diffusion equations with friction coefficients calculated with hydrodynamic models. Those for small molecules may be approximated by microviscosity and mutual viscosity formulations. Experiments that include NMR relaxation measurements at very high B_0 values and wide temperature ranges may yield more information on the rotational motions of molecules in liquids.

1 INTRODUCTION

Nuclear magnetic resonance is uniquely capable of revealing structure and dynamics on a molecular level. An understanding of nuclear spin relaxation is fundamental to an understanding of nuclear magnetic resonance in general. The theoretical framework needed to promote this understanding is conveniently constructed in terms of the time evolution of the density operator under the influence of some Hamiltonian as expressed by the Liouville–von Neuman equation. The emphasis here will be on molecules in liquids, though many of the principles presented are applicable to solids and gases. The experimental observables of NMR are oscillatory magnetizations induced in a sample as a consequence of subjecting it to various static and time-varying magnetic fields. The quantum mechanical operators corresponding to these observables act only on the nuclear spin degrees of freedom of the system. Furthermore, these operators are proportional to the spin angular momentum operators or products thereof, and, hence, can be dealt with using finite basis sets of states or operators. Relaxation, however, is a consequence of interactions between the nuclear spins and the rest of the system, referred to as the ‘lattice’. In most cases, the lattice cannot be treated exactly using quantum mechanics, because the density operator and the Hamiltonian cannot be defined exactly. The strategy generally employed, then, is to treat the effects of the lattice classically as a random time-dependent modulation of the nuclear spin operators while retaining a quantum mechanical description of the nuclear spins themselves. All externally applied magnetic fields are likewise treated classically. Our goal is to derive equations that correctly describe the observed temporal behavior of the experimental observables. This is done by proposing a Hamiltonian for the system under study, solving the Liouville–von Neuman equation for the time evolution of the density operator, computing the expected time evolution of the experimental observables, and comparing the result with measured values of these observables. Secondly, one wants to extract from this temporal behavior of the observables information about the fundamental nature of the system under investigation. For example, internuclear distances and rates of molecular reorientation due to Brownian motion can dramatically affect the

results of an NMR experiment. How can this kind of information be extracted from the behavior of the magnetization in a sample as a function of time? This article will lay out the theoretical framework of NMR experiments, with emphasis on an understanding of nuclear spin relaxation in liquids.

This article presumes a basic knowledge of the nuclear magnetic resonance phenomenon, including nuclear spin polarization in an external static magnetic field and interaction of nuclear spins with applied radiofrequency fields. For those not acquainted with these concepts, several basic texts may be consulted.^{1–3} The reader is assumed to have some grasp of basic quantum mechanics and angular momentum theory at the level generally taught in undergraduate physical chemistry courses. Some command of linear algebra and integral and differential calculus is also assumed. All abbreviations and symbols are either defined in the endpapers or are defined in context. Vectors and matrices will be distinguished by bold italic and bold roman type, respectively, and the same symbol in normal weight type will denote the magnitude of a vector or, with appropriate subscripts, components of a vector or elements of a matrix. Quantum mechanical operators will have a hat, for example, $\hat{H}$. Liouville space operators will have a double hat, for example $\hat{\hat{L}}$.

It is a familiar concept that the wavefunction embodies all that can be known about a quantum mechanical system and that any wavefunction can be expressed as a linear combination of the members of a complete set of eigenfunctions of the Hamiltonian of the system. However, in NMR, the density operator has proven to be a more convenient vehicle for this information, and the density operator, the Hamiltonian, and all other operators associated with the system can be cast as linear combinations of a complete set of orthonormal operators. These two descriptions are completely equivalent, and each can be formulated from the general concepts embodied in the bracket notation introduced by Dirac⁴ to describe abstract vector spaces. For nuclear spin systems in liquids, it is often possible to focus on a small number of spins (all the spins in one molecule, for example) and to consider the macroscopic sample as an ensemble of such systems, identical in their dependence on quantum mechanical operators but sampling the distribution of random classical variables. Since each nuclear spin has only a small number of eigenstates and the number of eigenstates for the whole system is the product of the numbers for each of the component spins, the necessary mathematics reduces, by means of an ensemble average, to a problem in linear algebra of reasonable dimension. In the following sections, the mathematics needed to discuss most of the experiments done on liquid samples will be formulated. Space limitations make it impossible to give a completely detailed exposition; for this, the reader may consult several excellent texts.^{5–9}

2 OPERATORS AND OPERATOR BASES

When a quantum mechanical system has a finite number of discrete energy levels (suppose there are n of them), the operators and states of the system can be represented as matrices and vectors in an n -dimensional vector space. Thus, the algebra of abstract n -dimensional vector spaces is essential to the theory we wish to develop. Dirac developed a convenient notation for describing these concepts.

2.1 Dirac Bracket Notation

For now, let us develop the bracket notation in a very abstract sense. It is important to realize that the bracket notation is just a formalism and can be applied to represent any desired vector space. Later, we shall apply it to both Hilbert and Liouville representations of the density operator. In the following equation is defined something called a *bra* and something called a *ket*:

$$\langle \text{bra} | (c) | \text{ket} \rangle \quad (1)$$

Bras and kets may have any kind of label inside to distinguish one from another. A ket may be converted into the corresponding bra by taking the Hermitian conjugate or adjoint, i.e., the complex conjugate transpose, and, of course, a bra can be converted into a ket in the same manner:

$$\langle \text{bra} | = [(| \text{ket} \rangle)^*]^T = (| \text{ket} \rangle)^\dagger \quad (2)$$

Multiplication of a bra and a ket in that order yields a number that can be real, imaginary, or complex:

$$\langle \text{bra} | \text{ket} \rangle = c \quad (3)$$

Note that this *scalar product* is not commutative, as we shall see in equation (9). Equation (3) is a key concept. In what follows, one must be able to recognize the $\langle | \rangle$ construct as a number that commutes with operators, bras, and kets. The scalar product is linear:

$$\left. \begin{aligned} \langle \text{bra} | (| \text{ket}_1 \rangle + | \text{ket}_2 \rangle) \rangle &= \langle \text{bra} | \text{ket}_1 \rangle + \langle \text{bra} | \text{ket}_2 \rangle \\ (\langle \text{bra}_1 | + \langle \text{bra}_2 |) | \text{ket} \rangle &= \langle \text{bra}_1 | \text{ket} \rangle + \langle \text{bra}_2 | \text{ket} \rangle \end{aligned} \right\} \quad (4)$$

Next we define something called an *operator* that converts a ket into some other ket:

$$\widehat{Op} | \text{ket} \rangle = | \text{new ket} \rangle \quad (5)$$

Operators will be distinguished by a hat (circumflex). Operators do not, in general, commute. The identity operator $\hat{E}$ just leaves a ket unaltered:

$$\hat{E} | \text{ket} \rangle = | \text{ket} \rangle \quad (6)$$

The identity operator does commute with all other operators.

Taking the adjoint of both sides of equation (5) yields the following relationship, which shows how an operator can act to the left on a bra:

$$(\widehat{Op} | \text{ket} \rangle)^\dagger = \langle \text{bra} | \widehat{Op}^\dagger = \langle \text{new bra} | \quad (7)$$

If $\widehat{Op}^\dagger = \widehat{Op}$, the operator is said to be *Hermitian* or *self-adjoint*.

If an operator acting on a ket yields the same ket multiplied by a number c (perhaps complex), the ket is said to be an *eigenket* of the operator, and c is the *eigenvalue*:

$$\widehat{Op} | \text{ket} \rangle = c | \text{ket} \rangle \quad (8)$$

As mentioned above, multiplication of bras and kets is not commutative, so the question arises of the meaning of the following product of a ket with a bra:

$$| \text{ket} \rangle \langle \text{bra} | = \text{operator} \quad (9)$$

This is called the *outer product* or *tensor product* of the bra and ket. Equation (9) asserts that this combination is an operator. This assertion can be easily proven by operating on some ket:

$$| a \rangle \langle b | c \rangle = | a \rangle \langle b | c \rangle = | a \rangle n_{bc} = n_{bc} | a \rangle \quad (10)$$

Remember that $\langle b | c \rangle$ is just a number, by equation (3), and a number will commute with a ket. Thus, $| a \rangle \langle b |$ satisfies the definition of an operator as in equation (5), because it produces a new ket $| a \rangle$ from $| c \rangle$. The numerical coefficient involved is not a problem, because a number times a ket is still a ket. The fact that one can reinterpret or regroup bras and kets in this way is a key concept of the formalism. In Section 2.2 it will become more obvious why these alternative interpretations are possible. We shall not put a hat over these operators, since there is no possibility of confusion; expressions of the type $| \rangle \langle |$ will always be interpretable as operators.

If we have a set of kets $\{ | i \rangle, i = 1, 2, 3, \dots, n \}$ such that

$$\langle i | j \rangle = \delta_{ij} \quad \text{for all } i, j = 1, 2, 3, \dots, n \quad (11)$$

then the set is said to be an *orthonormal* (orthogonal and normalized) basis. The Kronecker delta function is defined by

$$\delta_{ij} = \begin{cases} 1 & (i = j) \\ 0 & (i \neq j) \end{cases} \quad (12)$$

If for some member of the set $\langle i | i \rangle \neq 1$ then we simply define a new ket $| i' \rangle = | i \rangle / \langle i | i \rangle^{1/2}$ to replace $| i \rangle$ until all members of the set are normalized.

With just these simple rules for manipulating operators, bras, and kets as postulates, one can develop the mathematics necessary to treat nuclear spin dynamics.

2.2 Representations

Suppose we have some system in a state that corresponds to an abstract vector or ket designated as $| \psi(t) \rangle$. The indicated time dependence shows that the system may be evolving in time. We attempt to expand this state in the stationary orthonormal set of equation (11) as follows, and we want to know the form of the coefficients $c_i(t)$:

$$| \psi(t) \rangle = \sum_{i=1}^n c_i(t) | i \rangle \quad (13)$$

Multiplying from the left by $\langle i |$, a bra corresponding to one of the members of the basis set, and using equation (11) yields

$$\begin{aligned} \langle i | \psi(t) \rangle &= \langle i | \sum_{j=1}^n c_j(t) | j \rangle \\ &= \sum_{j=1}^n c_j(t) \langle i | j \rangle \\ &= \sum_{j=1}^n c_j(t) \delta_{ij} = c_i(t) \end{aligned} \quad (14)$$

The last step follows because, by equation (12), only the i th term survives in the sum. This is a formal prescription for computing the expansion coefficients; later, we shall see how it is implemented in real cases. The question of whether the set $\{|i\rangle\}$ is complete, i.e., contains all the basis vectors necessary to represent $|\psi(t)\rangle$, will not be addressed here. It will simply be asserted that such a set can be found. Taking the adjoint of both sides of equation (14) yields the analogous equation for bras:

$$\langle\psi(t)|i\rangle = c_i^*(t) \quad (15)$$

Having chosen a basis set, we can compute all the coefficients needed for equation (14) or equation (15). If these coefficients are arranged in a column or a row vector then we have the Hilbert space representation of the state (bra or ket) in the basis:

$$|\psi\rangle \xrightarrow{|i\rangle} \begin{bmatrix} \langle 1|\psi\rangle \\ \langle 2|\psi\rangle \\ \langle 3|\psi\rangle \\ \vdots \\ \langle n|\psi\rangle \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \\ c_3 \\ \vdots \\ c_n \end{bmatrix} \quad (16a)$$

$$\begin{aligned} \langle\psi| \xrightarrow{|i\rangle} & [\langle\psi|1\rangle \quad \langle\psi|2\rangle \quad \langle\psi|3\rangle \quad \dots \quad \langle\psi|n\rangle] \\ & = [c_1^* \quad c_2^* \quad c_3^* \quad \dots \quad c_n^*] \end{aligned} \quad (16b)$$

A mapping of this sort is sometimes written with an equals sign in the literature. This is not consistent with the notation we have developed, because the state $|\psi\rangle$ is an abstraction implying no particular basis, whereas the vector representing $|\psi\rangle$ requires that a particular basis be chosen. It is also inconsistent to equate a wavefunction to a ket, because a wavefunction is a representation of the ket in a continuous rather than a discrete basis. The result is a function rather than a vector with discrete elements; that is why it is called a *wavefunction*. In this article, mappings of this sort will be indicated by an arrow as in equation (16). The basis used will be indicated as shown or will be obvious from the context.

Of course, the members of the basis set can themselves be represented in the basis. If the j th member of the basis is represented then all the elements of the vector will be zero except the j th, which is one:

$$|j\rangle \xrightarrow{|i\rangle} \begin{bmatrix} \langle 1|j\rangle \\ \langle 2|j\rangle \\ \vdots \\ \langle j|j\rangle \\ \vdots \\ \langle n|j\rangle \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 1 \\ \vdots \\ 0 \end{bmatrix} \quad (17a)$$

$$\begin{aligned} \langle j| \xrightarrow{|i\rangle} & [\langle j|1\rangle \quad \langle j|2\rangle \quad \dots \quad \langle j|j\rangle \quad \dots \quad \langle j|n\rangle] \\ & = [0 \quad 0 \quad \dots \quad 1 \quad \dots \quad 0] \end{aligned} \quad (17b)$$

If we rewrite equation (13) using the result in equation (14) and commute the number with the ket on the right, we have

$$\begin{aligned} |\psi(t)\rangle &= \sum_{i=1}^n \langle i|\psi(t)\rangle |i\rangle \\ &= \sum_{i=1}^n |i\rangle \langle i|\psi(t)\rangle \\ &= \left(\sum_{i=1}^n |i\rangle \langle i| \right) |\psi(t)\rangle \end{aligned} \quad (18)$$

Written this way, the implication is

$$\sum_{i=1}^n |i\rangle \langle i| = \hat{E} \quad (19)$$

Rearranging and reinterpreting the brackets in this way may seem quite strange at first, but the examples given below should clarify the formalism. The operators $|i\rangle \langle i|$ are called *projection operators* because they project from any state the part that projects on the i th basis state. Summing over all the projection operators then just gives the unit operator.

Suppose we have two alternative sets of basis states, $\{|a,i\rangle\}$ and $\{|b,i\rangle\}$, spanning the same vector space; then we can effect a transformation between the bases using projection operators as in equation (19). Projecting the b basis onto the a basis, we have

$$\begin{aligned} |b,i\rangle &= \left(\sum_{j=1}^n |a,j\rangle \langle a,j| \right) |b,i\rangle \\ &= \sum_{j=1}^n |a,j\rangle \langle a,j|b,i\rangle \\ &= \sum_{j=1}^n \langle a,j|b,i\rangle |a,j\rangle \end{aligned} \quad (20)$$

If we have an arbitrary state represented in the b basis, it can be transformed to the a basis as follows:

$$\begin{aligned} \psi &= \sum_{i=1}^n \langle b,i|\psi\rangle |b,i\rangle \\ &= \sum_{i=1}^n \langle b,i|\psi\rangle \sum_{j=1}^n \langle a,j|b,i\rangle |a,j\rangle \\ &= \sum_{i,j=1}^n \langle a,j|b,i\rangle \langle b,i|\psi\rangle |a,j\rangle \end{aligned} \quad (21a)$$

$$\begin{aligned} \langle\psi| &= \sum_{i=1}^n \langle\psi|b,i\rangle \langle b,i| \\ &= \sum_{i=1}^n \langle\psi|b,i\rangle \sum_{j=1}^n \langle b,i|a,j\rangle \langle a,j| \\ &= \sum_{i,j=1}^n \langle\psi|b,i\rangle \langle b,i|a,j\rangle \langle a,j| \end{aligned} \quad (21b)$$

4 LIOUVILLE EQUATION OF MOTION

Comparing these results with equations (16a) and (16b), it is apparent that equations (21a) and (21b) can be represented as follows:
